$$R_{\mathrm{Pl}} \sim (G/\hbar c^3)^{1/2} \sim 10^{-33}\ \mathrm{cm}. \tag{9}$$

Using the gravitational fine structure constant, Eq. (3), these scales can be expressed as

$$M_{\mathrm{Pl}} \sim \alpha_G^{-1/2} m_p, \quad R_{\mathrm{Pl}} \sim \alpha_G^{1/2} r_p. \tag{10}$$

Thus M_{Pl} is much larger than m_p but R_{Pl} is much smaller than r_p (r_p being the size of a proton, which can be taken to be the Compton wavelength associated with its rest mass, $r_p \sim \hbar/m_p c \sim 10^{-13}$ cm; accordingly, the corresponding time scale is $t_p \sim r_p/c \sim 10^{-23}$ s). The Planck length is the scale on which quantum gravitational fluctuations in the metric become of the order of unity, so that the concept of space breaks down at such small scales. M_{Pl} can be interpreted as the mass of a black hole of radius R_{Pl}. Space may be thought of as being filled with virtual black holes of this size. Such "instantons" may play an important role in quantum gravity theory.

5.1.2 The Universe In the simplest Friedmann cosmological model, the age of the universe t_0, is of the order of H_0^{-1} where H_0 is the Hubble parameter (this relation fails only if the universe is closed and near its maximum expansion). Since $H_0 \sim 50$ km s^{-1} Mpc^{-1}, this implies $t_0 \sim 10^{10}$ yr, a conclusion that is supported by several independent arguments. The associated horizon size (the distance traveled by light since the birth of the universe) satisfies the approximate relationship

$$ct_0 \sim \alpha_g^{-1}(\hbar/m_e c) \sim (\alpha_e/\alpha_g)a_0, \tag{11}$$

where a_0 denotes the radius of the lowest-energy electron orbit of a hydrogen atom, $a_0 \sim \hbar^2/m_e e^2 \sim 10^{-8}$ cm ~ 1 Bohr. The ratio of the size of the observable universe to the size of an atom is comparable with the ratio of the electrical (or nuclear) and gravitational forces between elementary particles. There is no explanation for this well-known coincidence within conventional physics, but Dirac (1937, 1938) has conjectured that α_g is always given by

$$\alpha_g \sim \hbar/m_e c^2 t \sim (t/t_e)^{-1}. \tag{12}$$

Assuming that $\hbar$, c, and m_e are constant in time, this requires that G decreases as t^{-1}, and so Dirac invokes Eq. (12) as the basis for a new cosmology (Barrow, 1996). Such a variation of G is inconsistent with current observations. The total mass associated with the observable universe (the mass within the horizon volume) is $\sim \rho_0 c^3 t_0^3$, where ρ_0 is the present matter density, given by the Friedmann equation,

$$\rho_0 = \frac{3H_0^2}{8\pi G} + \frac{Kc^2}{16\pi G}. \tag{13}$$

Here K is the scalar curvature of the universe. Provided that the K term is smaller than the others, one deduces that the mass of the universe is

$$M_u \sim c^3 t_0^3 G^{-1} H_0^2 \sim \frac{c^3 t_0}{G} \sim \alpha_g^{-2}\left(\frac{m_p}{m_e}\right) m_p. \tag{14}$$

The fact that the number of protons in the universe is of the order of α_g^{-2} is thus explained provided one can justify neglecting the K term in Eq. (13). It has been argued that K must always be zero by appealing to Mach's principle but, apart from this, there may be reasons for expecting that the K term is small. If K is negative, galaxies could not have condensed out from the general expansion unless $-K$ were less than $G\rho/c^2$ at their formation epoch. Otherwise, their gravitational binding energy would not have been large enough to halt their expansion. The term $-K$ may exceed $G\rho/c^2$ at the present epoch, but not by a large factor. If K is positive, it must be $<G\rho_0/c^2$, otherwise the whole universe would have recollapsed before $t \simeq t_{\mathrm{MS}}$ where t_{MS} is the lifetime of a typical main-sequence star—say, the Sun. Relationships (11) and (14) also mean that the universe has an optical depth of the order of unity to electron scattering.

5.1.3 Galaxies It is not certain how galaxies form, and so any estimate of their scale is very model dependent (Rees and Ostriker, 1977; Silk, 1977; Sciama, 1953). One can assume that galaxies originate from overdense regions in the gaseous primordial material and that they have a mass M and radius R_B when they become bound. After binding, motions in the protogalaxy randomize and equilibrate in the gravitational field of the galaxy at a radius $\sim R_B/2$. Thereafter, they will deflate on a cooling time scale, with a virial temperature

$$T \sim GMm_p/kR. \tag{15}$$

Provided kT exceeds one Rydberg, the dominant cooling mechanism is bremsstrahlung and the associated cooling time scale is

$$t_{\text{cool}} \simeq \frac{m_e^2c^3}{\alpha_e e^4 n}\left(\frac{kT}{m_ec^2}\right)^{1/2}. \tag{16}$$

The free-fall time scale is

$$t_{ff} \sim (GM/R^3)^{-1/2}, \tag{17}$$

and this exceeds t_{cool} when R falls below a mass-independent value

$$R_g \sim \alpha_e^4\alpha_g^{-1}(m_p/m_e)^{1/2}a_0, \tag{18}$$

which, from a more precise calculation, is 75 kpc. Until a massive cloud gets within this radius, it will contract quasistatically and cannot fragment into stars. This argument applies only if the mass is so high that $kT_{\text{virial}} > \alpha_e^2m_ec^2$ at the "magic radius" R_g; that is,

$$M \geq M_g = \alpha_g^{-2}\alpha_e^5(m_p/m_e)^{1/2} \simeq 10^{12}M_\odot. \tag{19}$$

Gas clouds of mass $<M_g$ cool more efficiently as a result of recombination and can never be pressure supported. Thus, M_g is a characteristic maximum galactic mass. Primordial clouds of mass $<M_g$ are inhibited from fragmentation and may remain as hot pressure-supported clouds. This type of argument can be elaborated and made more realistic (White and Rees, 1978; Rees and Ostriker, 1977; Silk, 1977; Sciama, 1953); but one still obtains a mass $\sim M_g$ above which any fluctuations are likely to remain amorphous and gaseous, and which may thus relate to the mass scale of galaxies. The quantities M_g and R_g may thus characterize the mass and radius of a galaxy. These estimates are the least certain. The properties of galaxies may be a consequence of irregularities imprinted in the universe by processes at early epochs.

5.1.4 Stars The virial theorem implies that the gravitational binding energy of a star must be of the order of its internal energy. Its internal energy comprises the kinetic energy per particle (radiation pressure being assumed negligible for the moment) and the degeneracy energy per particle. The degeneracy energy will be associated primarily with the Fermi momentum of the free electrons, $p \sim \hbar/d$, where d is their average separation. Provided the electrons are nonrelativistic, the degeneracy energy is $p^2/2m_e$, and so the virial theorem implies (Dyson, 1972; Weisskopf, 1975; Haubold and Mathai, 1994)

$$kT + \frac{\hbar^2}{2m_ed^2} \sim \frac{GMm_p}{R} \sim \left(\frac{N}{N_0}\right)^{2/3}\frac{\hbar c}{d}. \tag{20}$$

Here N is the number of protons in the star, $N_0 \equiv \alpha_g^{-3/2}$, and $R \sim N^{1/3}d$ is its radius. As a cloud collapses under gravity, Eq. (20) implies that, for large d, T increases as d^{-1}. For small d, however, T will reach a maximum,

$$kT_{\max} \sim (N/N_0)^{4/3}m_ec^2, \tag{21}$$

and then decrease, reaching zero when d is

$$d_{\min} \sim (N/N_0)^{-2/3}r_e, \tag{22}$$

where r_e is the size of an electron, $r_e \sim \hbar/m_ec \sim 10^{-10}$ cm; accordingly, the electron time scale is defined as $t_e = r_e/c \sim 10^{-20}$ s. A collapsing cloud becomes a star only if $T_{\max}$ is high enough for nuclear reactions to occur, that is $kT_{\max} > qm_ec^2$ where q depends on the strong and electromagnetic interaction constants and is $\sim 10^{-2}$. From Eq. (21), one therefore needs $N > 0.1N_0$. Once a star has ignited, further collapse will be postponed until it has burned all its nuclear fuel. An upper limit to the mass of a star derives from the requirement that it should not be radiation-pressure dominated. Such a star would be unstable to pulsations that would probably result in its disruption. Using the virial theorem [that is, Eq. (20) with the degeneracy term assumed negligible] to relate a star's temperature T to its mass $M \sim Nm_p$ and radius R, the ratio of radiation pressure to matter pressure can be shown to be

$$\frac{P_{\text{rad}}}{P_{\text{mat}}} \sim \frac{aT^4R^3}{NkT} \sim \left(\frac{N}{N_0}\right)^2, \tag{23}$$

so that the upper limit to the mass of a star is also $\sim N_0 m_p$. A more careful calculation shows that there is an extra numerical factor of the order of 10, and so one expects all main-sequence stars to lie in the range $0.1 < N/N_0 < 10$ observed. Only assemblages of 10^{56}–10^{58} particles can turn into stable main-sequence stars with hydrogen-burning cores. Less massive bodies held together by their own gravity can be supported by electron "exclusion principle" forces at lower temperatures (they would not get hot enough to undergo nuclear fusion unless squeezed by an external pressure); heavier bodies are fragile and unstable on account of radiation-pressure effects. The central temperature T adjusts itself so that the nuclear energy-generation rate balances the luminosity, the radiant energy content divided by the photon leakage time,

$$L \simeq acT^4R^4/\kappa M, \tag{24}$$

where κ is the opacity. The appropriate κ decreases as M increases (electron scattering being the dominant opacity for upper main-sequence stars), but the energy generation increases so steeply with T that M/R depends only weakly on M.

5.1.5 White Dwarfs and Neutron Stars When a star has burned all its nuclear fuel, it will continue to collapse according to Eq. (20), and, provided it is not too large, it will end up as a cold electron-degeneracy–supported "white dwarf" with the radius $R \propto M^{-1/3}$ indicated by Eq. (22). However, when M gets so large that $kT_{\max} \sim m_ec^2$, the electrons will end up relativistic, with the degeneracy energy being pc rather than $p^2/2m_e$. Thus the degeneracy term in Eq. (20) acts as d^{-1} instead of d^{-2}, and consequently there is no $T = 0$ equilibrium state. From Eq. (21) this happens if M exceeds the mass

$$M_c \sim \alpha_g^{3/2} m_p \sim M_\odot, \tag{25}$$

which characterizes stars in general. A more precise expression for this critical value of M (Chandrasekhar mass) is $5.6\mu^2M_\odot$, where μ is the number of free electrons per nucleon (Chandrasekhar, 1935). For a star that has burned all the way up to iron, $\mu \approx 1/2$, and the limiting Chandrasekhar mass, taking into account the onset of inverse β decay when electrons get relativistic, is $\sim 1.25M_\odot$. Stars bigger than M_c will collapse beyond the white-dwarf density but may manage to shed some of their mass in a supernova explosion. The remnant core will comprise mainly neutrons, the electrons having been squeezed onto the protons through the reaction $p + e^- \rightarrow n + \nu$, and this core, if small enough, may be supported by neutron-degeneracy pressure. The limiting mass for a neutron star is more difficult to calculate than that for a white dwarf because of strong-interaction effects and because, from Eq. (21), with $m_e \rightarrow m_p$, the particles that dominate the neutron star's mass are relativistic. The maximum mass is still of the order of $M_\odot$, however, and a neutron star bigger than this must collapse to a black hole. The maximum mass lies close to the intercept of a black hole line, given by Eq. (26), and the nuclear density line $\rho \sim m_p/r_p^3$. The intricacies of the line that bridges white-dwarf and neutron-star regimes reflect the effects of gradual neutronization and strong interactions. Stars on this bridge would be unstable and so are not of immediate physical interest.

The above order-of magnitude arguments show why the effects of radiation pressure and relativistic degeneracy both become important for masses $>\alpha_g^{-3/2}m_p$. Note also that general relativity is unimportant for white dwarfs because the binding energy per unit mass is only $\sim(m_e/m_p)$ of c^2 at the Chandrasekhar limit.

5.1.6 Black Holes The radius of a spherically symmetrical black hole of mass M is

$$R = 2GM/c^2 \sim \alpha_g(M/m_p)r_p. \tag{26}$$

This is the radius of the event horizon, the region from within which nothing can escape, at least classically. Black holes larger than $M_\odot$ may form from the collapse of stars or dense star clusters. Smaller holes require much greater compression for their formation than could arise in the present epoch, but they might have been produced in the first instants after the big bang when the required compression could have occurred naturally. Such "primordial" black holes could have any mass down to the Planck mass. In fact, Hawking (1974) has shown that small black holes are not black at all; because of quantum effects *they emit particles* like a blackbody of temperature given by

$$k\theta \sim \frac{\hbar c^3}{GM} \sim \alpha_g^{-1}\left(\frac{M}{m_p}\right)^{-1} m_p c^2. \tag{27}$$

This means that a hole of mass M will evaporate completely in a time

$$t_{\text{evap}} \sim \alpha_g^2 (M/m_p)^3 t_p [N(\theta)]^{-1}. \tag{28}$$

$N(\theta)$ is the number of species contributing to the thermal radiation: For $k\theta < m_e c^2$ these include only photons, neutrinos, and gravitons; but at higher temperatures other species may contribute. The evaporation terminates in a violent explosion. For a solar-mass hole, this quantum radiance is negligible: θ is only 10^{-7} K and $t_{\text{evap}} \sim 10^{64}$ yr. But for small holes it is very important. A Planck-mass hole has a temperature of 10^{32} K and only survives for a time $\sim R_{\text{Pl}}/c \sim 10^{-43}$ s. Those holes that are terminating their evaporation in the present epoch are particularly interesting. As the age of the universe is $t_0 \sim \alpha_g^{-1} t_e$, the mass of such holes would be

$$M_h \sim \alpha_g^{-2/3}(t_0/r_p)^{1/3} m_p \sim \alpha_g^{-1} m_p \sim 10^{15}\ \text{g}, \tag{29}$$

and, from Eq. (26), their radius would be r_p. The corresponding temperature is ~10 MeV: low enough to eliminate any uncertainty in $N(\theta)$ due to species of exotic heavy particles.

5.2 Evolution of the Universe

The origin of the universe is governed by laws of physics that are still unknown at the time of writing the *Encyclopedia of Applied Physics* (see Plate 2).

At $t = 10^{-43}$ s, $T = 10^{32}$ K: The strong, weak, and electromagnetic forces may appear as unified into one indistinguishable force. This period is often referred to as the Grand Unification epoch. During this epoch, there may have been a very rapid, accelerating expansion of the universe called "inflation." The inflation made the universe very large and flat, but also produced ripples in the space-time it was expanding.

At $t = 10^{-34}$ s, $T = 10^{27}$ K: The strong force becomes distinct from the weak and electromagnetic forces. The universe is a plasma of quarks, electrons, and other particles. Inflation ends and the expanding universe coasts, gradually slowing its expansion under the pull of gravity.

At $t = 10^{-10}$ s, $T = 10^{15}$ K: The electromagnetic and weak forces separate (see Fig. 5). An excess of one part in a billion of matter over antimatter has developed. Quarks are able to merge to form protons and neutrons. Particles have acquired substance.

At $t = 1$ s, $T = 10^{10}$ K: Neutrinos decouple and the electrons and positrons annihilate, leaving residual electrons but predominantly the cosmic background radiation as the main active constituent of the universe.

At $t = 3$ min, $T = 10^9$ K: Protons and neutrons are able to bind together to form nuclei since their binding energy is now greater than the cosmic background-radiation energy. A rapid synthesis of light nuclei occurs—first deuterium (D), then heavier elements, primarily helium (^{3}He, ^{4}He) but up to lithium nuclei ^{7}Li (Tytler *et al.*, 1996; Gloeckler and Geiss, 1996). About 75% of the nuclei are hydrogen and 25% are helium; only a tiny amount are other elements. The heavier elements are later formed by nuclear burning stars.

At $t = 3 \times 10^5$ yr, $T = 3 \times 10^3$ K: Matter and the cosmic background radiation decouple as electrons bind with nuclei to produce neutral atoms. The universe becomes transparent to the cosmic background radiation, making it possible for the Cosmic Background Explorer satellite (COBE) to map this epoch of last scattering (see Plate 3).

A $t = 10^9$ yr, $T = 18$ K: Clusters of matter have formed from the primordial ripples to form quasars, primordial stars, and pro-

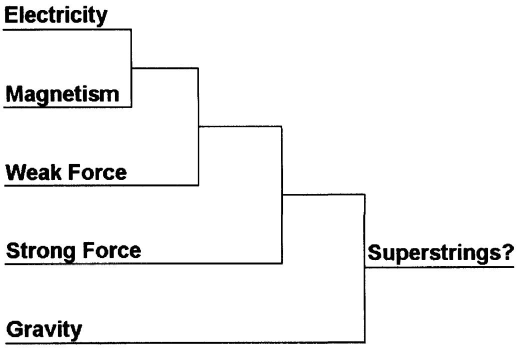

FIG. 5. Cosmology has been actively investigating the consequences of a new extension of the theory of matter within the evolution of the universe, in which the electricity, magnetism, weak force, strong force, and gravity are all unified at sufficiently high temperatures.

togalaxies. In the interior of stars, the burning of the primordial hydrogen and helium nuclei synthesizes heavier nuclei such as carbon, nitrogen, oxygen, and iron. These are dispersed by stellar winds and supernova explosions, making new stars, planets, and life possible.

At $t = 15 \times 10^9$ yr, $T = 3$ K: The present epoch is reached (see Plate 4). Five billion years earlier, the solar system condensed from the remnants of earlier stars. Chemical processes have linked atoms together to form molecules and then solids and liquids. Man has emerged from the dust of stars to contemplate the universe around him.

5.3 Large-Scale Distribution of Matter

The nearest large galaxy to the Milky Way is the "Andromeda galaxy," which is about 670 kpc away. Its mass is $\sim 3 \times 10^{11} M_\odot$ (or perhaps as much as $1.5 \times 10^{12} M_\odot$ if it has a massive halo), and it has a size of ~50 kpc. Studies show that it is a spiral galaxy. The Andromeda galaxy and the Milky Way lie nearly in each other's planes, but their spins are opposite. It may be noted that galaxies are packed in the universe in a manner very different from the way the stars are distributed inside a galaxy: The distance from the Milky Way to the nearest large galaxy is only 20 galactic diameters, while the distance from the Sun to the nearest star is 30 million times the diameter of such individual stars. There is some evidence to suggest that the Andromeda galaxy and the Milky Way are gravitationally bound to each other. They have a relative velocity—toward each other—of about 300 km s^{-1}. These two are only the two largest members of a group of more than 30 galaxies all of which together constitute what is known as the "Local Group." The entire Local Group is irregular in shape and can be contained within a spherical volume of ~2 Mpc in radius. This kind of clustering of galaxies into groups is typical in the distribution of the galaxies in the universe. A study within a size of about 20 Mpc from the Milky Way shows that only (10–20)% of the galaxies do not belong to any group; they are isolated galaxies, called "field" galaxies. Groups may typically consist of up to 100 galaxies; a system with more than 100 galaxies is conventionally called a "cluster." The sizes of groups range from a few hundred kpc to 2 Mpc. Clusters have a size of typically a few Mpc. Just like galaxies, one may approximate clusters and groups as gravitationally bound systems of effectively point particles. The large gravitational potential energy is counterbalanced by the large kinetic energy of random motion in the systems. The line-of-sight velocity dispersion in groups is typically 200 km s^{-1}, while that in clusters can be nearly 1000 km s^{-1}.

There are several similarities between clusters of galaxies and stars in an elliptical galaxy. For example, the radial distribution of galaxies in a cluster can be adequately fitted by the $R^{1/4}$ law with an effective radius $R_e \approx (1\text{–}2)h^{-1}$ Mpc ($0.5 \leq h \leq 1$ related to the Hubble constant). About 10% of all galaxies are members of large clusters. In addition to galaxies, clusters also contain very hot intracluster gas at temperatures 10^7–10^8 K. The two large clusters nearest to the Milky Way are the Virgo cluster and the Coma cluster. The Virgo cluster, located ~17 Mpc away, has a diameter of about 3 Mpc and contains more than 2500 galaxies. This is a prominent irregular cluster and does not exhibit a central condensation or a discernible shape. Virgo has an intracluster x-ray–emitting gas with a temperature of $\sim 10^8$ K, which has at least ten times the visible mass of the cluster. The Coma cluster, on the other hand, is almost spherically symmetric with a marked central condensation. It has an overall size of ~3 Mpc while its central core is ~600 kpc in size. The core is populated with elliptical and spheroidal galaxies with a density nearly 30 times larger than the Local Group. These values are typical for large clusters. Coma is located at a distance of ~80 Mpc and contains more than 1000 galaxies. The distribution of galaxies around the Local Group has been studied extensively. It turns out that most of the galaxies nearby lie predominantly in a plane—called the super-galactic plane—that is approximately perpendicular to the plane of the Milky Way galaxy. The dense set of galaxies in this plane is called the Local Supercluster (radius ~37 Mpc), and the Virgo cluster is nearly at the center of this highly flattened disclike system. The term "supercluster" is just used to denote structures bigger than clusters. Broadly speaking, the Local Supercluster consists of three components: About 20% of the brightest galaxies, forming the core, is the Virgo cluster itself; another 40% of galaxies lie in a flat disc with two extended, disjoint groups of galaxies; the remaining 40% is confined to a small number of groups scattered around. Nearly 80% of all matter in the Local Supercluster lies in a plane. The Local Supercluster is clearly expanding. Studies of distant galaxies show that there are many superclusters in our universe separated by large voids. The distribution of matter seems to be reasonably uniform when observed at scales bigger than about $100h^{-1}$ Mpc. For comparison, note that the size of the observed universe is about $3000h^{-1}$ Mpc. Thus, one may treat the matter distribution in the universe to be homogeneous while dealing with the phenomena at scales larger than 100 Mpc. The standard cosmological model is based on this assumption of "large-scale" homogeneity (see Fig. 6 and Table 4; Geller and Huchra, 1989).

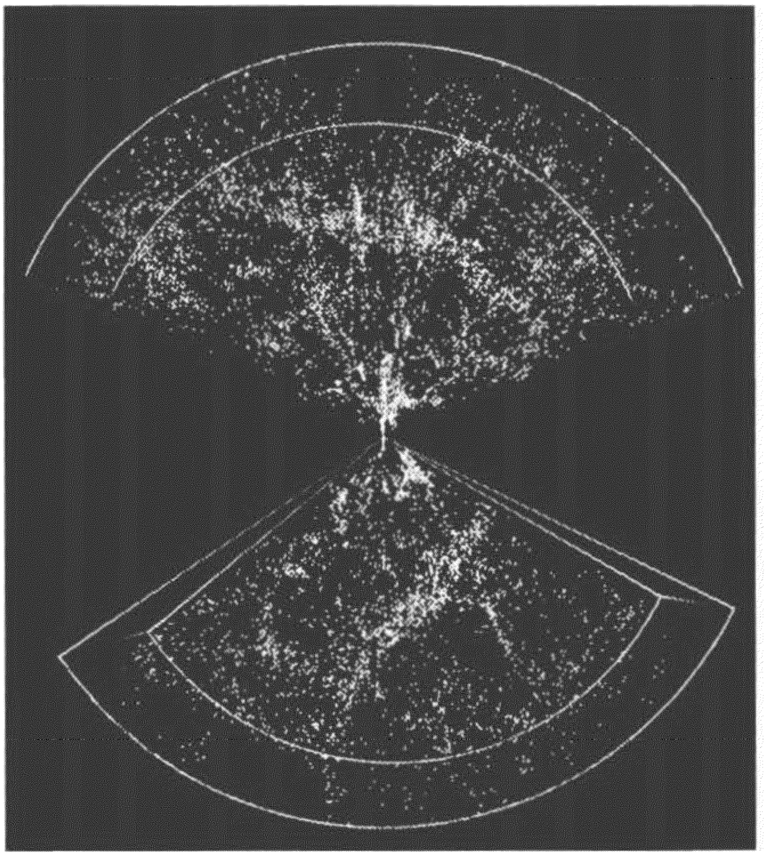

FIG. 6. A map of the nearby universe toward the north and south poles of the Milky Way. Each of the 9325 points in the image represents a galaxy similar to the Milky Way. The arcs that form the boundaries of the two wedgelike portions of the map are all at a distance of about 400 million light years from the Sun (Earth). The dark regions to the east and west are obscured by the plane of the Milky Way. The map shows that galaxies are arranged in patterns on an enormous scale. The Great Wall, a sheet containing thousands of galaxies, stretches nearly horizontally across the entire northern portion of the survey. A similar Southern Wall runs diagonally across the southern region. These walls delineate enormous dark voids where there are few if any galaxies. The voids are often 150 × 10^6 light years in diameter. The patterns in the north and south are similar. These large patterns are a tough challenge for attempts to model the development of structure in the universe. The curved boundaries are lines of constant declination (Galactic latitude): in the north they are at 8.5° and 44.5° (the wedge subtends an angle of 36° in the narrow direction). It runs from 8 to 17 h in right ascension (longitude) or of order 120°. In the south the declination runs from 0° to −40°, and the right ascension runs from 20.8 to 4 h. By permission of Margaret J. Geller, John P. Huchra, Luis A. N. da Costa, and Emilio E. Falco, Smithsonian Astrophysical Observatory, © 1994.

Table 4. Structural elements of the macrocosmos.

Object	Mass (g)	Radius (cm)
Jupiter	2×10^{30}	6×10^{9}
Sun	2×10^{33}	7×10^{10}
Red giant	$(2\text{–}6) \times 10^{34}$	10^{14}
White dwarf	2×10^{33}	10^{8}
Neutron star	3×10^{33}	10^{6}
Open cluster	5×10^{35}	3×10^{19}
Globular cluster	1.2×10^{39}	1.5×10^{20}
Spiral	$2 \times (10^{44}\text{–}10^{45})$	$(6\text{–}15) \times 10^{22}$
Elliptical	$2 \times (10^{43}\text{–}10^{45})$	$(1.5\text{–}3) \times 10^{23}$
Group	4×10^{46}	3×10^{24}
Cluster	2×10^{48}	1.2×10^{25}

5.4 Morphology of Galaxies

Galaxies range widely in their sizes, shapes, and masses; nevertheless, one may talk of a typical galaxy as something made out of $\sim 10^{11}$ stars. Taking the mass of a star to be that of the Sun, the luminous mass in a galaxy is $\sim 10^{11} M_\odot \approx 2 \times 10^{44}$ g.

This mass is distributed in a region with a size of ~20 kpc. Even though most galaxies have a mass of $\sim(10^{10}\text{–}10^{12})M_\odot$ and a size of ~10–30 kpc, there are several exceptions at both ends of this spectrum. For example, "dwarf galaxies" have masses in the range $\sim (10^{5}\text{–}10^{7})M_\odot$ and radii of ~1–3 kpc. There are also some "giant galaxies" with masses as high as $10^{13} M_\odot$. Galaxies exhibit a wide variety in their shapes as well and are usually classified according to their morphology (Hubble's classification of galaxies, for example). One may divide them into "ellipticals" and "discs." Ellipticals are smooth, featureless, distributions of stars, ranging in mass from $10^{8} M_\odot$ to $10^{13} M_\odot$. The proportion of elliptical galaxies in a region depends sensitively on the environment. They contribute ~10% of all galaxies in low-density regions of the universe but ~40% in dense clusters of galaxies. The second major type of galaxy is the "spiral" (or "disc") to which the Milky Way belongs. Spirals have a prominent disc, made of population I stars (see Sec. 5.6) and contain a significant amount of gas and dust. The name originates from the distinct spiral arms that exist in many of these galaxies. In low-density regions of the universe, ~80% of the galaxies are spirals while only ~10% of galaxies in dense clusters are spirals. This is complementary to the behavior of ellipticals. The stars in a disc galaxy are supported against gravity by their systematic rotation velocity. The rotational speed of stars $v(R)$ at radius R has the remarkable property that it remains constant for large R in almost all spirals; the constant value is typically 200–300 km s^{-1}. Most discs also contain a spheroidal component of population II stars. The luminosity of the spheroidal component relative to the disc correlates well with several properties of these galaxies. This fact has been used for classifying the disc galaxies into finer divisions. The stars in a galaxy are not distributed in a completely uniform manner. A typical galaxy contains several smaller stellar systems, each containing $\sim 10^{2}\text{–}10^{6}$ stars. These systems, usually called star clusters, can be broadly divided into two types called "open clusters" and "globular clusters." Open clusters consist of $\sim 10^{2}\text{–}10^{3}$ population I stars bound within a radius of ~1–10 pc. Most of the stars in these clusters are quite young. In contrast, globular clusters are population II systems with $\sim 10^{4}\text{–}10^{6}$ stars. The Milky Way contains ~200 globular clusters, which are distributed in a spherically symmetric manner about the center of the galaxy. Unlike open clusters, the stars in globular clusters are quite old. The mass density of stars in the core of a globular cluster, $\sim 10^{4} M_\odot\ \mathrm{pc}^{-3}$, is much higher than that of a typical galaxy, $\sim 0.05 M_\odot\ \mathrm{pc}^{-3}$. The core radius of the globular clusters is ~1.5 pc while the "tidal radius," which is the radius at which the density drops nearly to zero, is ~50 pc. In addition to the stars, the Milky Way also contains gas and dust that contribute ~(5–10)% of its mass. This interstellar medium may be roughly divided into a very dense, cold, molecular component (with about 10^{4} particles per cm^{-3} and a temperature of ~100 K), made of interstellar clouds, a second component that is atomic but neutral (with $n \approx 1\ \mathrm{cm}^{-3}$ and $T \approx 10^{3}$ K), and a third component that is ionized and very hot (with $n \approx 10^{-3}\ \mathrm{cm}^{-3}$ and $T \approx 10^{6}$ K). Though the interstellar medium is principally made of hydrogen, it also contains numerous other chemical species and an appreciable quantity of tiny solid particles ("dust"). The spiral arms are concentrations of stars and interstellar gas and are characterized by the presence of ionized hydrogen. This is also the region in which young stars are being formed. For a more detailed study of galaxies, one can divide ellipticals and spirals into subsets and also add two more classes of galaxies, called "lenticulars" and "irregulars." The ellipticals are subdivided as (E1, . . . ,En, . . .) where $n = 10(a - b)/a$ with a and b denoting the major and minor axes of the ellipticals. The lenticulars (also called SO) are the galaxies "in between" ellipticals and spirals. They have a prominent disc, which contains no gas, dust, bright young stars, or spiral arms. Though they are smooth and featureless like ellipticals, their surface brightness follows the exponential law of the spirals. They are rare in low-density regions (less than 10%) but constitute nearly half of the galaxies in the high-density regions. The spirals are subdivided into Sa, Sb, Sc, and Sd with the relative luminosity of the spheroidal component decreasing along the sequence. The amount of gas increases and the spiral arm becomes more loosely spiraled along the sequence from Sa to Sd. The Milky Way is between the types Sb and Sc. There also exists another class of spirals called "barred spirals," which exhibit a barlike structure in the center. They are classified as SBa, SBb, etc. Finally, irregulars are the galaxies that do not fall in the abovementioned morphological classification. These are low-luminosity, gas-rich systems with massive young stars and large HII regions (i.e., regions containing ionized hydrogen). More than one-third of the galaxies in the Milky Way's neighborhood are irregulars. They are intrinsically more difficult to detect at larger distances because of their low luminosity. As seen earlier, stars evolve and their luminosity and hence their color change. Since galaxies are made of stars, galaxies will also exhibit color evolution. Besides, the gas content and elemental abundances of the galaxies will change as the stars are formed and end as planetary nebulae or supernovae.

5.5 Quasars

Most galaxies that are observed have a fairly low redshift ($z < 0$–5) and an extended appearance on a photographic plate. There exists another important class of objects, called "quasars," that exhibit large redshifts (up to $z \approx 5$) and appear as point sources in the photographic plate (Shaver *et al.*, 1996). Estimating the distance from the redshift and using the observed luminosity, it is found that quasars must have a luminosity of about $L_q \approx 10^{46}$–10^{47} erg s^{-1}. It is possible to estimate the size of the region emitting the radiation from the time scale in which the radiation pattern is changing. It turns out that the energy from the quasar is emitted from a very compact region. One can easily show that nuclear fusion cannot be a viable energy source for quasars. It is generally believed that quasars are fueled by the accretion of matter into a supermassive black hole ($M \approx 10^8 M_\odot$) in the center of the host galaxy. The friction in the accretion disc causes the matter to lose angular momentum and hence spiral into the black hole; the friction also heats up the disc. Several physical processes transform this heat energy into radiation of different wavelengths. Part of this energy can also come out in the form of long, powerful, jets. The innermost regions of the quasar emit x and γ rays. Outer shells emit UV, optical, and radio continuum radiation in the order of increasing radius. Very bright quasars have an apparent magnitude of $m_B \approx 14$ (which corresponds to a flux of 10^{-25} erg s^{-1} cm^{-2} Hz^{-1}) while the faintest ones have $m_B \approx 23$. The absolute magnitudes of the quasars are typically $-30 < M_B < -23$; in contrast, galaxies fall in the band $-23 < M_B < -16$. The relation between m and M for any given quasar depends on the estimated distance to the quasar, which in turn depends on the cosmological model and the quasar's redshift. The luminosity function of the quasars, as a function of their redshift, has been a subject of extensive study. These investigations show that

1. the space density of bright galaxies (about 10^{-2} Mpc^{-3}) is much higher than that of quasars (about 10^{-5} Mpc^{-3}) with $z < 2$, and
2. bright quasars were more common in the past ($z \approx 2$) than today ($z \approx 0$).

Quasars serve as an important probe of the high-redshift universe. Quasars are believed to be one extreme example of a wide class of objects called "active galaxies." This term denotes a galaxy that seems to have a very energetic central source of energy. This source is most likely to be a black hole powered by accretion. One kind of active galaxy that has been studied extensively is radio galaxies. The most interesting feature about these radio galaxies is that the radio emission does not arise from the galaxy itself but from two jets of matter extending from the galaxy in opposite directions. It is generally believed that this emission is caused by the synchrotron radiation of relativistic electrons moving in the jets. The moving electrons generate two elongated clouds containing magnetic fields that, in turn, trap the electrons and lead to the synchrotron radiation.

5.6 Stellar Evolution

The time evolution of a star, which can be depicted as a path in the Hertzsprung–Russell diagram, is quite complicated because of the many physical processes that need to be taken into account. Detailed calculations, based on the numerical integration of the relevant differential equations, have provided a fairly comprehensive picture of stellar evolution. One of the primary sources of stellar energy is a series of nuclear reactions converting four protons into a helium nucleus. Since the simultaneous collision of four particles is extremely improbable, this process of converting hydrogen into helium proceeds through two different sequences of intermediate reactions, one called proton–proton chain and the other called carbon–nitrogen–oxygen cycle. In the *p–p* chain, helium is formed through deuterium and ^{3}He in the intermediate steps; this reaction is the dominant mechanism for hydrogen–helium conversion at temperatures below $\sim 2 \times 10^7$ K. In the CNO cycle, hydrogen is converted into helium through a sequence of steps involving ^{12}C as a catalyst; i.e., the amount of ^{12}C remains constant at the end of the cycle of reactions. Since the Coulomb barrier for carbon nuclei is quite high, the CNO cycle is dominant only at higher temperature. The evolution of a star like the Sun during the phase of hydrogen–helium conversion, called the "main sequence" phase, is fairly stable. The stability is essentially due to the following regulatory mechanism: Suppose the temperature decreases slightly causing the nuclear reaction rate to decrease. This will make gravity slightly more dominant, causing a contraction. Once the star contracts, the temperature will again increase, thereby increasing the rate of nuclear reactions and the pressure support. This will restore the balance. After the burning of core hydrogen ends, the core will undergo a contraction, increasing its temperature; if the star now heats up beyond the helium ignition temperature, then the burning of helium will start and stabilize the star. In principle, such a process can continue with the building up of heavier and heavier elements. But to synthesize elements heavier than He is not straightforward because He has a very high binding energy per nucleon among the light elements. Stars achieve synthesis of post-helium elements through a process known as "triple-alpha reaction" that proceeds as $^4\mathrm{He}(^4\mathrm{He},^8\mathrm{Be})\gamma$; $^8\mathrm{Be}(^4\mathrm{He},^{12}\mathrm{C})\gamma$. Once ^{12}C has been synthesized, production of heavier elements like ^{16}O, ^{20}Ne, ^{24}Mg, etc., can occur through various channels, provided temperatures are high enough, and the star can evolve through successive stages of nuclear burning. The ashes of one stage can become the fuel for the next stage as long as each ignition temperature is reached. Such stars will evolve into structures that contain concentric shells of elements. For example, a $15M_\odot$ star during its final phase can have layers of iron, silicon, oxygen, neon, carbon, helium, and hydrogen all burning at their inner edges.

The details of the above process, which occurs after the exhaustion of most of the fuel in the core, depend sensitively on the core mass. Consider, for example, a star with $M > M_\odot$. Its evolution proceeds in the following manner: Once the hydrogen is exhausted in the core, the core, containing predominantly helium, undergoes gravitational contraction. This increases the temperature of the material just beyond the core and causes renewed burning of hydrogen in a shell-like region. Soon, the core contracts rapidly, increasing the energy production and the pressure in the shell, thereby causing the outer envelope to expand. Such an expansion leads to the cooling of the surface of the star. About this time, convection becomes the dominant mechanism for energy transport in the envelope and the luminosity of the star increases due to convective mixing. This is usually called the "red-giant" phase. During the core contraction, the matter gets compressed to very high densities ($\sim 10^5$ g cm^{-3}) so that it behaves like a degenerate gas and not as a perfect gas. Once the core temperature is high enough to initiate the triple-alpha reaction, helium burning occurs at the core. Since degenerate gas has a high thermal conductivity, this process occurs very rapidly, called "helium flash." If the core had been dominated by gas pressure, such an explosive ignition would have increased the pressure and led to an expansion; but since the degeneracy pressure is reasonably independent of temperature, this does not happen. Instead the evolution proceeds as a runaway process: The increase in temperature causes an increase in the triple-alpha reaction rate, causing further increase in temperature, etc. Finally, when the temperature becomes $\sim 3.5 \times 10^8$ K, the electrons become nondegenerate; the core then expands and cools. The star has now reached a stage with helium burning in the core and hydrogen burning in a shell around the core. Soon the core is mostly converted into carbon and the reaction again stops. The process described above occurs once again, this time with a carbon-rich, degenerate core, and a helium-burning shell. This situation, however, turns out to be unstable because the triple-alpha reaction is highly sensitive to temperature. This reaction can overrespond to any fluctuations in pressure or temperature, thereby causing pulsations of the star with increasing amplitude. Such violent pulsation can eject the cool, outer layers of the star, leaving behind a hot core. The ejected envelope becomes what is known as a "planetary nebula." The above discussion assumes that the core could contract sufficiently to reach the ignition temperature for carbon burning. In low-mass stars, degeneracy pressure stops the star from reaching this phase and it ends up as a "white dwarf" supported by the degeneracy pressure of electrons against gravity. A more complicated sequence of nuclear burning is possible in stars with $M \gg M_{\odot}$. After the exhaustion of carbon burning in the core, one can have successive phases with neon, oxygen, and silicon burning in the core with successive shells of lighter elements around it. This process can proceed until ^{56}Fe is produced in the core.

The binding energy per nucleon is maximum for the ^{56}Fe nucleus; hence it will not be energetically feasible for heavier elements to be synthesized by nuclear fusion. The core now collapses violently reaching very high temperatures, about 10^{10} K. The ^{56}Fe photodisintegrates into alpha particles, and then even the alpha particles disintegrate at such high temperatures to become protons. The collapse of the core squeezes together protons and electrons to form neutrons, and the material reaches near-nuclear densities forming a "neutron star." There exist several physical processes that can transfer the gravitational energy from core collapse to the envelope, thereby leading to the forceful ejection of the outer envelope causing a "supernova explosion." A remnant with smaller mass is left behind. Numerical studies show that stars with $M > 8M_{\odot}$ burn hydrogen, helium, and carbon and evolve rather smoothly. During the final phase, such a star explodes as a supernova leaving behind a remnant that could be a white dwarf, neutron star, or black hole. It is generally believed that stars with masses in the intermediate range, $2M_{\odot} < M < 8M_{\odot}$, do not burn hydrogen and helium in degenerate cores but evolve through carbon burning in degenerate matter (for $M > 4M_{\odot}$) ending again in a supernova explosion. Stars with lower mass do not explode but end up as planetary nebulae. Low-mass stars with $M < 2M_{\odot}$ ignite helium in degenerate cores at the tip of the red-giant branch and then evolve in a complicated manner. The synthesis of elements as described above proceeds smoothly up to ^{56}Fe. Heavier elements are formed by nuclei absorbing free neutrons, produced in earlier reactions by two different processes called the "r-process" (rapid neutron-capture process) and the "s-process" (slow neutron-capture process). During the supernova explosion, a significant part of the heavy elements synthesized in the star will be ejected out into the interstellar space. A second generation of stars can form from these gaseous remnants. The initial composition of material in this second generation will contain a higher proportion of heavier elements (called "metals") compared to the first-generation stars. Both these types of stars are observed in the universe; for historical reasons, stars in the second generation are called population I stars while those in the first generation are called population II stars.

The foregoing discussion shows how stars could synthesize heavier elements, even if they originally start as gaseous spheres of hydrogen. The study of the spectra of stars allows us to determine the relative proportion of various elements present in the stars. Such studies show that population II stars are made of about 75% hydrogen and 25% helium; even population I stars consist of almost similar proportions of hydrogen and helium with a small percentage of heavier elements (~2%). It is possible to show, using stellar evolution calculations, that it is difficult for the stars to have synthesized elements in such a proportion if they originally had only hydrogen (called primordial or population III stars). Hence, such a universal composition leads us to conjecture that the primordial gas from which population II stars have formed must have been a mixture of hydrogen and helium in the ratio 3:1 by weight. Heavier elements synthesized by these population II stars would have been dispersed in the interstellar medium by supernova explosions. The population I stars are supposed to have been formed from this medium, containing a trace of heavier elements. The helium present in the primordial gas should have been synthesized at a still earlier epoch, the big bang, and cannot be accounted for by stellar evolution. Cosmological models provide an explanation for the presence of this primordial helium.

6. MATHEMATICS AND PHYSICS AND THE STRUCTURE OF THE UNIVERSE

6.1 General Relativity and Quantum Field Theory

A mathematician represents the motion of the planets of the solar system by a flow line of an incompressible fluid in a 54-dimensional phase space, whose volume is given by the Liouville measure; while a famous physicist is said to have made the statement that the whole purpose of physics is to find a number, with decimal points, etc. (!), otherwise you have not done anything (Manin, 1981). Despite such extreme points of view, it can be safely said that the relations between mathematics and physics (and astronomy) have been very productive in past epochs of the evolution of these disciplines (Barrow and Tipler, 1988).

Mathematical structures entered the development of physics, and problems emanating from physics influenced developments in mathematics. Examples are the role of differential geometry in general relativity, the dynamical theory of space and time, and the influence of quantum mechanics in the development of functional analysis and built on the understanding of Hilbert spaces. A prospective similar development occurred only recently when non-Abelian gauge theories emerged as the quantum field theories for describing fundamental-particle interactions. Yang–Mills theory found its mathematical formulation in the theory of principal fiber bundles. The understanding of anomalies in gauge theories involved the theory of families of elliptic operators and representation theory of infinite-dimensional Lie algebras and their cohomologies. Based on these developments, there are two fundamental theories in modern physics: general relativity and quantum field theory. General relativity describes gravitational forces on an astronomical scale. Quantum field theory describes the interaction of fundamental particles, electromagnetism, weak, and strong forces. The formal quantization of general relativity is leading to infinities, and the current understanding is that the mathematical machinery is missing to accomplish the unification of general relativity and quantum field theory. This is particularly due to the nonlinear character of general relativity, which is incompatible with the linearity needed for the superposition principle in quantum theory. More recently, attention has turned to the exploration of the mathematical structure of non-Abelian gauge theories and to the more ambitious attempts to construct unified theories of all the fundamental interactions of matter together with gravity. A success of such attempts may reveal new insights for structural elements of the microcosmos and macrocosmos (Schmid, 1992).

6.2 Macroscopic Dimension of Space

Of all the fundamental constants, the most familiar one is the dimension of physical space, $N = 3$. Variation of such a fundamental characteristic as the dimension N may lead to unpredictable changes of physical laws. It was Paul Ehrenfest (1880–1933) who, in 1917, was trying to answer the question of why physical space is three-dimensional. From physics, we are familiar with the analogy between Coulomb's law and Newton's law [Eqs. (1) and (2)]. In both cases, the force is $F \propto r^{-2}$. In physics these laws are treated separately. This lack of coherency obscures a profound relationship of the electromagnetic and the gravitational forces with the properties of space—in particular, with its dimension. Two properties are common to the gravitational and the electromagnetic interactions: Both are weak and long range. In modern language, this means that the mass of the gauge boson is zero in both cases, implying that the interaction radius is infinite and that the interaction constants are small, $\alpha_g, \alpha_e \ll 1$ [Eqs. (3) and (4)]. In the language of physics these properties mean that the lines of force, originating at the point where their source is located, run to infinity, not intersecting with each other, provided that no other source is present. The fact that the lines of force extend to infinity reflects the long-range character of the gravitational and electromagnetic forces; the absence of intercepts signifies that there is no reciprocal action between the lines of force, i.e., that the interactions under consideration are weak. The combination of the two properties, the weakness and the long-range action, is not characteristic for the other interactions. The force F exerted by one particle on another particle a distance r apart is proportional to the density n_i of the lines of force. Accordingly,

$$F \propto n_i = f/4\pi r^2. \tag{30}$$

The proportionality constant f in (30) is by definition equal to the product of the charges of the two particles (Coulomb's law) or of their masses (Newton's law). The denominator in (30) gives the surface area S of a sphere of radius r. For the three-dimensional space, this quantity equals $S_3 = 4\pi r^2 = a_3 r^{3-1}$. These considerations can be repeated for the more general case of an N-dimensional space. The surface area of a sphere in such a space is $S_N = a_N r^{N-1}$. Therefore, the force F_N acting in an N-dimensional space is

$$F_N = b_N/r^{N-1}. \tag{31}$$

Accordingly, the potential energy has the form

$$U_N = -b_N/(N-2)r^{N-2}, \tag{32}$$

where $N \neq 2$; for $N = 2$, the dependence is logarithmic. It should be stressed that these expressions apply only for integer N, and only for long-range forces in the quasistatic approximation, i.e., for motion in a central force field. The existence of stable orbits in a central force field in an N-dimensional space is determined by (31) and consequently by the dimension N. From mechanics, it is known that the existence of stable orbits depends on the form of the r dependence of the effective potential

$$U_{Ne} = U_N + M^2/2mr^2, \tag{33}$$

where $M^2/2mr^2$ is the centrifugal energy, M the angular momentum, and m the mass of the body moving at a distance r. A stable state is possible if the dependence $U_{Ne}(r)$ has a minimum at a value of r different from zero or infinity. Henceforth only the attractive forces are considered, for which $U_N < 0$. The results of an analysis of the function $U_{Ne}(r)$ with regard to the existence of an extremum are the following:

For $N > 4$, the dependence $U_{Ne}(r)$ has a maximum at $r \neq 0$ and a minimum at $r = 0$, which corresponds to merging of the two particles.

For $N = 4$, the dependence $U_{Ne}(r)$ is given by a monotonically decreasing function exhibiting no extrema.

For $N = 2$ and $N = 3$, the function $U_{Ne}(r)$ has a minimum at $r \neq 0$ and $r \neq \infty$.

For $N = 1$, the function $U_{Ne}(r)$ is monotonically increasing.

The existence of a minimum in the dependence $U_{Ne}(r)$ is a necessary condition for the stability of motion. For this reason, the existence and the properties of closed orbits are determined by the dimension of space, N. For $N > 4$, there is no minimum at $r \neq 0, \infty$; consequently, there are no stable closed orbits. Any motion caused by long-range forces would be of one of the following two types: Either it is infinite (the body escapes to infinity) or, otherwise, the moving body falls on a massive central body. At $N = 2$ or $N = 3$, all types of motion are possible: Infinite motion, fall onto a central body, and, notably, motion in stable, closed orbits. For $N = 1$, only finite motion is possible; a body cannot escape to infinity. In the one-dimensional case, no orbital motion occurs, and the centrifugal potential is zero ($M = 0$). The effective potential, Eq. (32), is then $U_1 = b_1 r$, and the force $F_1 =$ const. This corresponds to an infinitely deep potential well. To remove the body from this well, an infinitely large force has to be applied; this means it would be impossible for the body to escape to infinity. Hence, the degree of stability grows as the dimension N decreases. For $N > 4$, there are no analogues to planetary systems. Similar considerations in the framework of quantum mechanics have demonstrated that for $N > 4$, stable atomic systems do not exist, either. It appears that the absence of analogs of planets and atoms for $N > 4$ is a clue to the understanding of the significance of the space dimension $N = 3$, with regard to the existence of structural elements in the universe.

6.3 Microscopic Dimension of Space

In classical physics, particles have definite locations and follow exact trajectories in space-time. In quantum mechanics, wave packets propagate through space-time, their positions and velocities uncertain according to Heisenberg's uncertainty principle. In string theory, point particles are replaced by tiny loops with the result that the concept of space-time becomes "fuzzy" at scales comparable to the square root of a new fundamental constant, $\alpha' \approx (10^{-32}\ \mathrm{cm})^2$, introduced as string tension in string theory. Employing both string tension ($\alpha' \neq 0$) and quantum effects ($\hbar \neq 0$) leads to results that may change the conventional notion of space-time (Donaldson, 1996). The situation of introducing α' in string theory is similar to passing from classical to quantum mechanics by the introduction of Planck's constant $\hbar$. In string theory the one-dimensional trajectory of a particle in space-time is replaced by a two-dimensional orbit of a string. According to Heisenberg's uncertainty principle, at a momentum p one can probe a distance $x \approx \hbar/p$. However, the introduction of α' acts as if Heisenberg's uncertainty principle would have two terms, $\Delta x \geq \hbar/\Delta p + \alpha'(\Delta p/\hbar)$, where the second term reflects the fuzziness due to string theory. Then, the constant α' would be the absolute minimum uncertainty in length in any physical experiment. The consequences of this type of quantum field theory for fundamental particles and the structure of the universe are still to be discovered.

GLOSSARY

Antiparticle: A particle of opposite charge but otherwise identical to its partner. Most of the observable universe consists of particles and matter, as opposed to antiparticles and antimatter.

Asteroids: Small planetlike bodies of the solar system.

Atom: The basic building block of matter. Each atom consists of a nucleus with positive electric charge and a surrounding cloud of electrons with negative charge.

Baryon: Type of hadron, including the proton, the neutron, and the unstable hyperons (and their antiparticles).

Binary System: A system of two objects orbiting around a common center. The objects may be stars or black holes or a star and a black hole.

Black Hole: A region in which matter has collapsed to such an extent that light can no longer escape from it.

Boson: A class of particles with integer units of the basic unit of spin $h/2\pi$.

Cluster of Galaxies: An aggregate of galaxies. Clusters may range in richness from loose groups, such as the Local Group, with 10 to 100 members, to great clusters of over 1000 galaxies.

Cluster of Stars (Globular Star Cluster): An aggregate of stars. Globular star clusters contain the oldest stars in the galaxy and high-velocity stars.

Comet: A diffuse body of gas and solid particles that orbits the Sun in a highly eccentric trajectory.

Cosmic Microwave Background Radiation: Diffuse isotropic radiation whose spectrum is that of a blackbody at 3 K and consequently is most intense in the microwave region of the spectrum.

Cosmic String: A hypothetical one-dimensional, stringlike object that is made from a curvature of space.

Cosmogony: The study of the origin of celestial systems, ranging from the solar system to stars, galaxies, and clusters of galaxies.

Cosmology: The study of the large-scale structure and evolution of the universe.

Dark Matter: Matter whose presence is inferred from dynamical measurements but which has no optical counterpart.

Electron: A particle of matter with negative electric charge. All chemical properties of atoms and molecules are determined by the electrical interactions of electrons with each other and with the atomic nuclei.

Fermion: A particle with half-odd-integral units of the basic unit of spin, $h/2\pi$.

Galactic Nucleus: Innermost region of a galaxy exhibiting a concentration of stars and gas.

Galaxy: A large gravitationally bound cluster of stars that all orbit around a common center. Galaxies are basic building blocks of the universe.

Graviton: The particle that, according to wave-particle duality, is associated with gravitational waves.

Group of Galaxies: Gravitationally bound system of a few galaxies.

Group of Stars: Gravitationally bound system of a few stars (multiple stars).

HI Cloud: Cloud of cool, neutral hydrogen.

HII Region: Cloud of hot, ionized hydrogen, usually heated by a massive young hot star.

Hadrons: Particles (protons, neutrons, and mesons) that take part in strong nuclear reactions.

Halo: The diffuse, nearly spherical cloud of old stars and globular clusters that surrounds a spiral galaxy.

Hertzsprung–Russell Diagram: Plot of stellar luminosity (or absolute magnitude) against effective temperature (or color), in which the evolution of stars of different masses may be followed.

Hubble Classification of Galaxies: Organizes galaxies according to shape. They range from amorphous, relatively uniform elliptical systems to highly flattened spiral disks with prominent nuclei. It is not a classification based on evolution but one of different rates of star formation.

Hypergalaxy: A system consisting of a dominant spiral galaxy surrounded by a cloud of dwarf satellite galaxies, often ellipticals. The Milky Way and the Andromeda galaxy are hypergalaxies.

Intergalactic Gas: Matter that is present in the region between galaxies. It has been detected in considerable amounts in great clusters of galaxies, where the intergalactic gas is so hot that it emits copious amounts of x rays.

Interstellar Grains: Small needle-shaped particles in the interstellar gas with dimensions from 10^{-6} to 10^{-5} cm. They are primarily composed of silicates and strongly absorb, scatter, and polarize visible light in the far-infrared region of the spectrum.

Irregular Galaxy: A galaxy without spiral structure or smooth, spheroidal shape, often filamentary or very clumpy, and generally of low mass $[(10^7 \text{ to } 10^{10})M_\odot]$.

Leptons: Particles (neutrinos, electrons, and muons) that do not take part in strong interactions.

Local Group: Small group of 30 or so galaxies of which the Milky Way and the Andromeda galaxy are the two dominant members.

Meson: A class of strongly interacting particles with zero baryon number, among them the pi meson.

Meteorite: A solid portion of a meteoroid that has reached the Earth's surface.

Molecular Cloud: An interstellar cloud consisting predominantly of molecular hydrogen, with trace amounts of other molecules such as carbon monoxide and ammonia.

Molecule: An entity made of several atoms that share their electron clouds with each other.

Neutrino: A particle that resembles the photon, except that it interacts weakly with matter. Neutrinos come in at least three varieties, known as electron type, muon type, and tauon type.

Neutron: The uncharged particle found along with protons in atomic nuclei.

Neutron Star: Cold, degenerate, compact star in which nuclear fuels have been exhausted and pressure support against gravity is provided by the degeneracy pressure of neutrons.

Nucleons: Nuclear particles, i.e., neutrons and protons.

Observable Universe: The extent of the universe that we can see with the aid of large telescopes. Its ultimate boundary is determined by the horizon size.

Photon: A discrete unit of electromagnetic energy; the particle that, according to wave-particle duality, is associated with electromagnetic energy.

Population I: Young stars with relatively high abundances of metals, found in the disk of a galaxy, especially the spiral arms, and in dense regions of interstellar gas. The Sun is a population I star.

Population II: Old stars with relatively low abundances of metals, found in the nuclear bulge of a galaxy or in globular clusters.

Positron: The antiparticle of an electron, having positive charge but being otherwise similar.

Proton: The positively charged particle found along with neutrons in atomic nuclei.

Pulsar: A magnetized, spinning neutron star that emits a beam of radiation (radio waves and sometimes also light and x rays).

Quarks: Particles of which all hadrons are supposed to be composed.

Quasar: Luminous and compact quasistellar radio source related to violent events in the nuclei of a galaxy, believed to be powered by a massive black hole.

Red Giant: Phase in star's evolution after completion of hydrogen burning when outer layers become very extended.

Spiral Galaxy: A galaxy with a prominent nuclear bulge and luminous spiral arms of gas, dust, and young stars that wind out from the nucleus.

Star: The basic building blocks of the macroscopic universe.

Supercluster: A cluster of clusters of galaxies.

Universe: Our universe.

White Dwarf: Cool, degenerate, compact star, in which nuclear fuels are exhausted and pressure support against gravity is provided by the degeneracy pressure of electrons.

INTRODUCTION

Vacuum electronics is the field of electronics associated with a vacuum medium within a gas-tight envelope. The vacuum medium considered here is an evacuated region in which electron motion is essentially unaffected by the presence of residual gas or vapor. In this way vacuum electronics is different from gaseous electronics.

Vacuum electronics has a wide range of uses and capabilities. It is used for the generation, amplification, and detection of electromagnetic waves in many applications including, among other things, radio and video communications, navigation, and remote control and sensing. It can also be used for collecting and displaying video images. This versatility is why vacuum electronics is quite commonly employed in both industrial and consumer electronic products.

Two advantages of vacuum electronics over other types of devices are

1. high power-handling capacity and
2. the ability to operate in harsh environmental conditions, such as extreme temperatures, where most solid-state electronics cease to function.

The topics to be discussed in rest of this article include various kinds of electron tubes and specific vacuum electron devices for scientific investigation.

1. VACUUM DIODES

1.1 Detector Diodes

A vacuum tube consisting of a cathode and an anode is called a vacuum diode. An example of the cross-sectional view of a

digital Encyclopedia of Applied Physics

vacuum diode with a coaxial cylindrical structure is shown in Fig. 1. The anode is often called the plate. When the plate is positive with respect to the cathode, electrons emitted from the cathode may reach the plate, and electric conduction occurs. When the plate is negative with respect to the cathode, electrons emitted from the cathode are pushed back toward the cathode, and few electrons, if any, reach the plate. Therefore, under such bias there is no electric conduction between the plate and the cathode. This property of the vacuum diode can be used for converting ac to dc. The process of converting ac to dc is called rectification. Similarly, the conversion of rf signals to dc is known as detection. Vacuum detector diodes are used in harsh environments in which solid-state diodes cannot function properly, or for cases where different functional characteristics of detection than solid-state diodes are required.

Vacuum diodes can be either planar or cylindrical. In a planar vacuum diode, both the anode and cathode are flat, or planar, and are parallel to each other. In a cylindrical vacuum diode, both the anode and the cathode are cylindrical in shape and coaxial to each other as shown in Fig. 1. Usually the center cylinder is the electron-emitting cathode, and the outer cylinder is the anode, as shown in the figure.

When the anode is positive with respect to the cathode under constant cathode temperature, the anode current increases with the anode voltage, up to a certain point. If the anode voltage is increased beyond this point, the anode current will increase no further. This condition is called saturation. The anode current under saturation is called the saturation current, or the temperature-limited current. The saturation current is limited by the finite rate of electron emission from the cathode at a given cathode temperature. The saturation current I_s is given by

$$I_s = 1.2 \times 10^6 A T^2 \epsilon^{-e\phi/kT}, \tag{1}$$

where A is the total emitting area of cathode in square meters, T is the cathode temperature in kelvins, $e\phi$ is the work function of the heated cathode in joules, and k is Boltzmann's constant, 1.38×10^{-23} J/K. If the anode voltage is low and the vacuum diode is not saturated, the anode current is called the space-charge current, or the space-charge limited current. The current is then primarily determined by the speed of the emitted electrons, which is controlled by the anode voltage. The space-charge current observed at the anode is given by the Child–Langmuir–Schottky equation (IEEE, 1972),

$$I_p = GV_p^{3/2}, \tag{2}$$

where I_p is the space-charge current, G is a proportionality constant called the perveance, and V_p is the anode voltage. The perveance is determined by the electrode geometry and the material of both the anode and the cathode. When a vacuum diode is used for rf detection, the operating rf signals are generally small, and so the vacuum diode will not enter the saturation condition. The vacuum diode is then operating under space-charge current conditions. The vacuum detector diode operates based on the principle that the diode conducts only for the positive half-cycles of the rf signals to be detected. This principle fails at high frequencies. When the electron transit time from the cathode to the anode, τ, is small in comparison to the period of the operating rf signals, T, the principle works well. If the electron transit time is comparable to or significantly large in comparison to the period of the rf signals, the diode does not work well in detection.

The minimum electron transit time, $\tau_{\min}$, is

$$\tau_{\min} = d/u_{\max} = d\sqrt{m/2ev}, \tag{3}$$

where d is the distance between the cathode

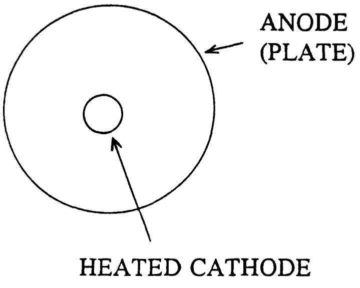

FIG. 1. Cross-sectional view of a vacuum diode with coaxial cylindrical structure.

and the anode, $u_{\max}$ is the maximum speed of the electrons (m/s) driven by the rf voltage v that is to be detected, m is the mass of an electron (kg), and e is the electric charge of an electron (C). For the satisfactory operation of a vacuum detector diode,

$$\tau_{\min} \ll T. \tag{4}$$

As a "rule of thumb,"

$$\tau_{\min} \leq 0.1T. \tag{5}$$

This means that the maximum operating frequency of a given vacuum detector diode is

$$f_{\max} \leqq \frac{1}{10\tau_{\min}} = \frac{\sqrt{2ev}}{10d\sqrt{m}}. \tag{6}$$

If the vacuum diode is constructed in such a way that the cathode and the anode are plane parallel at a distance d (m) apart, the electron current density due to the anode voltage V_a is (Nakamura, 1969)

$$J = 2.33 \times 10^{-6} V_a^{3/2}/d^2. \tag{7}$$

If the structure is cathode-centered coaxial, then the electron current density is (Nakamura, 1969)

$$J = 2.33 \times 10^{-6} V_a^{3/2}/\beta_1^2 r_a^2, \tag{8}$$

where r_a is the radius of the anode cylinder. The symbol β_1 represents the Langmuir constant. It ranges from 0 to $\sqrt{1.1}$ for an r_a/r_c ratio of 1 to 100, with $\beta_1 = \sqrt{1.1}$ at $r_a/r_c = 3$.

1.2 Power Rectifiers

For high-current or high-power rectifiers, vacuum diodes use a small amount of argon gas or mercury vapor. In the positive half-cycle of rectification, electrons from the heated cathode strike atoms of gas or vapor and ionize them. Thus, multiple-impact ionization takes place. The resultant electrons are driven toward the anode while the positive ions that are generated move toward the cathode. This multiplication of charge carriers makes for a larger forward current than that of a purely vacuum diode of the same size and structure. In the reverse cycle, nearly all charge-carrier movement is suppressed. Therefore, there is no reverse current in the reverse cycle.

There are high-current, low-voltage power rectifiers and low-current, high-voltage power rectifiers. In high-current, low-voltage power rectifiers, the cathode is made of tungsten or thoriated tungsten, and the anode is made of carbonated lead. The gas or vapor pressure inside the rectifier is relatively high, as much as 20 to 30 mm Hg. This high gas or vapor pressure aids in high-temperature (2400–2800 K) operation of the cathode (Nakamura, 1969). The high cathode temperature results in a large amount of electron emission, a large yield of multiple-impact ionization, a large forward current, and a small internal voltage drop across the rectifier tube. However, the large concentration of charge carriers per unit volume makes the inverse breakdown voltage relatively low during the reverse cycle, approximately 0.3 kV (Nakamura, 1969).

For low-current, high-voltage applications, mercury rectifiers are used. This type of vacuum power-rectifier diode contains a few tiny balls of mercury in it. The cathode is either a direct-heating tungsten cathode or an indirect-heating oxide cathode ($BaSrO_2$ coated on Ni), which has better electron emission efficiency. The anode is made of either carbonated metal or lead. The vapor pressure is kept low in order to obtain a high reverse breakdown voltage of 5 to 20 kV (Nakamura, 1969).

1.3 Switching Tubes

Vacuum diodes are sometimes used for turning on and off high-power microwave waveguides. This type of vacuum diode contains a small amount of gas, and there is no cathode or anode. Instead, there are two sharp, pointed metallic electrodes as illustrated in Fig. 2. The vacuum diode is mounted across the waveguide that is to be turned on and off. When a surge of high microwave power is present at the spark gap, the electrical spark short circuits the waveguide. Thus, high microwave power cannot propagate past the vacuum diode. When the microwave power is small enough, there is no spark at the spark gap, so that small microwave power can propagate beyond the diode. This type of vacuum diode is known as

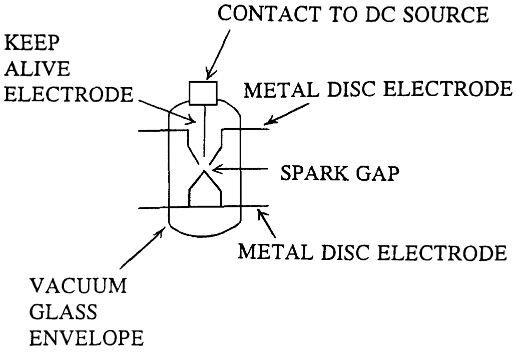

FIG. 2. Schematic diagram of a T-R tube (transmit–receive tube).

the transmit–receive tube, or the T-R tube (Reich *et al.*, 1953).

In order to increase sparking sensitivity to microwaves, the electron supply is kept alive by a dc discharge into the inside of one of the truncated cone-shaped electrodes as illustrated in Fig. 2. T-R tubes are used for protecting a radar receiver from the high microwave power of its own transmitter. When a T-R tube sparks, the waveguide is short circuited. When the T-R tube stops sparking, the waveguide is connected for transmission.

When a quarter-wavelength waveguide is attached to a T-R tube, the input impedance of the waveguide loaded with the T-R tube becomes infinity, effectively an open circuit. When the T-R tube is not sparking, the waveguide input impedance is zero, effectively a short circuit. This combination of a quarter-wavelength waveguide and a T-R tube is called the anti-transmit–receive tube, or the ATR tube.

1.4 Photodiodes

Photodiodes are used for converting light signals into electrical signals. They consist of an anode and a photocathode. The photocathode emits electrons when illuminated by light. The emitted electrons are attracted to the anode, forming the anode current. The number of photoelectrons emitted is proportional to the intensity of the incident light. The magnitude of the anode current, which is called the photocurrent, is proportional to the number of photoelectrons that reach the anode per unit time.

The volt-ampere characteristic of a generic photodiode under various levels of light intensity is shown in Fig. 3. When the anode voltage is low, there is a space-charge effect. The photoelectron emission is somewhat suppressed by the space charge of photoelectrons that have already been emitted. Therefore, for the lower anode voltage range, the anode current is proportional to the anode voltage.

Before the saturation, the anode current signal is calculated by

$$\Delta i_A = \frac{\partial i_A}{\partial I}\Delta I\left(1 + \frac{\partial i_A}{\partial v_A}Z\right)^{-1} \tag{9}$$

where i_A is the anode current (A), I is the light intensity (W), Z is the anode impedance (Ω), and v_A is the anode voltage.

2. VACUUM TRIODES

2.1 Audio and rf Triodes

If a metallic grid is inserted between the hot cathode and the anode of a vacuum diode as shown in Fig. 4, a vacuum triode is formed. A negative voltage is given to the metallic grid and the grid voltage controls the flow of electrons from the cathode to the anode by the repulsion between the negatively charged grid and electrons. The amount of the repulsive force is controlled by the amount of the negative voltage on the grid. Therefore the metallic grid is called the control grid. Vacuum triodes described here are used for the generation, amplification, and control of audio and rf signals. In most audio and rf vacuum triodes in practical use,

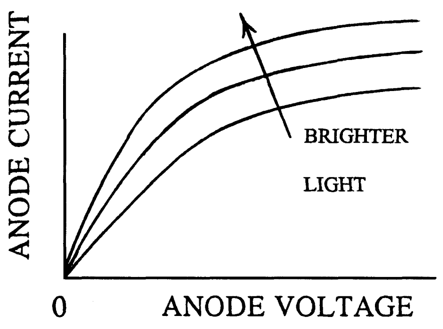

FIG. 3. An anode volt-ampere curve of a generic photodiode under various levels of light intensity.

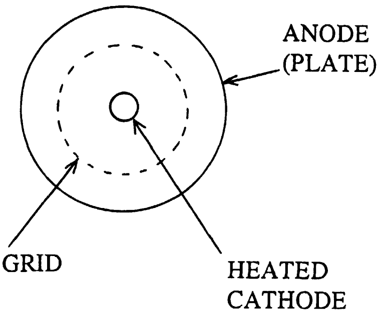

FIG. 4. A cross-sectional view of a vacuum triode with a coaxial structure.

for a given geometry of electrode structure and operating voltages, the electron transit time between electrodes is negligibly small in comparison to the operating period of the signal frequency. Interelectrode capacitance and lead inductance are also negligibly small in comparison to the lumped-parameter circuit components in the rest of the circuit. For a given geometry of a vacuum triode structure, if the operating frequency is increased, then the electron transit time among the electrodes and the effects of interelectrode capacitances and lead inductances become significant. At this point in operating frequency, proper function of the triode ceases.

Under normal operation in audio and rf, the performance of a vacuum triode tube is represented by the transconductance g_m, the internal resistance r_i, and the amplification factor μ. The transconductance g_m is defined as

$$g_m = \left.\frac{\partial I_A}{\partial V_g}\right|_{V_A=\text{constant}}, \tag{10}$$

where I_A is the anode current, V_g is the grid voltage, and V_A is the anode voltage. The internal resistance r_i is defined as

$$r_i = \left.\frac{\partial V_A}{\partial I_A}\right|_{V_g=\text{constant}}, \tag{11}$$

The amplification factor μ is defined as

$$\mu = \left.\frac{\partial V_A}{\partial V_G}\right|_{I_A=\text{constant}}. \tag{12}$$

When a vacuum triode is operated under space-charge limited condition before saturation, the anode current I_A, the grid voltage V_g, and the anode voltage V_A are related by

$$I_A = G(V_g + V_A/\mu)^{3/2}, \tag{13}$$

where G is the space-charge limited current coefficient (perveance) determined by the tube geometry and the space-charge density; then (Nakamura, 1969)

$$g_m = \tfrac{3}{2}G(V_g + V_A/\mu)^{1/2} = \tfrac{3}{2}G^{2/3}I_A^{1/2} \tag{14}$$

$$r_i = \tfrac{2}{3}\mu G^{-2/3}I_A^{-1/3}, \tag{15}$$

$$\mu = g_m r_i. \tag{16}$$

When the grid is negatively biased, there is a value of the grid voltage at which the anode current becomes zero. The grid voltage at that point is called the grid cutoff voltage and is given by

$$V_g = -V_A/\mu. \tag{17}$$

2.2 Microwave Triodes

For microwave-frequency operation of vacuum triodes, the lead inductance must be reduced, and the electron transit time between the cathode and anode must be much smaller than the period of the microwave operating frequency. To meet these requirements, the electrodes are of a planar shape and connected to the external circuit as illustrated in Fig. 5. Such a vacuum tube with sealed disc electrodes is called a lighthouse tube because its shape resembles that of a lighthouse.

The electron transit time between the anode and cathode is approximately given by

$$\tau \approx d(2eV_a/m)^{-1/2}, \tag{18}$$

where V_a is the potential difference, in volts, between the anode and the cathode; e is the charge of an electron, 1.6021×10^{-19} C; m is the mass of an electron, 9.1091×10^{-31} kg; and d is the distance between the anode and cathode in meters. It is desirable that τ be significantly smaller than the operating microwave period. As a general rule,

$$\tau < T/10, \tag{19}$$

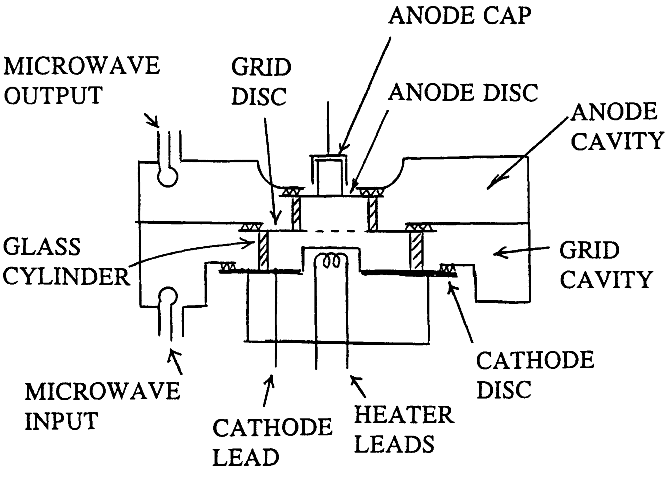

FIG. 5. A disc sealed lighthouse tube and its cavity resonator circuits.

where T is the period of the operating microwave frequency. Equations (10) through (17) also apply to microwave tubes.

2.3 Field-Emission Triodes

Field-emission triodes are fabricated using vacuum microelectronic techniques. The triodes are like transistors, with thousands of monolithic units fabricated simultaneously on a wafer.

Differing from transistors, the active region of the field-emission triode is a vacuum, and the materials used are not semiconductors. The device is made up of layers of metal and insulators as illustrated in Fig. 6 (Brodie, 1989). Since the materials are metals and insulators, the interelectrode distance can be reduced to submicrons instead of microns as in the case of semiconductor devices. In addition, electron mobility in a vacuum is much higher than electron mobility in semiconductors. For these two reasons the field-emission vacuum triode is well suited for high-speed and high-frequency applications.

The field-emission triode operates in the following manner. A bias voltage is applied to the metallic cathode and anode, setting up an electric field in the gap between them. The field is very strong because the distance from the cathode to the anode is small, approximately 0.5 μm. The electric-field intensity is even stronger at the pointed tip of the cathode, on account of its shape. This high field strength at the cathode tip causes field emission of electrons, which travel to the metal anode, forming the anode current. The electron flow is controlled by the metal gate. The metal gate has the same function as a grid in a conventional vacuum triode.

The insulator layers can be TeOS, SiO_2, or intrinsic Si. The field-emission metal can be molybdenum or some form of coated molybdenum. The metal for the base, gate, and anode may be W or TiW. The operating anode voltage can be as high as 20 V, though operation may begin with less than 5 V of anode voltage. The electron transit time from the cathode to the anode, ~0.5 μm, is on the order of picoseconds.

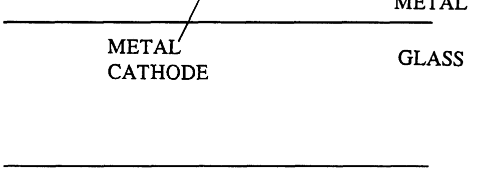

FIG. 6. A cross-sectional view of a monolithically developed field-emission vacuum triode.

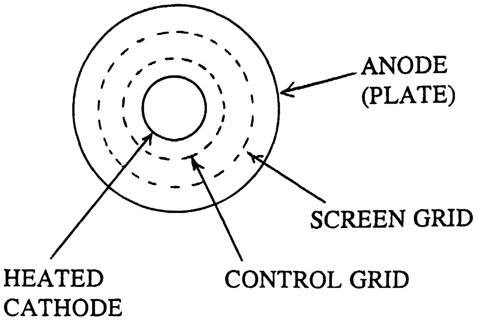

FIG. 7. A cross-sectional view of a vacuum tetrode with a coaxial cylindrical structure.

3. VACUUM TETRODES

3.1 Audio and rf Vacuum Tetrodes

If one more grid is added between the control grid and the anode of a vacuum triode, as illustrated in Fig. 7, the additional grid is called the screen grid, and the vacuum tube is called the vacuum tetrode. The purpose of the screen grid is to reduce the interelectrode capacitance between the grid and the anode. The screen grid is positively biased with a dc voltage slightly lower than the anode voltage, and the audio or rf signal on the screen grid is grounded through a bypass capacitor. The presence of the screen grid makes the internal resistance of the tube, r_i, larger.

As seen from Eq. (16), the larger r_i makes for a proportionately larger amplification factor μ. The reduced interelectrode capacitance is helpful for reducing interelectrode feedback so that the tetrode can be operated as a stable voltage amplifier at higher frequency. The volt-ampere characteristic is expressed by Eq. (13) with controlled G due to the screen grid. A specific volt-ampere curve of a specific vacuum tube can be obtained from the manufacturer of the tube.

3.2 Microwave Tetrodes

A disc-sealed–type microwave lighthouse-shaped vacuum tetrode is illustrated in Fig. 8. For microwave amplification, the input microwave cavity resonator is attached across the control grid disc and the cathode cylinder. The output microwave cavity is built around the anode block and the screen grid disc in a manner similar to the one shown in Fig. 5. A microwave tetrode is usually a medium-power microwave amplifier. Cooling fins are often attached to the anode block for forced-air cooling. The interelectrode distance is made as small as possible to reduce the electron transit time. The electron transit time should be significantly small in comparison with the period of operating frequency. The biasing scheme for the anode, screen grid, control grid, and cathode is identical to that of audio and rf tetrodes.

4. VACUUM PENTODES

4.1 Audio and rf Vacuum Pentodes

A cross-sectional view of a vacuum pentode with a coaxial cylindrical structure is illustrated in Fig. 9. A coarse metallic grid has been added between the anode and the screen grid as shown. This additional grid is called the suppressor grid. The suppressor grid is usually biased to the same dc electrical potential as the cathode to suppress sec-

ondary electron emission from the anode. The volt-ampere curve of a pentode is represented by Eq. (13) with a modified value of *G* due to the presence of both the screen grid and the suppressor grid. Specific volt-ampere curve of a specific vacuum tube can be obtained from the manufacturer of the tube.

4.2 Microwave Pentodes

Disc-sealed lighthouse-type microwave pentodes are used in microwave power amplification, and their configuration is similar to the microwave vacuum tetrode shown in Fig. 8, except that a suppressor grid disc is added in front of the anode block. The biasing requirements of a microwave pentode are identical to those of audio and rf vacuum pentodes. As other vacuum tubes, the interelectrode distance is made as small as possible to minimize the electron transit-time effect.

5. KLYSTRONS

5.1 Multicavity Klystrons

A schematic diagram of a multicavity klystron is shown in Fig. 10. A multicavity klystron is a microwave power amplifier. Electrons are emitted from the electron gun, which shoots out an electrostatically focused electron beam. This electron beam is further focused to stay on course by a longitudinally applied magnetic flux density *B*. At the end opposite the electron gun, the electron beam is terminated by a collector. On the way from the electron gun to the collector, the electron beam goes through a series of microwave cavity resonators. Each cavity resonator is doughnut shaped, and a pair of grids are attached in the middle as illustrated in Fig. 10. These cavities resonate at

FIG. 10. A schematic diagram of a multicavity klystron.

the operating frequency of microwave signals to be amplified.

The microwave input signals are fed to the first cavity resonator through a waveguide as shown in Fig. 10. This first cavity resonator is called the first buncher resonator. Due to the input excitation, a microwave input voltage

$$v = v_1 \sin\omega t \tag{20}$$

develops across the grid of the first buncher resonator. In this equation, v_1 is the amplitude of the microwave voltage across the grid of the resonator and $\omega = 2\pi f$ is the angular frequency of the signal. The electron beam is accelerated by the dc voltage V_a and the microwave voltage v across the grid of the first buncher resonator. The speed of electrons just before passing through the first grid is

$$u_0 = \sqrt{2eV_a/m}, \tag{21}$$

where e is the charge of an electron and m is the mass of an electron. But after passing through the first pair of grids,

$$u \approx u_0[1 + (Kv_1/2V_a)\sin\omega t], \tag{22}$$

where K is the beam coupling coefficient. This coupling coefficient is the ratio of microwave-frequency current in the cavity resonator to the microwave-frequency electron current in the beam. It is calculated to be

$$K = \frac{\sin(\omega l/2u)}{\omega l/2u}, \tag{23}$$

where l is the distance between the two grids in the first buncher resonator. As seen from Eq. (21), u_0 is a dc velocity, and u is a microwave-modulated velocity. This process is called velocity modulation, and the ratio $Kv_1/2V_a$ is called the depth of velocity modulation.

After the velocity modulation in the first buncher cavity, the electrons enter a drift space where they experience no acceleration or deceleration. The cavity resonators are electrically connected to each other and are therefore at the same dc voltage. Acceleration and deceleration of the electrons occur only between the grids of cavity resonators. The process of velocity modulation is repeated at the grids of the second and third buncher. These cavities are idler cavities. They are not directly connected to the input circuit. The cavities pick up tuned frequency voltage across the grids out of the velocity-modulated and weakly bunched electron beam. The induced voltage across the grids gives the velocity modulation back to the electron beam. By this time the depth of velocity modulation becomes deep. After passing through the third buncher resonator, the electrons enter the final drift space. With deeper velocity modulation, the electron bunching in the beam becomes tighter. The velocity modulation produces faster electrons and slower electrons. In the drift space accelerated electrons catch up with slower electrons that left the last buncher resonator grids earlier. Thus, the velocity modulation of the electron beam is transformed into density modulation.

The electric current associated with the velocity-modulated electron beam in the drift space is given by (Ishii, 1990)

$$I \approx I_0\left(1 + \frac{MKv_1}{2V_a}\frac{l_d}{u_0}\,\omega\cos\omega t\right), \tag{24}$$

where V_a is the anode voltage, I_0 is the dc beam current, l_d is the drifted distance in the last drift space, and M is the multiplication factor due to the number of buncher cavity stages. This is not primarily or directly related to the number of bunches created in the drift space. Both l_d and u_0 are adjusted so that the catcher-cavity resonator grids are located where the tightest bunch is. The density-modulated electron beam causes a large microwave voltage across the grids of the catcher cavity by electrostatic induction. In Eq. (24), the quantity $Kv_i l_d \omega/2V_a u_0$ is called the bunching parameter.

The induced microwave voltage across the grids of the catcher cavity resonator is

$$v_c = (MK^2 v_1 I_0/2V_a)R_c, \tag{25}$$

where R_c is the resonance resistance of catcher cavity resonator circuit at its resonant frequency. Therefore, the voltage gain of this klystron amplifier is

$$A_n = \frac{v_c}{v_1} = \frac{MK^2 I_0 R_c}{2V_a}. \tag{26}$$

A phasor voltage gain for large signals is (Ishii, 1990)

$$A_v = 2\frac{2MKZ_cI_0J_1(X_b)}{v_1}\epsilon^{-j(\theta-\pi/2)}, \qquad (27)$$

where Z_c is the catcher cavity impedance and X_b is the bunching parameter. $J_1(X_b)$ is the Bessel function of the first kind of order one with argument X_b. The quantity $\theta - \pi/2$ is the phase delay between the catcher gap voltage and the input voltage, including the electron transit delays between the multiple buncher stages and the final drift spaces and grid gaps.

The power gain for small-signal operation at the resonant frequency is

$$A_p = \frac{\omega^2MK^3R_cI^2l_d}{4G_gV_a^2u_0^2}. \qquad (28)$$

Multicavity klystrons are used for microwave power amplification, radar transmitters, UHF television transmitters, particle-accelerator transmitters, and industrial microwave-heater transmitters. The volt-ampere characteristic curve of a klystron is represented by Eq. (24) with both u_0 and I_0 functions of v_a as seen from Eq. (21). Specific volt-ampere curves of a specific klystron can be obtained from the specific manufacturer of the tube.

5.2 Reflex Klystrons

A reflex klystron is a low-power microwave-frequency oscillator vacuum tube. A schematic diagram of a reflex klystron is shown in Fig. 11. It operates on the basis of the principle of electron-beam velocity modulation in a manner similar to the klystron explained in Sec. 5.1. The electron beam is emitted from the electron gun, accelerated by the anode cavity, and then velocity modulated at the grid gap by a microwave signal voltage originating from noise already present. The noise includes thermal noise, shot noise, flicker noise, and partition noise. The microwave-frequency voltage is amplified by the high Q of the cavity resonator.

Since the repeller is negatively biased, the electron beam is repelled back to the grids of the cavity resonator. The velocity-modulated electrons are bunched on their return trip to the resonator gap. For the bunched returning electrons, the cavity resonator acts as the catcher cavity in multicavity klystrons. If the timing is correctly adjusted, the bunched returning electrons induce a large microwave voltage in phase with the existing microwave grid signal. Thus, positive feedback is accomplished and microwave oscillation begins.

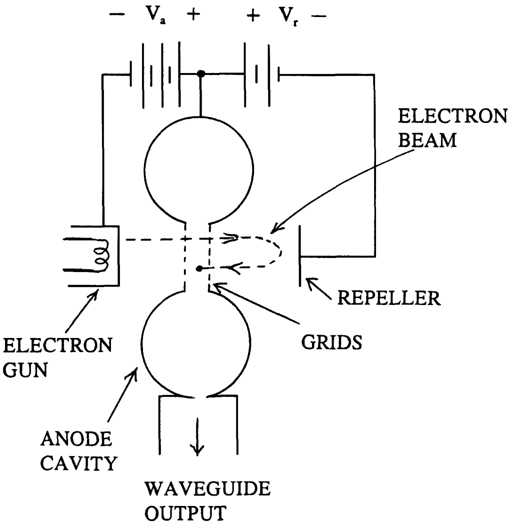

FIG. 11. A schematic diagram of a reflex klystron.

For positive feedback to occur, the number of electron transit cycles in the repeller space must be

$$N = n + \tfrac{3}{4}, \qquad (29)$$

where n is zero or an integer (Ishii, 1989). To produce a proper value of N for the positive feedback, the anode voltage V_a and the repeller voltage V_r must be adjusted to satisfy (Ishii, 1989)

$$N = 6.67 \times 10^{-3}(2l + d_g)f\frac{\sqrt{V_a}}{V_a - V_r}, \qquad (30)$$

where l is the distance from the second grid to the repeller, d_g is the gap distance between the two grids, and f is the operating microwave frequency.

Reflex klystrons are durable in harsh environment conditions, such as extreme high or low temperature, in which most solid-state devices are not convenient to operate. Reflex klystrons also have different tuning characteristics than solid-state oscillators. The inherent oscillator noise of reflex klystron oscillators is generally comparable to or smaller than solid-state oscillators. So, as a low-power microwave signal source or a local oscillator application, reflex klystrons are employed to complement solid-state oscillators wherever their superiority in performance is needed. The volt-ampere curves of a reflex klystron are represented by Eq. (24) with $M = 1$ and additional conditions that both the anode voltage and the repeller voltage satisfy conditions expressed by Eqs. (29) and (30). A specific volt-ampere curve of a specific reflex klystron can be obtained from the manufacturer of the tube.

6. MAGNETRONS

6.1 Heating Magnetrons

Magnetrons are high-power microwave oscillators. Heating magnetrons, in particular, are magnetrons made for microwave heating. In domestic, commercial, or industrial microwave heating, the heating is done by essentially unmodulated continuous-wave microwaves. Therefore, most heating magnetrons are designed to operate in continuous-wave operation. Since the application is domestic and commercial, cost effectiveness is one of the most important factors to be considered. Most heating magnetrons are designed with this in mind.

A heating magnetron consists of a heated cylindrical cathode and a resonator-loaded anode coaxially arranged as shown in Fig. 12. A strong magnetic flux is applied axially by either a permanent magnet or an electromagnet, depending on the design. As a result of the radially directed electric force and axially applied magnetic field, electrons emitted from the cathode circulate around the cathode without reaching the anode. The circulating electrons are velocity modulated by the cavity resonators around the anode, which act like buncher cavity resonators in a multicavity klystron. The velocity-modulated electrons form bunches called electron poles. A number of tightly bunched electron poles are formed as the electrons circle around the cathode. These electron poles induce high microwave voltage in the cavities as in the case of the catcher cavity in the klystron. In the case of a magnetron, all cavity resonators act as both bunchers and catchers. So if a pick-up antenna is coupled to one of the cavity resonators, the high-power microwaves induced in the cavity resonator are coupled out of the magnetron for external use.

Magnetron oscillation occurs when the anode voltage V_a and the axial magnetic flux density B_c (in gauss) are related to the anode radius r_a (cm) and the cathode radius r_c by

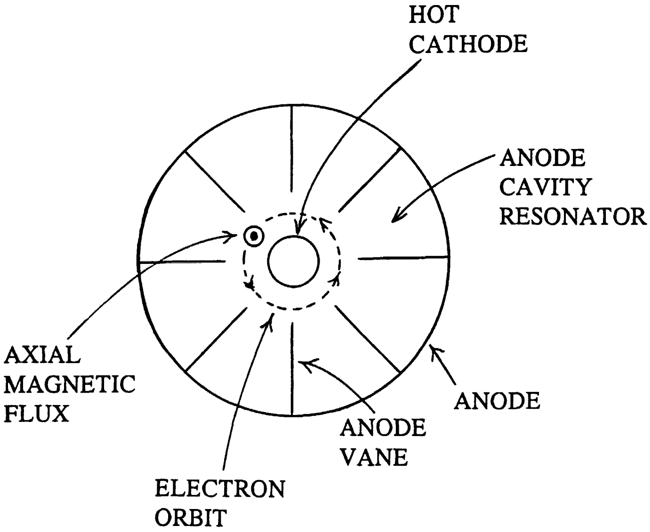

FIG. 12. A schematic cross-sectional view of a heating magnetron.

$$\frac{B_c^2}{V_a} = 45.5\left(\frac{r_a}{r_a^2 - r_c^2}\right)^2. \tag{31}$$

The microwave power generated by the magnetron is (Liao, 1988)

$$P = \tfrac{1}{2}Nv^2\omega C/Q \quad \text{(watt)}, \tag{32}$$

where N is the number of resonator cavities, v is the microwave voltage across the vane tips, ω is the operating angular frequency, C is the capacitance across the vane tips, and Q is the load Q (quality factor) of the resonator. The efficiency of the magnetron is

$$\eta = P/V_aI_a, \tag{33}$$

where V_a is the dc anode voltage and I_a is the dc anode current of the magnetron.

6.2 Radar Magnetrons

Radar magnetrons are designed for pulsed operation. To form an interrogation pulse for a long-range radar, a magnetron must produce a large amount of power for a short time. To allow a sufficient radar echo receiving time, the magnetron must wait for a while for the radar reflections to return before the next transmission of short-pulse modulated microwaves. A radar magnetron is on for a microsecond or so and off for a millisecond or so. The ratio of "on" time and the pulse repetition period is called the duty cycle. When the radar magnetron is on, it emits tens of kilowatts of microwaves, but the averaged power for the entire period is not so great. If the average power over the pulse repetition period T is P and the peak power in the transmission period is P_p for τ seconds, then

$$P = P_p\tau/T. \tag{34}$$

This is the reason that even high–pulse-power rated magnetrons are not excessively bulky. A typical radar magnetron configuration is shown in Fig. 13. Most radar magnetrons employ permanent magnets for magnetic biasing. The principle of radar magnetron oscillation is identical to the principle of operation for a heating magnetron. Most radar magnetrons are designed and operated in the π-mode. This means that phase-angle difference of the microwave voltage from one anode-block pole to the next is π radians. The anode-block pole is the part of the anode block that is protruding toward the cathode. To ensure π-mode operation, the two alternating sets of anode-block poles are strapped together by a pair of conducting rings called the strapping rings. A strapping ring equalizes microwave electric potential.

The performance characteristics of a radar magnetron are represented by a performance chart and a Rieke diagram. The performance chart is a family of volt-ampere

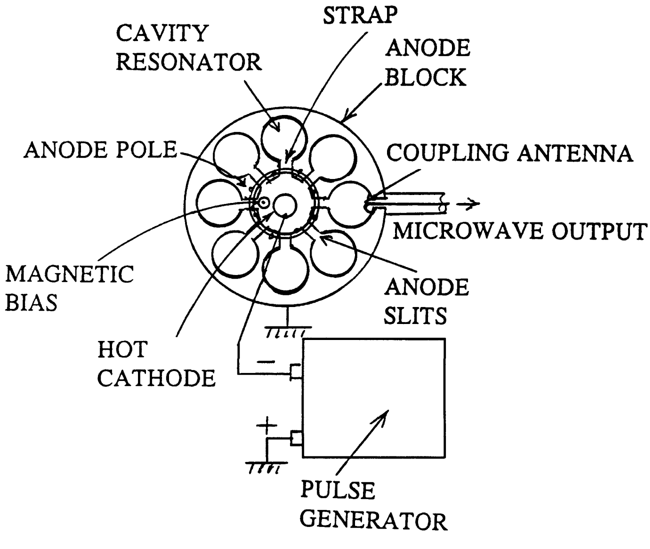

FIG. 13. A schematic cross-sectional view of a radar magnetron.

curves for various levels of output power, magnetic flux density, and efficiency, as illustrated in Fig. 14(a). The chart shows the value of the anode voltage, expected anode current, the required magnetic flux density, the expected microwave output power, and the expected operational efficiency.

A Rieke diagram is a family of plots of constant-frequency curves and constant-output power contours of a microwave oscillator tube on a Smith circuit admittance diagram as shown in Fig. 14(b). The Smith diagram is a diagram of microwave voltage reflection coefficient for various load admittances at various operating frequencies on a complex polar coordinate plot with the origin at the center, unmarked. The diagram was invented by P. H. Smith in 1939 (Smith, 1939, 1944). A point on the Rieke diagram in Fig. 14(b) shows the operating frequency, the output power, corresponding output admittance, voltage reflection coefficient, voltage standing-wave ratio, and the pulling figure of the magnetron (Ishii, 1989). The area marked as sink indicates the value of the load admittance with which the magnetron will not oscillate. The pulling figure is an amount of frequency deviation from the center frequency at the maximum power output where the voltage standing-wave ratio becomes 1.5. It is the indication of frequency stability against the variation of the load admittance. A small pulling figure indicates good frequency stability.

FIG. 14. (a) Performance chart and (b) Rieke diagram of a radar magnetron.

7. GYROTRONS AND FAST-WAVE TUBES

7.1 Gyrotrons

By properly adjusting the magnitude and direction of a dc magnetic field and a dc electric field, it is possible to impart gyrating motion to thermally emitted electrons. This is accomplished by adjusting both the axial acceleration velocity of electrons and axial and radial magnetic flux density together with the cathode geometry and the structure. Electrons are launched from a side-emitting cathode into a long cylinder-shaped anode that constitutes a cylindrical waveguide. The electron beam is formed by electrons in Larmor orbits. The frequency of electron gyrations in the Larmor orbits is Doppler-shifted relativistic cyclotron frequency (Granatstein, 1987; Coleman, 1982). Electrons in Larmor orbits interact with microwave electric fields. If the motion of electron gyration and microwave fields are synchronized so that the electrons are decelerated and lose kinetic energy, that lost energy is transferred into the interacting microwave electric energy fields, and the microwave fields grow stronger. The microwave electric fields are initially induced by the gyrating motion of the electrons and are subsequently strengthened by positive interaction between the gyrating electrons and the induced microwave field. The speed of electron gyration is fast, and the mass of the electron is weakly relativistic (Granatstein, 1987; Coleman, 1983). Vacuum electron devices based on gyrating electron beams are called gyrotrons. If the gyrating electron beam is launched into only one cylindrical waveguide, it is called the gyromonotron (Coleman, 1982).

Gyrotrons generally generate high frequencies, on the order of 100 GHz, and high power, on the order of 100 kW (Coleman, 1982).

In the gyromonotron, if a small microwave signal is fed at the input opening of the waveguide, the signal is amplified if the voltage and emission current are properly adjusted. Such a gyrotron amplifier is called the gyrotraveling-wave-tube. When the anode waveguide of a gyromonotron is split in the middle, the gyrotron is called the gyroklystron. The first waveguide resonator is called the buncher resonator. In this buncher waveguide resonator, the electron beam interacts with the microwave fields and becomes velocity modulated. Electrons are bunched together when they drift out from the buncher waveguide resonator and enter the second waveguide resonator, which is called the catcher. In the catcher waveguide, the bunched electrons amplify microwave electric fields by transferring their kinetic energy to the microwave electric-field strength due to relativistic variation of the mass of electrons.

For more detailed information, readers are encouraged to refer to Granatstein (1987).

7.2 Novel Microwave Tubes

Gyrotrons are considered to be fast-wave tubes. In gyrotrons, electrons are interacting with microwaves of natural speed in a natural, smooth waveguide. This microwave with natural speed is called the fast wave in this particular case. A number of novel microwave tubes are fast-wave tubes. The fast-wave tubes operate on the principle of interaction between the kinetic energy of bunched electrons and a microwave field traveling at its natural speed on a natural waveguide without any slow-wave structure. The features of the fast-wave tubes are, as seen in gyrotrons, high-frequency capability on the order of 100 GHz and, at the same time, high power capability on the order of a megawatt. Besides gyrotrons, Ubitrons and Peniotrons are also considered to be different versions of fast-wave tubes. The fast-wave microwave vacuum electron devices are also called free-electron masers or free-electron lasers depending on the operating wavelength. In Ubitrons, a spatially periodic transverse motion of electrons is created in an electron beam by periodically arranged dc magnets along its path. The periodicity and the phase of the transverse motion of electrons in the electron beam are adjusted to match with the periodicity of microwaves interacting in a multimode cavity resonator in which the electron beam is launched so that the transverse motion of electrons is decelerated by the microwave fields, thereby the kinetic energy is transferred to the energy of microwave fields. Thus the microwave is amplified (Ishii, 1989; Liao, 1988).

In Peniotrons a single helical electron

beam is launched along the center axis of a double-ridge dominant-mode rectangular waveguide. The transverse and tangential component of electron motion in the helical electron beam interacts with the high transverse microwave electric field created by the waveguide ridges. The diameter of the helix formed by the electron beam is adjusted to be equal to the center-to-center distance of the double ridges of the waveguide. The periods and phase of the helical motion of the electrons are synchronized and phased to the interacting microwave fields so that the transverse and tangential component of the electron motion is decelerated by the microwave electric fields. Thus the kinetic energy of the electron motion is transferred to the interacting microwave electric field, and the microwave is amplified (Ishii, 1989; Liao, 1988).

8. TRAVELING-WAVE TUBES (TWTs)

8.1 O-Type TWT

Traveling-wave tubes are vacuum tubes in which the speed of microwave propagation is nearly equal to the speed of electrons in an electron beam. By positive interaction of microwave electric fields and the electron beam, microwaves in TWTs are amplified. In an O-type TWT, an electron beam is focused by a longitudinal magnetic field that is parallel to the direction of electron beam as shown in Fig. 15. The trajectory of an individual electron is a helix.

The electron beam is accelerated by an anode that consists of a long helical conducting transmission line. The microwaves to be amplified are coupled to one end of this helical transmission line. The axial speed of microwave transmission is slowed down to

$$v = c \sin\psi, \tag{35}$$

where ψ is the pitch angle of the helix and c is the tangential speed of the microwaves propagating along the conductor of the helix, which is assumed to be equal to the speed of light in vacuum, 300 Mm/s. In a traveling-wave tube, the acceleration voltage V_a and the helix pitch angle are adjusted so that the electron speed

$$u \approx v. \tag{36}$$

Under this condition the electron beam interacts with the input microwaves. The electron beam is velocity modulated near the input. The acceleration and the deceleration relationships last a long period of time because $u \approx v$. The velocity-modulated electrons bunch as they travel inside the helical transmission line. As they approach the end of the helical line, the tightly bunched electrons lose a part of their kinetic energy through deceleration by microwave electric field, and the lost kinetic energy of the electron beam is transferred to the microwave energy. Thus, the microwaves are amplified. After the energy transfer and induction of the output signal, the electron beam is ter-

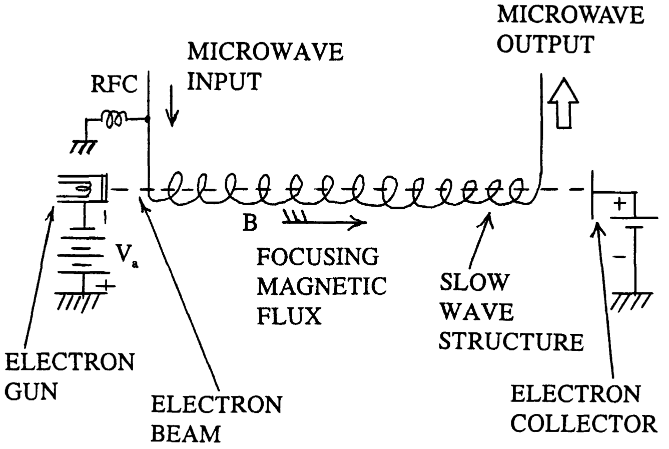

FIG. 15. A schematic diagram of an O-type TWT.

minated by the electron collector as shown in Fig. 15.

The output microwave voltage of a traveling-wave tube is

$$v_0 = v_i \exp\left(\frac{\sqrt{3}}{2} C \frac{\omega l}{u}\right), \tag{37}$$

where l is the length of the interaction region, ω is the operating angular frequency, u is the speed of electrons, v_i is the microwave input voltage, and C is the gain parameter given by

$$C = (Z_0 I_a / 4V_a)^{1/3}, \tag{38}$$

where Z_0 is the characteristic impedance, I_a is the beam current, and V_a is the anode voltage of the TWT.

The voltage gain of the TWT is

$$G \equiv \frac{v_0}{v_i} = \exp\left(\frac{\sqrt{3}C\omega l}{2u}\right) \tag{39}$$

or

$$G[\text{Neper}] = \sqrt{3}C\omega l/2u. \tag{40}$$

Because of the condition that $u \approx v$, the frequency bandwidth of the TWT is generally wide. It is not unusual for a TWT to have a bandwidth more than an octave wide.

8.2 M-Type TWT

The principle of microwave–electron-beam interaction and microwave amplification in an M-type TWT is similar to the principle in the O-type TWT. The difference is in the way that the electron beam is formed and focused. An example of a schematic diagram of an M-type TWT is shown in Fig. 16. Electrons are emitted from a side-mounted electron gun. The electron beam is focused by the vertical dc electric fields between the anode and the sole and the horizontal dc magnetic field, B, which is applied perpendicular to the plane of the paper. Under this condition, the individual electron orbit is a cycloid. As a whole, the electron beam is shaped like a ribbon.

The electron beam then undergoes velocity modulation, bunching, and electrodynamic induction, producing amplified microwaves at the output of the slow-wave transmission structure as in the case of the O-type TWT.

9. DISPLAY TUBES

9.1 Cathode-Ray Oscilloscopes

Electrical phenomena are often graphically displayed by means of a cathode-ray oscilloscope. A schematic diagram of a generic cathode-ray oscilloscope is shown in Fig. 17. An electron beam is launched into a vacuum into the space between two pairs of parallel-plate electrodes. The plate electrodes are for

PHOSPHORESCENT SCREEN

FIG. 17. A schematic diagram of a cathode-ray oscilloscope.

electron-beam deflection. Therefore, these plates are called the electron deflection terminals. If a voltage is applied across the pair of horizontally mounted deflection plates, the electron beam is vertically deflected by the Coulomb force. If a voltage is applied across the pair of vertically mounted deflection plates, the electron beam is horizontally deflected. Where the electron beam hits the phosphorescent screen, it produces visible light. Thus the landing spot of the electron beam on the screen is visible. The landing spot is controlled by the voltages applied across the deflecting plates. Therefore, electrical quantities applied across the deflecting plates are visible on the phosphorescent screen. Normally, a sawtooth wave is applied to the horizontal deflecting plates to produce a time axis.

The deflection angle α of the electron beam is given by (Martin, 1993)

$$\alpha = \tan^{-1}\left(\frac{1}{2}\frac{V_D}{V_0}\frac{l}{d}\right), \tag{41}$$

where V_D is the deflection voltage, V_0 is the anode voltage or the acceleration voltage of the electron beam, l is the length of the deflection plate, and d is the plate separation.

The control grid in Fig. 18 is negatively biased. The amount of negative voltage controls the brightness of the spot on the screen.

9.2 Monitor Tubes

In many video monitor tubes for computers and television picture display, the electron deflection is done magnetically by two

FIG. 18. A schematic diagram of a video monitor tube.

pairs of magnetic coils: one pair for the horizontal deflection and the other pair for the vertical deflection as shown in Fig. 18. These deflection coils control the landing location of the electron beam on the screen, and the video signals applied on the control grid controls the brightness of the spot on the screen. Usually the deflection coils are installed outside of the vacuum envelope.

The deflection angle of the beam, θ, is given by (Martin, 1993)

$$\theta = \sin^{-1}\frac{Nil}{2.68D\sqrt{V_0}}, \qquad (42)$$

where N is the number of turns in the deflection coil, l is the length of the magnetic interaction region, D is the height of the interaction region, V_0 is the anode acceleration voltage of the beam, and i is the coil excitation current.

For a color monitor, usually a multicolor screen is used. Electrons are directed to land at a specific location on the screen to produce the desired color by controlling the deflection coil current and the control grid voltage.

10. IMAGING TUBES

10.1 Vidicon Tubes

Vidicon tubes are vacuum tubes that convert optical images on the front face of the tube into electrical video signals. The electron beam is focused and scanned by the use of the longitudinal focusing magnetic coils and deflecting magnetic coils as in the case of video monitor tubes. However, the target that the electron beam strikes is not a phosphorescent screen, but a rather complicated optical image–electrical video conversion screen.

A schematic diagram of the video conversion screen of a vidicon tube is shown in Fig. 19. Using optics, an image is formed on the target plate. In front of it, there is a transparent semiconductor film a few micrometers thick, called the signal plate, which is electrically connected to the metal ring encircling the front of the tube. The signal plate is positively biased with respect to the electron gun that emits the electron beam. The target plate is coated with a thin film of a photoconductive coating. This photoconductive coating is almost an insulator in the dark. Therefore, in the dark the signal plate and scanning electron beam are virtually insulated from each other and there is very little conduction from the dc supply to the electron beam. When illuminated, the photoconductive coating becomes a conductor, connecting the signal plate and electron beam so that electric current flows from the dc supply to the electron beam. The amount of the current is proportional to the intensity of the light.

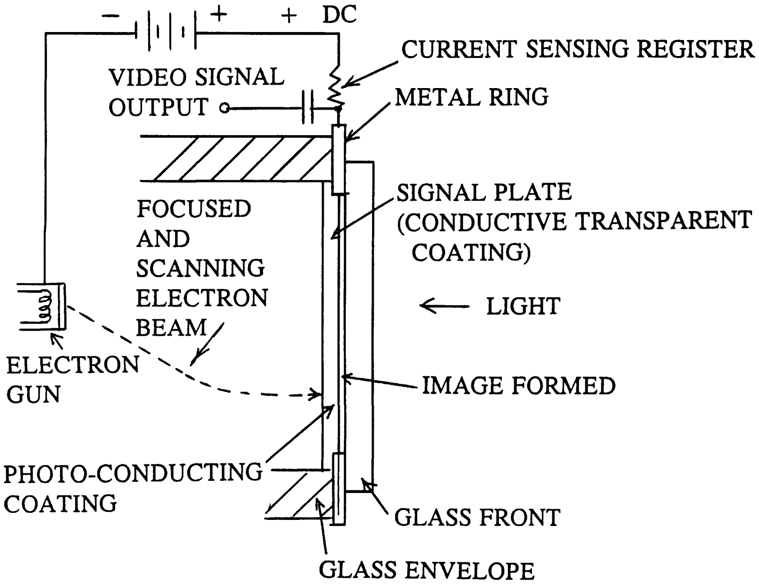

FIG. 19. A schematic diagram of the imaging area of a vidicon tube.

As the electron beam scans across the bright and dark spots of the image on the target plate, a video current proportional to incident light intensity at the beam landing spot flows from the dc supply through the current-sensing resistor, signal plate, and electron beam into the electron gun. Thus, a video voltage signal is developed across the current-sensing resistor shown in Fig. 19. From there the video voltage signal is capacitively coupled out and processed for remote television imaging systems.

A family of imaging tubes such as the infrared vidicon, silicon-target vidicon, plumbicon, and orthicon operate using basic principles similar to those of the vidicon tube (Liao, 1988).

10.2 Thermicon Tubes

The thermicon tube is a vacuum tube that converts infrared images into electrical video signals by temperature-dependent photoelectron emission. This is useful for seeing through darkness and fog. An essential part of the thermicon is schematically shown in Fig. 20. There is a plate that is electrically conductive, as well as thermally and optically transparent. One side of the plate is coated with a thin layer of material that absorbs infrared light but is transparent to visible light. An infrared image is formed by optics on this infrared absorbing layer. The infrared image heats up the plate according to its light and dark spots, creating a specific heat distribution pattern on the plate depending on the infrared image. The heat distribution is transmitted to the other side of the plate where photoelectron emitting layer is formed by coating with thermally sensitive photoemitting material. The photoemission efficiency depends on the temperature of the material.

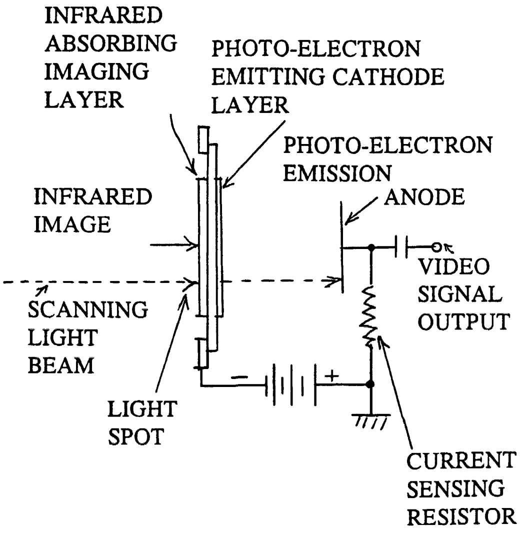

FIG. 20. A schematic diagram of the essential part of a thermicon.

If a bright infrared spot on the image plate is illuminated by a scanning spot of visible light, photoelectrons will be emitted. More infrared illumination will cause more photoelectron emission when spotlighted. The emitted electrons are collected by the anode, and the anode current is sensed by the current-sensing resistor. Across the current-sensing resistor, the video signal voltage develops as the light spot is scanned on the infrared image plate. This infrared image plate is called the retina of the thermicon (Liao, 1988).

11. SCIENTIFIC VACUUM ELECTRONICS

11.1 Electron Microscopes

Details of electron microscopes are covered in ELECTRON MICROSCOPY. Here a summary of the basic principles of electron microscopy is presented.

The main objective of electron microscopy is to obtain higher resolution and higher magnification than optical microscopy. The higher resolution is obtainable if the operating wavelength is shorter. The wavelength of visible light ranges from 400 to 700 nm. The wavelength of waves associated with the electron beam is (Harman, 1953)

$$\lambda = 1.23 \times 10^{-9}/\sqrt{V}, \qquad (43)$$

where V is the acceleration voltage of the electron. If V is 1000 V, the wavelength is only 0.04 nm. In practice, due to limitations in electron-focusing systems, the resolution obtainable by electron microscopy is on the order of 1 nm (Harman, 1953). In visible-light microscopy, the resolution is on the order of a micron.

It should be noted that the waves associated with an electron beam are electron waves, not electromagnetic waves like visible light (Harman, 1953). The wavelength of an electron wave associated with an electron beam is

$$\lambda = h/mv, \tag{44}$$

where h is Planck's constant, 6.62×10^{-34} J-s, m is the electron mass, and v is the electron velocity (Sproull, 1958);

$$mv = m_0 v/\sqrt{1 - v^2/c^2}, \tag{45}$$

where m_0 is the rest mass of an electron and c is the speed of light in a vacuum; mv is the momentum of an electron in the beam.

The moving electrons can be focused by the Lorentz magnetic force, which is

$$\mathbf{F} = e\mathbf{B} \times \mathbf{v} \quad \text{(Newton)}, \tag{46}$$

where $\mathbf{B}$ is the magnetic flux density vector, $\mathbf{v}$ is the velocity vector of the moving electrons, and e is the electric charge of an electron.

Therefore, if a magnetic focusing system is arranged as shown in Fig. 21, it is possible to form a microscope using electron waves. The electron gun emits an electron beam in a vacuum environment. The electron beam is then focused to form a paraxial beam by the longitudinally parallel magnetic flux created by the focusing magnet. The paraxial electron beam hits the specimen and, according to the nature of the specimen, experiences absorption and scattering of the electron waves. Therefore, the electron-wave beam transmitted through the specimen is influenced by the image of the specimen. The electron-wave beam transmitted through the specimen is focused again and diverged by properly shaped magnetic flux of the first electron-beam focusing and diverging magnet. This magnet is called the magnetic objective lens. Thus the first enlarged image is formed. The middle part of the first image is further focused and diverged by the second beam focusing and diverging magnet, which is called the magnetic projector lens. The electron-wave beam through this last magnet is projected onto an imaging screen that is either a photographic plate or a fluorescent screen. Thus a great magnification and resolution are obtainable using an electron microscope.

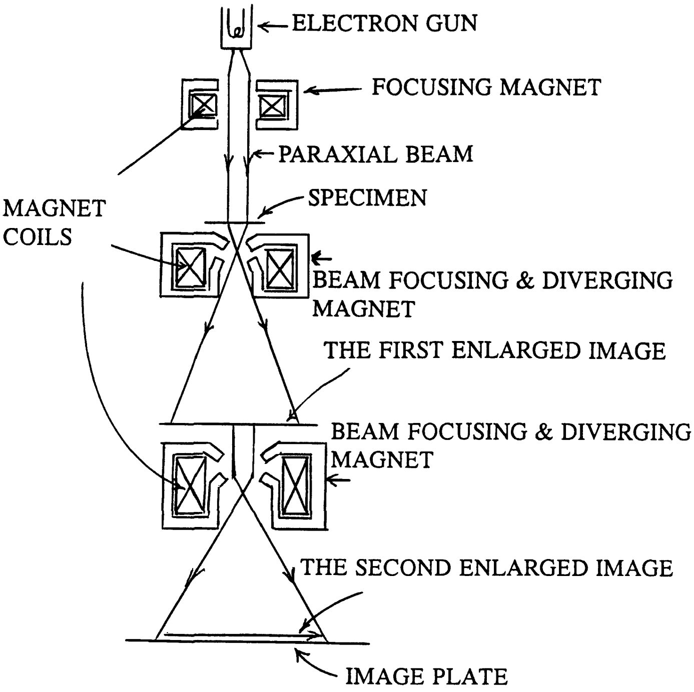

FIG. 21. A functional diagram of an electron microscope.

11.2 Particle Accelerators

Particle accelerators are used for the study of elementary particles and structure of atoms and molecules. There are a number of different types of particle accelerators including cyclotrons, synchrotrons, and linear accelerators. Details of these devices are given in CYCLOTRONS; SYNCHOTRONS; and ACCELERATORS, LINEAR. It should be noted here that particle accelerators are applications of vacuum electronics.

GLOSSARY

Convection Current: An electric current due to the motion of electrically charged particles.

Electrodynamic Induction: Induction of a time-varying electric current in a circuit by the motion of electrically charged particles in a space that is coupled to the circuit.

Electron Bunching: The formation of localized groups of electrons.

Electron Gun: A vacuum electron device consisting of a heated cathode, accelerating anodes, and focusing electrodes used as an electron-beam source.

Electron Multiplier: A thermionic device to multiply the number of electrons by the use of cascading electron multiplication by collision with secondary-electron producing electrodes and production and acceleration of secondary electrons.

Electron Transit Cycles: Number of microwave cycles elapsed while an electron is traveling a given distance.

Grid Cutoff Voltage: The value of negative grid voltage to make zero anode current in a vacuum tube.

Kinetic Potential: Electric potential generated by the motion of charged particles.

Perveance: Ratio of the anode current to the $\frac{3}{2}$ power of the anode or equivalent anode voltage of a vacuum tube.

Transconductance: The ratio of change of the anode current to the change of control grid voltage in a vacuum tube.

INTRODUCTION

Producing a low-pressure working environment requires understanding of pumping techniques, materials of construction, and sources of gas and the manner in which they flow, as well as practical issues such as chamber cleaning and leak detecting. This article briefly reviews these issues.

1. PUMPING TECHNIQUES

Removal of gas from an enclosed volume is accomplished by either displacement or capture pumping. Displacement pumps are compressors, and capture pumps are condensers or adsorbers. Displacement pumps transport gas to their exits, whereas capture pumps store gas.

1.1 Displacement Pumps

Displacement pumps admit and compress gas and exhaust it to another pump or to the atmosphere. The parameters that describe the performance of a displacement pump are pumping speed and compression ratio, and both are functions of inlet pressure. The compression ratio is the ratio of pump outlet pressure to pump inlet pressure. The (volumetric) speed is the ease with which gas can flow across a surface—the volumetric gas flow divided by the pressure at the plane of the measurement. The compression ratio of some pumps is so high that one rarely quotes numerical values. Oil-sealed vane, piston, lobe, turbomolecular, and diffusion pumps are displacement pumps used for research, development, and manufacturing applications. Dry pumps operate without using oil as a sealing medium.

1.1.1 Rotary Oil-Sealed Rotary vane and piston pumps are oil-sealed mechanical pumps. The vane pump has a cylindrical rotor with, usually, two vanes located within, but offset from the axis of, a hollow stator cylinder. The vacuum seal is made between the vane tips and stator walls, and between the rotor cylinder and stator. See Fig. 1. Gas is admitted into the region between the rotor and stator, compressed, and forced past the exhaust valve to the atmosphere. A single-stage pump can exhaust to pressures of order 1 Pa, whereas a double-stage pump can exhaust to pressures of 0.01 Pa. In practical applications one rarely uses either pump below 10 Pa, or backstreaming to the chamber will result. Backstreaming is the flow of oil or other undesirable vapor in the direction counter to the desired flow.

Piston pumps are rugged, but their asymmetric design generates vibration, which can be controlled with a balancing design. The principle, sketched in Fig. 2, involves rotation of a cylindrical piston and hinge bar such that gas is allowed to enter the cavity between the cylinder and stator where it is compressed and ejected. The piston is mechanically constrained from touching the stator. The sealing surfaces are located at the hinge bar and the point of closest approach of the piston and stator wall. Two complete revolutions of the piston are required for each pumping cycle. They have the advantage of simplicity—no vanes to stick—and they must be physically mounted to the floor.

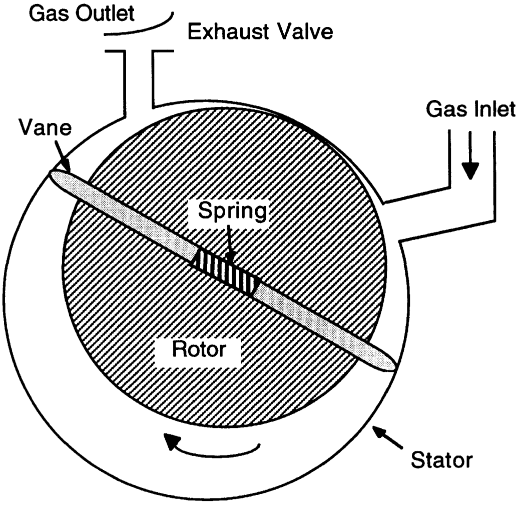

FIG. 1. Rotary oil-sealed mechanical pump; the axis of rotation of the cylindrical rotor is offset from the axis of rotation of the cylindrical stator housing.

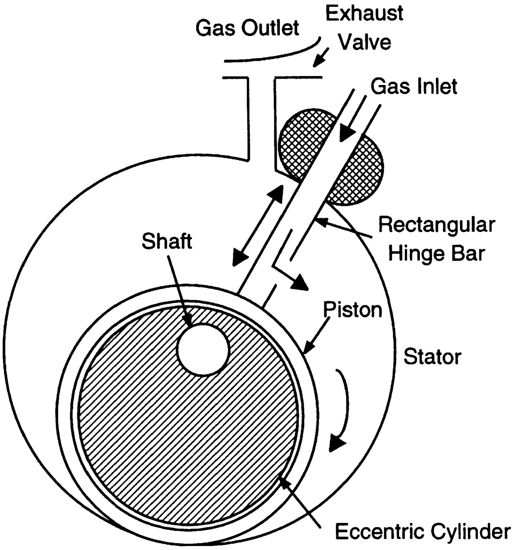

FIG. 2. Rotary piston pump; the axis of rotation of the shaft is concentric with the stator housing. The hinge bar is a rectangular cylinder that slides within the stator; it forms the path by which gas enters the pump. The hinge bar turns or hinges about the shaft such that a small gap remains between the rotor and stator.

1.1.2 Lobe Lobe pumps or blowers can move large volumes of gas efficiently. The two "figure 8" lobes, illustrated in Fig. 3, rotate in opposition and never touch each other or the stator housing. No fluid is used to seal the 0.9-mm gap between the two surfaces. Useful compression is obtained by spinning the rotors at speeds of order 3 500 rpm. The compression ratio is a maximum at about 100 Pa. For lobe blowers designed to work in vacuum, the work of compression will generate enough heat above 1 000 Pa to cause rotor expansion and pump damage, if the staging ratio is >1. The staging ratio is the ratio of lobe blower displacement to mechanical pump displacement. Thus, power is not applied to the shaft until this pressure is reached. Lobe blowers must exhaust into a mechanical pump. A typical staging ratio is 5:1 or 10:1. Lobe blower–mechanical pump sets are useful for achieving low pressures

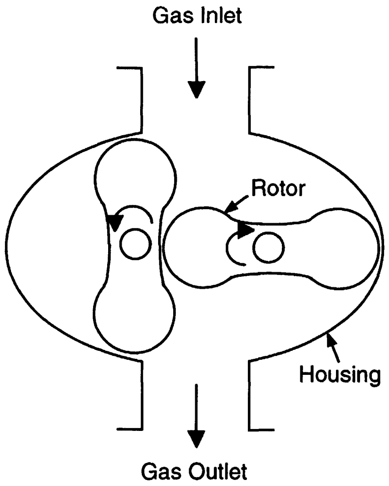

FIG. 3. Lobe pump, or Roots blower; the lobes rotate in opposite directions. They do not touch each other or the wall.

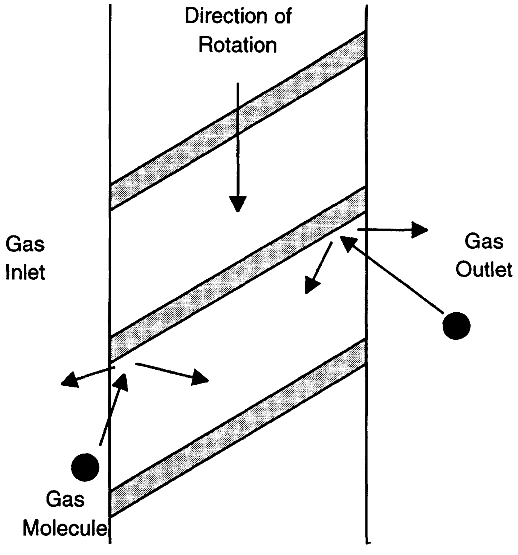

FIG. 4. End view of a moving blade in a turbomolecular pump illustrating how the moving blade preferentially adds momentum directed to the right. Molecules entering the pump are preferentially transmitted, whereas those molecules that have left the pump are prevented from backstreaming.

and high speeds. For a lower practical pressure limit of a mechanical pump—say, 10 Pa—to reduce oil backstreaming from the mechanical pump, the minimum inlet pressure of the lobe blower will be about 2 to 5 Pa. Speeds above 200 to 300 m^3/h are obtainable with either pump but are more economically obtained with a series combination of lobe and mechanical pump than with a large mechanical pump.

1.1.3 Turbomolecular Turbopumps use metal blades as "molecular bats." The blades compress gas by transferring momentum from moving blades to gas molecules, as sketched in Fig. 4. The blade tip velocity is comparable to the thermal velocity of a nitrogen molecule. Heavy gases are compressed well, but the maximum compression ratio, with no flow, for hydrogen is only 1 500 to 15 000 in modern pumps with about 20 blade pairs. See Kruger and Shapiro (1961). If the exhaust pressure of a turbopump is too high, say 20 Pa, the blade speed will decrease on account of viscous drag. In a similar manner, increasing the inlet pressure above 0.4 Pa will reduce the blade speed. Turbopumps are used where oil contamination must be minimized or where high gas flows must be pumped without interruption. They are manufactured with coated aluminum blades for pumping corrosive gases and with magnetically levitated blades for dry pumping applications. They can reach pressures of 10^{-8} Pa. When power is removed from a turbo pump, it must be properly vented to prevent vapors from the foreline side of the pump from reaching the inlet. This is best accomplished by closing the valve between the chamber and the turbo, followed by venting with dry nitrogen through the turbo pump inlet, after the blades have slowed to approximately 50% of their natural rotational velocity (Nesseldreher, 1976).

1.1.4 Dry In addition to the lobe pump, several other vacuum pumps have been designed that do not use organic fluids as a sealing medium. Carbon-vane, PTFE-sealed piston, claw, and scroll pumps have been used in a variety of applications. PTFE-sealed pumps and carbon-vane pumps are capable of roughing from atmosphere, but they generate contamination and do not operate well when pumping on the dust-laden gas streams characteristic of certain industrial processes. Wide-range turbopumps incorporating a molecular drag stage after a turbo stage can exhaust at 0.2 to 0.3 Pa into a diaphragm pump and provide "oil-free"

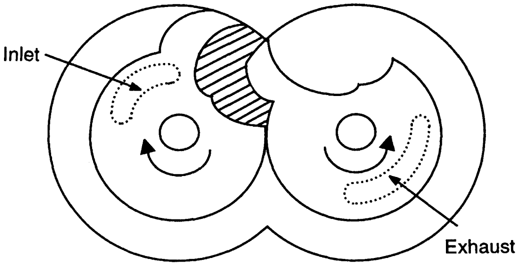

FIG. 5. Lobe pump using claw-shaped rotor; gas enters in the left-hand entrance arc and exits through the right-hand arc.

pumping. The claw, scroll, and lobe pumps are three pumps used where oil-free pumping of particle-laden gases is required. The claw mechanism, shown in Fig. 5, is a compressor, which produces a high compression ratio at pressures higher than in a lobe blower. One commercial design utilizes a lobe (inlet) blower in series with several claw pumps to produce a high gas flow, a high compression ratio, and a low ultimate pressure. The scroll pump consists of fixed and rotating scrolls that mesh to form crescent-shaped volumes. Gas is transported from the entrance slot to the exit slot, where it is discharged to atmosphere. Scroll pumps have usable speeds in the pressure range 1 000 Pa to atmosphere. Scroll pumps have only recently been considered for commercial use.

1.1.5 Diffusion Like the turbo pump, the diffusion pump is a momentum-transfer pump in which large organic molecules are the molecular "bats." See Fig. 6. Pumps are constructed with three or four jet stages in series. The fluid is heated in a boiler, and the vapors, traveling at supersonic speeds, exit the jets and travel to the walls where they are cooled and condense. The critical inlet pressure of a diffusion pump depends on its diameter and is typically 0.1 to 0.01 Pa for pumps smaller than 300 mm in diameter. Above this pressure the upper jet will collapse. The critical forepressure is of order 40–50 Pa, or about half the vapor pressure of the fluid at its operating temperature. If the exhaust is raised above this pressure, the back pressure will prevent the vapor jets

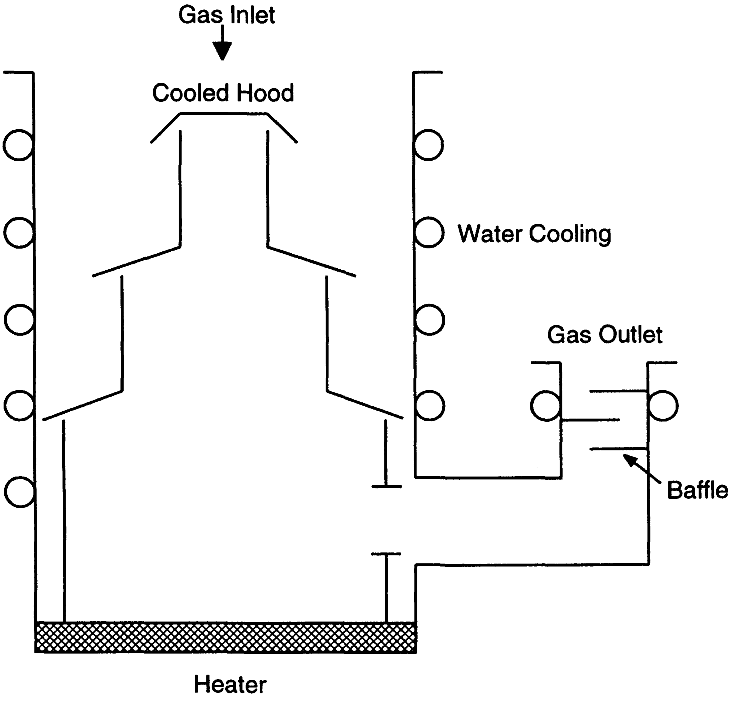

FIG. 6. Oil diffusion pump; oil vapors streaming from the jet assemblies travel to the wall where they condense and return to the boiler.

from reaching the walls and cause a cloud of pump fluid vapor to form at the top of the pump, where it can be transported to the chamber. Thus, the diffusion pump must be exhausted into a mechanical pump. The ultimate pressure of an oil diffusion pump will be determined by the fluid type, chamber materials, and cleaning techniques. Pressures as low as 10^{-10} Pa have been obtained with a liquid-nitrogen–cooled trap.

1.1.6 Pump Fluids A mechanical pump fluid must seal, lubricate, and cool. Turbomolecular and lobe-blower fluids cool and lubricate bearings, whereas diffusion-pump fluids must boil with low heat, be stable at high temperatures, and have extremely low vapor pressures. Petroleum (mineral) oils find application in all pumps. The best mineral oils are those containing mainly paraffin with lesser fractions of naphthalene and ring compounds. Fluids of different viscosity are blended to produce vane, piston, and lobe-blower fluids. Turbomolecular and diffusion-pump oils are distilled once to remove low–molecular-weight fractions, which would increase the fluid's vapor pressure. Pentaphenyl silicone and polyphenyl ether fluids are high-quality diffusion-pump fluids, with extremely low vapor pressures.

The fluids described above are not suitable for use in applications involving corrosive or oxidizing gases. For those applications a perfluoropoly ether (PFPE) fluid is preferred. PFPE fluids are rather expensive, but reasonably inert to a large range of chemicals. They are bases in the Lewis sense, and so the corresponding acids, such as boron trichloride (used for etching aluminum films) or aluminum trichloride (an etch by-product), will cause slow decomposition at the temperatures found in mechanical or turbo pumps. One would not pump on these gases with a PFPE-filled diffusion pump, as the high temperature would cause decomposition in minutes. Older fluids, e.g., phosphate esters, present disposal problems and are no longer used; they have been supplanted by PFPE. Reclamation has been reviewed by Whitman (1987).

1.2 Capture Pumps

Capture pumps condense, physisorb, and chemisorb gases and vapors, which are stored on surfaces or diffuse into deposited films. Their pumping speed is not constant with time but depends on the species being pumped, as well as the species and quantity of gas previously pumped. Capture pumps saturate periodically and require regeneration. Regeneration provides a fresh surface, either by desorbing the entrapped gas or by covering it with a newly deposited film. Cryogenic, sorption, titanium sublimation, nonevaporable getter, and ion pumps are important capture pumps.

1.2.1 Cryogenic and Sorption. The cryogenic pump captures gas molecules by condensation and sorption. A cryopump consists of a source of low temperatures and an array of surfaces on which molecules can become entrapped. The simplest source is a liquid cryogen such as nitrogen or helium, and indeed the former has long been used as a cold trap or Meissner trap to enhance the pumping of water vapor. Commercial cryopumps achieve low temperatures by means of a two-stage helium gas refrigerator (Gifford, 1966). The pumping arrays are connected to the two stages, which cool the arrays to ranges of 15 to 25 K and 70 to 100 K, respectively. The warm stage pumps water and some CO_2 by condensation, just as does a liquid-nitrogen trap. The cold stage has two surfaces: an outer (condensation) surface that pumps all other gases except H_2, He, and Ne, and an inner charcoal-coated (sorption) surface that pumps these three gases.

As the charcoal surface becomes saturated with sorbate, it ceases to pump. The cryocondensing surfaces will continue to pump. However, their "ice" surface temperatures increase, and ultimately the "ice" on the cold stage can make a thermal short to the warm stage, or the water ice on the warm stage can make a thermal short to the pump housing. Cryopumps are regenerated by admitting warm nitrogen gas directly onto the cold stage while the released gases are purged. Regeneration is needed rather infrequently on high-vacuum systems but frequently on sputter deposition systems, or other systems that pump large gas loads. The cryopump is widely used because it is organic free and not easily damaged if the system is accidentally mistreated.

Sorption pumps are containers filled with a zeolite, which is cooled until it equilibrates with its surrounding liquid-nitrogen bath. Zeolites possess an extremely large interior surface onto which gases can sorb to a depth of one monolayer. A quantity of zeolite the size of a softball contains one acre of surface one monolayer deep. Sorption pumps do not pump any noble gases. Noble gases can be partially pumped by using a series of pump modules. Each module can be opened, then closed quickly, while the gas remains in the viscous flow regime. During that brief time, all gases enter in viscous flow, without mass discrimination. A large fraction of the nonadsorbed gases are thus isolated from the system. A series of three pump modules can pump below the natural atmospheric partial pressure of neon. Sorption pumps are used as roughing pumps on systems in which the high vacuum is produced with titanium sublimation pumps (TSPs) and ion pumps to produce an all oil-free pumped environment.

1.2.2 Getter and Ion Getters are used alone, as in the TSP and nonevaporable getter (NEG) pump, or form part of the mechanism of the ion pump. The TSP is a getter pump that sorbs gases in freshly deposited titanium films. Water dissociates into oxygen and hydrogen. Oxygen and nitrogen are chemisorbed. Hydrogen diffuses inward to form a hydride, whereas methane is only weakly bonded—its adsorption is extremely small. Inert gases are not pumped. Periodically, fresh titanium films must be redeposited. This deposition frequency may be only once or twice daily at 10^{-10} Pa; however, at 10^{-3} Pa the filament must continually sublime. These pumps find application in research environments where, in combination with ion pumps, they provide a low-cost, oil-free method for achieving ultrahigh vacuum.

The NEG pumps find application in maintaining pressure in small isolated systems, as well as in distributed pumping for multikilometer-long accelerator systems. The NEG pumps are fabricated from Zr-Al or Zr-V-Fe alloys. Activation requires heating, which allows the oxide formed on the surface to diffuse inward, leaving a fresh surface to pump reactive gases. All gases except inert and hydrogen are pumped as compounds. Hydrogen is pumped as a hydride and can be expelled by heating, if regeneration is necessary. The NEG pumps begin to operate at 1 Pa. They have also found application as ultrapure gas purifiers.

The basic ion-pump cell consists of a cylindrical anode centered between two cathode disks. A dc voltage of order 5 000 V is applied between the anode and cathodes. A magnetic field of order 0.1 T is applied along the axial direction of the anode. An array of these cells forms a basic module. The module is located within the vacuum wall, which is surrounded by magnets located outside of the vacuum. This field creates an electromagnetic mirror, which traps electrons in circular orbits within the cell and increases their probability of colliding with and ionizing gas molecules. A number of modules can be connected to increase the total pumping speed. Active gases are pumped by burial in the titanium cathode or by reaction with titanium sputtered on the anode. Noble gases are only buried and have low pumping rates. Organic gases are first dissociated and then adsorbed. Ion pumps were the first to pump to ultrahigh vacuum without producing an organic contaminant. They are used in laboratory systems, high-power electron tubes, and small isolated systems and to supplement NEG pumps in large accelerator facilities.

2. GAS SOURCES

Gases and vapors to be removed from a vacuum vessel originate from within the volume of the chamber and from its internal surfaces. Volume sources are quite easily removed, whereas surface sources present the most serious obstacles in achieving low pressures.

2.1 Volume

The differential equation describing the time dependence of the pressure in a vacuum vessel during pumping of the gas within the chamber volume is given by

$$\frac{d(VP)}{dt} = -SP, \tag{1}$$

where VP is the volumetric gas quantity and S is the pumping speed. Volume V is measured in cubic meters, pressure P in pascals, and speed S in cubic meters per second. Alternatively, this equation may be recast in units commonly used in North America (pressure in units of Torr and speed in units of liters/second) or in units used in Europe (pressure in units of millibars, and speed in units of cubic meters per hour). VdP/dt is the rate at which gas flows from the chamber (the volumetric flow), and SP is the rate at which gas flows to the pump. These terms both have units of power—Pa·m^3/s or J/s. This "power" is the power dissipated in transporting the volumetric gas quantity. Volumetric pumping speed, flow, and gas quantity are not conservable. The volumetric gas quantity PV, according to the ideal gas law, equates to NkT; thus the number of molecules N in the volumetric quantity is dependent on the absolute temperature T. k is Boltzmann's constant. If the pumping speed is constant with pressure, the solution to (1) is

$$P = P_0 \exp(-St/V), \tag{2}$$

where $V/S = \tau$, the system time constant, is typically a few seconds, implying that a system could pump to a useful high vacuum pressure, say 10^{-5} Pa, from atmosphere in, say, 100 s. In practice it takes hours, because there is always gas released from real surfaces.

2.2 Surface

At low gas pressures the atoms and molecules originate from a number of surface sources. Gas adsorbed on the walls can be desorbed by thermal or other stimulated mechanisms. Gas dissolved within a solid can diffuse to the surface and desorb. Gas can permeate through some materials by the three-step processes of adsorption, diffusion, and desorption. Pumps are also sources of gas, as are chambers that contain trapped gas pockets or virtual leaks, such as those found at the end of a blind tapped screw thread, or closely spaced surfaces.

A quick mental exercise reveals the pressure at which volume gas sources become less important than surface gas sources. Envision a chamber containing no gas atoms in the volume and containing one atomic layer of adsorbed gas. The ideal gas law shows that the pressure associated with the instant release of this surface layer is of order 4 Pa for a 1-L chamber. Pressures below this range cannot be obtained without attention to reducing the surface gas load.

Surface gases release slowly. An approximate time dependence of the surface outgassing term Q_s is $Q_m t^{-n}$, where n ranges from 0.5 to 1.5 and m denotes the time at which the coefficient was measured. Permeation Q_p is constant with time. A quasistatic solution to (1) with these terms added is

$$P = P_0 e^{St/V} + (Q_m/S)t^{-n} + Q_P/S. \tag{3}$$

Outgassing and permeation data have been extensively reviewed in a number of textbooks and articles. Representative outgassing data are given in Dylla *et al.* (1993), Elsey (1975), and Nuovolone (1977). Peacock (1980) has reviewed the performance and selection of elastomer seals. Dylla *et al.* (1993) have described procedures for reducing the gas load in systems during pumping. Oxygen and water-vapor permeation data for new and established elastomers have been published by Ma *et al.* (1995).

3. GAS-FLOW FUNDAMENTALS

3.1 Molecular

Molecular flow occurs at low pressures, where Knudsen's number is >1. Knudsen's number is the ratio of mean free path to chamber dimension. The mean free path is the average distance that a molecule travels before colliding with another molecule. In molecular flow, molecules travel in straight lines and, because the mean free path is longer than a chamber dimension, collide with walls rather than other molecules. Molecules arriving at a wall lose their directed momentum and leave the wall in a diffuse (cosine) distribution, where the most likely direction of departure is normal to the surface. Molecular conductance, the gas flow through an object divided by the pressure difference across the object, is given by $C = A(v/4)a$ and is constant for pressures low enough for the mean free path to be longer than the dimension of the object, and is proportional to the cross-sectional area of the object. Here $v = (8kT/\pi m)^{1/2}$ is the thermal velocity, A is the cross-sectional area, and a is the transmission probability. In 1932 the transmission probability was first calculated for round tubes by Clausing (1971). Clausing's results, as well as the (Monte Carlo) transmission probabilities for many complex components, are found in most vacuum texts. For very long, round tubes the conductance is proportional to the third power of the diameter, because the transmission probability for long tubes is inversely proportional to l/d, the ratio of pipe length to pipe diameter.

Components in series have a net conductance less than any one component. Series conductances add as reciprocals, to within an accuracy of 20%. Oatley (1957) derived the following equation, which is valid to a few percent:

$$1/C_{\text{net}} = 1/C_1 + 1/C_2 \ldots + 1/C_m - (m - 1). \tag{4}$$

This relationship is valid for components with equal cross-sectional areas. Unequal areas are best dealt with by a method developed by Haefer (1980). The low series conductance of objects such as pipes, valves, and traps is a significant contributing factor to the low pumping speeds and slow pressure decrease observed in the molecular regime.

3.2 Viscous Laminar

Laminar flow is characterized by stream flow and occurs in pipes in which Knudsen's number is <0.01 and Reynolds number is <2 200—typically, in the pressure region 10^4 Pa to 0.1 Pa. For extremely long pipes, where the Hagen–Poiseuille equation is valid, the conductivity is proportional to the fourth power of the pipe diameter times the average pressure. However, this equation is not normally applicable to real pumping lines, as they are rarely long enough to meet the conditions of validity. Santeler (1986) has developed an excellent model where the viscous flow in a short tube is considered to be Poiseuille flow in series with a choked aperture.

3.3 Choke

Choke flow is the limiting turbulent flow through an orifice, determined by the speed of sound. Turbulent flow is chaotic flow characterized by a Reynolds number of >2 200 and a Knudsen's number <0.001. The magnitude of the choke flow through an orifice is proportional to the upstream pressure and the orifice area provided that the downstream pressure, for air, is $\leq 0.52\ P_{\text{upstream}}$. For other gases, this value will differ. The important concept is that the gas flow is limited by the speed of sound. This allows the construction of simple fixed-flow orifices, which are used in calibration fixtures as well as for improved safety on flammable gas cylinders. Choke flow is observed in the initial or "rough" pumping of a vacuum system. Often a choke is used to limit the flow until a pressure of approximately 0.1 atmosphere is reached, so that the chamber will not cool rapidly and cause condensation, as described in Sec. 4.3.

4. SYSTEM PERFORMANCE

A number of issues affect the performance of a vacuum system. The ultimate pressure of a pump is $P = Q/S$. The pumping speed can be doubled or tripled by use of a larger pump, but it is not physically possible to increase it much beyond that value; this is a costly and inefficient way to reduce pressure. Note that the conductances added in series with a diffusion pump (valve, trap, and pipe) typically reduce the speed at the chamber entrance to a value equal to $\frac{1}{3}$ of the basic diffusion pump speed. Gas sources contributing to the total load Q can be reduced by several orders of magnitude; therefore, anything that can be done to reduce the total load will contribute greatly to reducing the total pressure. Backstreaming, outgassing, permeation, surface treatments, conditioning procedures, exposures to ambient gases, and condensation of vapors are all issues that affect the total gas load. Doubling the speed of the pump would only decrease the ultimate pressure by a factor of 2.

4.1 Backstreaming

Backstreaming in displacement pumps results from a small but finite transmission probability in the reverse direction for exhausted gases and working fluids. Working-fluid vapors enter the chamber either from the inlet of the diffusion pump or from the inlet of the mechanical pump. Diffusion-pump vapors can be reduced to extremely small levels by use of a liquid-nitrogen cold trap and a low–vapor-pressure fluid and by not exceeding the critical inlet pressure. In systems not using a liquid-nitrogen trap, back-migration of diffusion-pump fluid is most easily reduced by using either pentaphenyl ether or pentaphenyl silicone, which have the lowest known vapor pressures of any commercially available fluid. These two fluids have vapor pressures, determined by extrapolation, of order 10^{-8} Pa at 25 °C. Contamination from the mechanical pump can be reduced by remaining in the viscous flow range where counterflow diffusion is dominant: >15 to 20 Pa in a 5- to 10-cm-diameter pipe. Residual-gas spectra from diffusion-pumped chambers invariably show that the contamination originates in the mechanical pump, so that correct mechanical pumping procedures are the single most important method of reducing organic vapor contamination.

In capture pumps backstreaming results from the release of entrapped gases. Backstreaming is often equated with organic fluid vapors; however, more generally it is any gas released by a pump that migrates to the chamber. In a cryopump it may be helium, hydrogen, or neon released from a warming surface. In an ion pump it may be release of buried argon. In a TSP or NEG pump it may be the retrograde solubility-limited release of hydrogen.

4.2 Outgassing and Permeation

Performance of representative systems can be estimated from three typical outgassing rates [units of Pa-m^3/(s-cm^2) or W]: unbaked stainless steel, aluminum, or Pyrex, 10×10^{-7}; baked stainless steel or aluminum, 2×10^{-11} (Ishimaru, 1993); and Viton elastomer, 1×10^{-3}. If one considers the three example systems described here, the relative roles of these materials become clear. Each example system has an internal area of 1 m^2, a pumping speed of 1 m^3/s, and, if using an elastomer O-ring, an added area of 100 cm^2. The calculated base pressures are 2×10^{-11} Pa (baked), 1×10^{-6} Pa (unbaked, no O-ring), and 1.1×10^{-5} Pa (unbaked with O-ring). To this we must add permeation. The permeation rate of Perspex is 3×10^{-12} m^2/s; thus, a 15-cm-diameter × 1-cm-thick Perspex window will raise the base pressure of this example system to 10^{-3} Pa. These simple examples illustrate the essence of vacuum technology: Ultrahigh-vacuum systems need to use all-metal gaskets, be cleaned extensively, and be thoroughly baked. The performance of unbaked vacuum systems is limited by the water permeation of elastomeric O-rings and water desorption from walls; dirty walls can contribute more outgassing than O-rings. Polymeric windows can result in significant water permeation.

A properly designed vacuum system should have short, large-diameter tubulations connecting the pumps and chamber, in order to reduce their conductance-limiting effect. Good design will also minimize locations where gas can become entrapped. Even with the best designs, which use load locks to prevent atmospheric water vapor from reaching the process chamber, the outgassing from all surfaces not baked will limit the purity of the process gas. Process gases, e.g., argon for sputtering, are available with impurity levels of order 1 part per billion (i.e., 10^{-9}). Even when gases of this purity are used, the outgassing load from the cleanest load-locked chamber will result in a net impurity in the parts-per-thousand range. Geyari (1976) discussed effects of corrosion on the properties of stainless steel.

4.3 Dynamic Effects

Adiabatic expansion causes gas cooling on sudden pumping. When gas expands, it does work on its surroundings and becomes colder. The ratio of initial to final temperature is related to the ratio of initial to final pressure in an adiabatic system. Real systems will act adiabatic initially but will soon become isothermal. That is, the chamber temperature will drop to a minimum of about -30 to -80 °C in about 0.5 to 1 s, corresponding to a pressure of about 80 000 Pa, and then recover to ambient in 20 to 30 s. During this brief temperature excursion, water and other condensable vapors become supersaturated and condense heterogeneously on ions or submicron particles or condense homogeneously. These (≈ 20 μm) droplets will fall and carry the entrapped particles to surfaces below. This effect, commonly observed when pumping from atmosphere, can also be seen when the sudden pressure drop is initiated from a low pressure, say 10 Pa; however, the amount of condensation is reduced proportionally. Several articles describe this effect in detail and provide solutions: Zhao *et al.* (1990), Wu *et al.* (1990), and O'Hanlon and Shieh (1990).

Pumping time will be increased if the chamber has had time to equilibrate with the ambient after opening. During the exposure to atmosphere, water will diffuse into material surfaces and elastomer gaskets. The amount of surface adsorption is related to the nature of the oxide layer on the chamber interior, and the amount of diffusion into elastomer gaskets is material dependent. Dayton (1995) and Ma *et al.* (1995) have developed models for surface and elastomer readsorption. Li and Dylla (1993) have shown that the amount of water adsorbed on stainless steel is proportional to the atmospheric exposure time and relative humidity. These studies quantitatively verify historically well-known practices. Most importantly, one should vent a system to atmosphere with nitrogen or other very dry gas. It is also important to minimize the atmospheric exposure time and to maintain an outward purge flow of dry nitrogen gas when transferring samples. In some systems, e.g., with large doors, the nitrogen flow is of no value. For those systems, one can maintain the walls at 40 to 50 °C to reduce readsorption.

5. VACUUM INSTRUMENTATION

Pressure and flow are two basic quantities measured routinely in vacuum. Both quantities need to be measured in ranges spanning as many as 16 decades, with the result that no one instrument can measure either quantity over this range. Additional quantities are derived from these measurements. Four total-pressure gauges, two partial-pressure gauges, and one flow meter are described here.

5.1 Total-Pressure Gauges

Total-pressure gauges either are direct—that is, they measure force on a solid or liquid surface—or they are indirect, and infer the pressure from a gas property, such as heat flow or ionization. A thorough discussion of total-pressure measurement has been given by Berman (1985).

5.1.1 Thermocouple and Pirani Gauges

Thermocouple and Pirani gauges are thermal-conductivity gauges, and they measure the rate of heat flow from a heated wire to a surrounding surface. At high pressure, the rate of heat flow due only to thermal conductivity is constant, and it decreases toward zero at low pressures. These gauges are useful in a range typically covering three orders of magnitude, from 0.1 to 100 Pa. In the thermocouple gauge, a wire is heated from an external source and the temperature is measured by means of a small thermocouple. See Fig. 7. It is also possible to measure the changing temperature of the wire by observing its change in resistance. This principal is used in the Pirani gauge, which has a shorter time response than the thermocouple gauge. Figure 8 sketches the heated wire used in the Pirani tube, which forms one arm of a Wheatsone bridge.

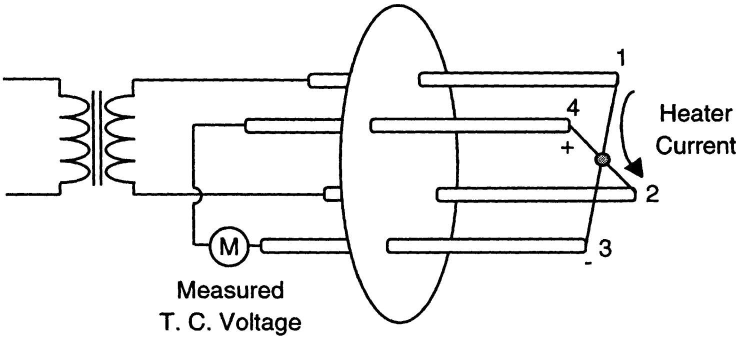

FIG. 7. Thermocouple gauge. A small ac voltage is applied between terminals 1 and 2, and the temperature is sensed across terminals 3 and 4. The two wires, 1–3 and 2–4, form a thermocouple at the weld junction.

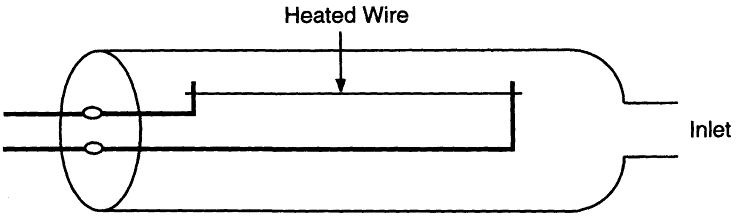

FIG. 8. Pirani gauge. The heated fine tungsten wire is strung between two support posts. An identical tube is exhausted and used as a balance arm in the bridge.

A version that can read to one atmosphere takes advantage of the small but measurable gas convection current flowing in the tube at high pressures. Thermal-conductivity gauges are not precise gauges but are extremely useful in monitoring the pressure of chambers and pumping lines in the region where pumps are first valved onto the chamber, and for monitoring the fore pressures of high-vacuum displacement pumps and the inlet pressures of oil-sealed pumps. Thermal-conductivity gauges are sensitive to gas species. All manufacturers can provide calibration curves.

5.1.2 Capacitance Manometer Total force is measured in a capacitance manometer by sensing the deflection of a thin diaphragm. A nearby, rigid counter-electrode forms the other half of a variable capacitor. See Fig. 9. This instrument can measure pressure over four orders of magnitude and is fabricated with full-scale deflections of 10^5, 10^4, 10^3, and 10^2 Pa. It can be used as a tertiary standard when the measuring head is temperature controlled. Capacitance manometers are typically constructed with the sense element on the vacuum side. These gauges are independent of gas species and are also useful for measuring corrosive and radioactive gases.

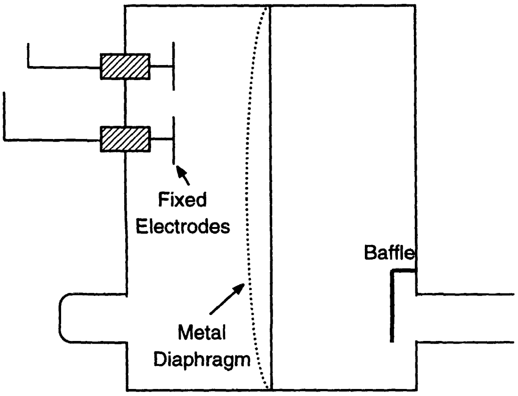

FIG. 9. Capacitance manometer. The metal diaphragm rests against the fixed electrodes at atmospheric pressure, whereas it is not deflected at its lowest pressure of operation.

5.1.3 Ionization Gauge The Bayard–Alpert hot-filament ionization gauge is the primary and most common high-vacuum gauge used in modern vacuum systems. It was developed over 47 years ago by Alpert and Bayard (1950). In the ionization gauge, sketched in Fig. 10, electrons are emitted from a hot filament, typically W or thoriated iridium, and collected on a cylindrical grid biased at a potential of 150 V. Molecules within this region have a probability of being ionized positively, after which they are collected by a fine wire cathode biased at 30 V negative with respect to the filament. External to the gauge tube, a sensitive amplifier is used to measure the collected ion current. The standard gauge tube is available in a glass tubulation or on a metal flange, and it will read pressures in the range 0.1 to 10^{-8} Pa. The lower pressure limit is due to electron-stimulated x-ray emission from the grid, which produces photoelectrons at the cathode. The ion gauge is sensitive to gas species, as ionization cross sections are species dependent. It is common practice to calibrate an ionization gauge for nitrogen (air) and to divide the meter reading by a relative sensitivity—that is, the sensitivity of the meter to the unknown gas divided by the sensitivity to nitrogen. Relative sensitivity data are available from the gauge manufacturer.

5.2 Residual-Gas Analyzers

Residual-gas analyzers (RGAs) are extremely useful diagnostic tools. They are commercially available with either magnetic

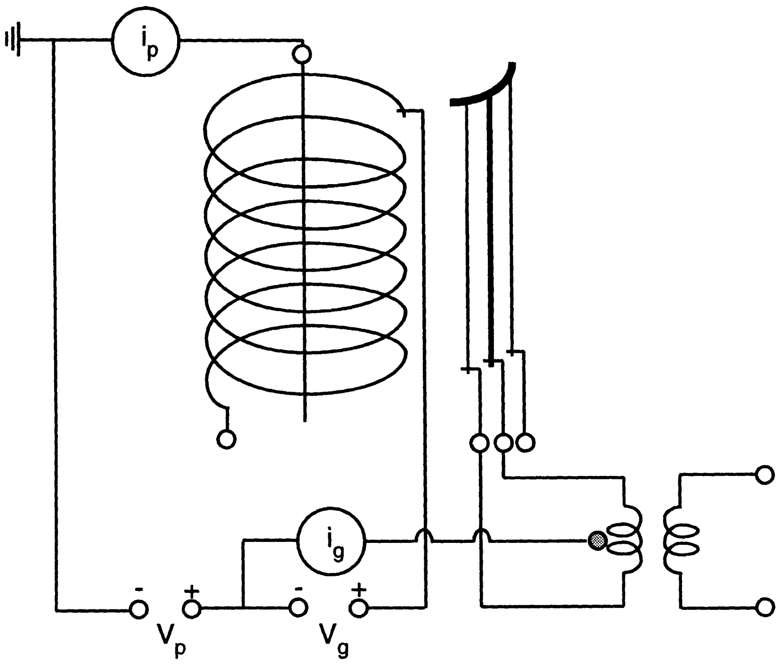

FIG. 10. Bayard–Alpert ionization gauge, showing the biasing potentials. Most gauges have two filaments, which can be electrically interchanged without removal from the system.

sector or quadrupole mass filters and are important in analyzing system problems, as well as determining the parameters required for a deposition, etch, or analytical process. A degree of skill is required to interpret the resulting mass spectra, as each individual molecular or atomic gas will have a cracking pattern determined by its isotopic abundance, degree of multiple ionization, and molecular fragmentation in the ion beam. One discussion of RGA analytical interpretation has been given by O'Hanlon (1989).

All RGAs have three subcomponents: an ionizer, a mass filter, and a detector. In all instruments the ionizer is a hot filament similar to that in a hot-filament ion gauge, with the exceptions that the ionization voltage will be typically 70 V; some ion sources are designed with shielding to minimize the ionization of desorbed gases from nearby walls. The detector will be a Faraday cup, often followed by an electron multiplier. Partial pressures of 10^{-7} and 10^{-12} Pa, respectively, are measurable with these detectors. The two mass filters differ considerably.

5.2.1 Quadrupole In one type, positive ions are axially injected in the region between four parallel rods, which form a radio-frequency mass filter. Only ions with the proper mass-to-charge ratio (m/e) exit the filter and are detected. The mathematical description of the filtering process has been reviewed by Dawson (1976). This mass filter is typically constructed with a resolution of one atomic mass unit, and with m/e ranges of 1 to several hundred. The mass-to-charge scans are linear and, thus, easy to read.

5.2.2 Magnetic Sector In the second type, positive ions leaving the ionizer are first accelerated to a constant voltage, and then directed to a magnetic sector where they travel in circular orbits following elementary electromagnetics. The orbit radii are given by $r = (1/B)(2mV/ze)^{1/2}$, where B is the magnetic field strength, V is the acceleration potential, and z is the number of elemental charges on the ion. Light ions are deflected more strongly than heavy ions, and the mass range is analyzed by scanning either the acceleration voltage or magnetic field while the filtered current is detected following an exit slit. Magnetic-sector instruments are less user friendly, in the sense that they need two magnets to analyze a wide m/e range and that the resulting plots are not linear with mass, unless the voltage or magnetic field are scanned in a nonlinear time-varying manner. However, they are less expensive than quadrupoles and are well suited for process control requiring the range below $e/m = 50$. In this range all the common atmospheric background gases—N_2, O_2, H_2O, CO, and CO_2—are easily observed.

5.3 Thermal Mass-Flow Meter

Thermal mass-flow meters are the most commonly used flow metering technique in modern systems over the range 0.01 to 10^{-5} Pa·L/s. They measure mass flow by heating the gas with known power and measuring its temperature rise with a thermocouple. Mass flow, the flow of gas through a pipe or orifice in conservable units, such as moles/second, is proportional to the heat input and inversely proportional to the heat capacity and temperature rise. The instrument is constructed around a small (0.25-mm-diameter) tube, which is heated at its center and thermally clamped at its ends. The symmetrically mounted thermocouples sense a temperature difference when gas is flowing, and this difference is converted to mass flow. Although the instrument is sensitive to mass flow, it is usually scaled in volumetric units (for nitrogen), which can be converted to mass flow. If the gas is other than nitrogen, the scale reading must be corrected by the ratio of the product heat capacity × density of nitrogen to that same quantity of the second gas.

5.4 Leak Detection

The primary instrument for detecting leaks in chambers whose pressures are $<10^{-2}$ Pa is the helium mass-spectrometer leak detector—a magnetic-sector instrument tuned to He, and containing its own high-vacuum, backing, and roughing pumps. Leaks are found by measuring the response to helium sprayed on the system exterior. He leak detectors respond to a helium flux as low as 10^{-9} Pa·L/s. Sensitivity and response time are important parameters. Sensitivity is determined by the fraction of the helium pumped through the detector, whereas the He response time is $\tau = V/S$.

Maximum sensitivity is obtained in a displacement-pumped system by connecting the leak detector to the foreline, valving off the forepump, and using the leak detector's pumps to back the system. In a capture pump this technique is not possible, so that maximum sensitivity is obtained, at the expense of response time, by connecting the leak detector to the chamber and reducing the main pump speed with a throttle valve. O-rings should be exposed only briefly to helium, 1 to 2 s, when leak checking, to minimize its permeation. In practice one leak checks from the top of the system and, if O-rings are used, periodically stops to allow permeated helium to outdiffuse from the elastomer. Permeation times are of order 15 to 20 min for most common elastomers.

Above 0.01 Pa alternative methods are used. Gross leaks can be observed by listening to the change in pitch of the mechanical pump when a leak is sprayed with He. Thermocouple and ion gauges are also sensitive to alcohol or He entering a leak. Cryopumps must be regenerated after helium leak checking. Helium leak detectors are available with "sniffer" probes. These instruments sample atmospheric air flowing through a capillary tube or porous orifice. They can detect helium exiting a leak in a pressurized vessel. Unless used in a helium-free environment, their sensitivity is limited by the background concentration of helium in the atmosphere.

5.5 Calibration Metrology

Rarely does one calibrate a pump, gauge, or flow meter. Speeds of mechanical and high-vacuum pumps are measured by manufacturers using specialized test domes. See, for example, O'Hanlon (1989). There are two simple methods, which are most helpful in checking system performance. If a mass flow meter is available, the net speed may be obtained by admitting a small volumetric flow Q and recording the change in pressure; $S = Q/(\Delta P)$ is the pumping speed. Without a flow meter, the speed may be obtained by measuring the temporal pressure increase after closing the main pumping valve. After pumping to the base pressure, a gas flow is admitted, raising the pressure well above background. The speed is given by $S = (V/P)dP/dt$. These two methods are extremely useful in checking performance quickly.

6. SAFETY

Safe operation of a vacuum system is the responsibility of the user. It is expected that the system installation and operational procedures will have been reviewed and approved by appropriate risk management personnel. Any system or component manufacturer will be able to answer questions regarding safe operation or installation. In this brief discussion, we note a few vacuum safety issues. Additional issues have been discussed by O'Hanlon and Fraser (1988).

The system controller should incorporate basic safety measures including disabling all high-voltage power supplies unless the chamber is closed and under vacuum; removal of power from all water-cooled pumps and furnaces on loss of cooling water; removal of power from diffusion and turbo pumps on loss of pumping or lubricating fluid; and closure of main chamber valves on loss of vacuum. Toxic, corrosive, or flammable gases need the approval of risk management prior to use. Other safety issues are pump or gauge specific. U.S. diffusion-pump makers prefer tetraphenyl silicone fluids, presumably for safety reasons. Cryopumps must have an operating safety gas release on the pump body, and in addition one should never mount a hot-filament gauge on a cryopump body, lest it ignite desorbed oxidizers and flammables. Convection-gauge readings are gas-species dependent, and it is possible to overpressurize a system when venting with certain gases—for example, Freons or argon. Substitutes for specialty pumping fluids, especially in turbo pumps, should never be used as they could damage the pump. Pump-oil vapors should always be vented into a proper exhaust duct. Liquid cryogens can absorb in clothing and cause serious burns. Lastly, never perform a helium leak check or maintenance on any system that has high-voltage power supplies operational. Insulators that are designed to withstand the voltage across an air gap will arc when surrounded by helium, because its breakdown voltage is only 1/10 that of air.

GLOSSARY

Backstreaming: The flow of a vapor or gas in the direction counter to the desired flow—for example, oil vapors from a mechanical pump to the chamber, hydrogen from an ion pump, process gas from a load lock to a process chamber.

Choke Flow: The limiting turbulent flow through an orifice, determined by the speed of sound.

Compression Ratio: The ratio of pump outlet pressure to inlet pressure.

Conductance (Volumetric): The ease with which gas can flow through an object; the volumetric flow divided by the pressure difference.

Flow (Mass): The flow of gas through a pipe or orifice given in conservable units such as moles/s, atoms/s, or kg/s. See also **Flow, Volumetric.**

Flow (Volumetric): The flow of gas through a pipe or orifice given in nonconservable units such as $\mathrm{Pa \cdot m^3/s}$, or $\mathrm{Torr \cdot L/s}$.

Knudsen's Number: The ratio of mean free path to chamber dimension.

Mean Free Path: The average distance a molecule travels before colliding with another, given by $\lambda = (2^{1/2} \pi d_0^2 n)^{-1}$.

Molecular Flow: Flow in a region in which the Reynolds number is <2 000 and Knudsen's number is >1.0. Characterized by molecular collisions with the walls of the system or pipe, i.e., wall–gas collisions dominate gas–gas collisions.

Pressure: The force on a wall divided by the wall area. $1\ \mathrm{N/m^2} = 1\ \mathrm{Pa}$, and $10^5\ \mathrm{Pa} = 760\ \mathrm{Torr} = 1\ 000\ \mathrm{mbar}$. Direct gauges measure force on a liquid or solid wall (capacitance manometer); indirect gauges measure force through some other property of the gas (thermal-conductivity gauge, ion gauge).

Speed (Volumetric): The ease with which gas can flow across a surface; the volumetric gas flow divided by the pressure at the plane of measurement.

Staging Ratio: The ratio of the displacement ratio of a turbopump or a lobe blower to that of its mechanical fore pump.

Turbulent Flow: Chaotic flow when the Reynolds number >2 200 and Knudsen's number <0.01.

Viscous Laminar Flow: Flow in a region of Reynolds number <2 000 and Knudsen's number <0.01. Characterized by laminar parallel streamlines gently flowing around obstructions.

INTRODUCTION

Variational principles derive from a certain aesthetic and metaphysical ideal of simplicity in the search for the principles underlying physical phenomena. The origins date back to the earliest Greek philosophers Thales (c. 600 B.C.) and Pythagoras (c. 550 B.C.). Aristotle (384–322 B.C.) clearly makes use of a variational principle to justify circular orbits for the planets when he says in *de Caelo II*

> Now of lines which return upon themselves, the line which bounds the circle is the shortest, and that movement is the swiftest which follows the shortest line.

This marks the first use of a "minimum" postulate, and the conclusion held sway until the time of Kepler (1571–1630). Hero of Alexandria (c. 125 B.C.) made the first rigorous use of a variational principle when he proved that when the angle of incidence equals the angle of reflection, the path taken by a ray of light from the object to the observer is shorter than any other possible path with fixed end points (see *Catoptrics* by Hero in

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

Cohen and Drabkin, 1958). This later became Fermat's principle of least time in geometrical optics.

The belief that nature is in some sense "simple" and can be explained by some economically small number of postulates pervades the works of Galileo (1564–1642), Newton (1642–1727), and Leibniz (1646–1716). Although some of the early conclusions turned out to be scientifically unfounded, the philosophical basis for variational principles has great antiquity. They continue to guide the development of new physical theories at the most fundamental level and to provide powerful methods of practical computation. Perhaps most importantly, they bring out the structural analogies between superficially different phenomena and allow techniques developed in one field to be readily applied in another. At a fundamental level, practically all physical phenomena can be expressed in terms of variational principles that have a striking similarity.

The *calculus of variations* provides the basic mathematical tool for formulating and analyzing variational principles. The purposes of this article are first to give an overview of the calculus of variations, and then to discuss its application to a variety of physical phenomena. There is a vast literature on both aspects, and only a few of the most important points can be covered in the space available. Only a few principal references are given, with further general references in the reading list at the end. The main emphasis is on applications to classical mechanics and bound-state problems in quantum mechanics. Except for a brief discussion of the Feynman path integral, applications to scattering problems are not covered. An informal and instructive introduction to variational methods can be found in Hildebrand and Tromba (1985).

1. TECHNIQUES OF THE CALCULUS OF VARIATIONS

In its simplest form, the calculus of variations addresses the problem of finding the function $y(x)$ for which the integral

$$J = \int_{x_1}^{x_2} f(x,y,y_x)dx \tag{1}$$

is an extremum. The integrand $f(x,y,y_x)$ is some prescribed function of the indicated variables, where $y_x = dy/dx$, and x_1, x_2 are fixed end points. J is termed a *functional* of $y(x)$. As originally formulated by Euler, the problem is solved by considering infinitesimal variations $\delta y(x)$ about a particular path $y(x)$ connecting x_1 and x_2 (see Fig. 1) and demanding that the variation δJ induced in J vanish. For example, one might choose the variations to be $\delta y(x) = \epsilon\eta(x)$, where $\eta(x)$ is an arbitrary function such that $\eta(x_1) = \eta(x_2) = 0$ (to make the variation vanish at the end points), and ϵ is a small parameter controlling the size of the variation. Then $\delta y_x(x) = \epsilon d\eta(x)/dx$, and from a Taylor series expansion of $f(x,y,y_x)$ about $\epsilon = 0$ in Eq. (1), the induced variation in J is

$$\delta J = \epsilon \int_{x_1}^{x_2} \left[\frac{\partial f}{\partial y}\eta(x) + \frac{\partial f}{\partial y_x}\frac{d\eta(x)}{dx}\right]dx \tag{2}$$

up to terms of first order in ϵ. An integration of the second term by parts yields

$$\delta J = \epsilon \frac{\partial f}{\partial y_x}\eta(x)\Big|_{x_1}^{x_2} + \epsilon \int_{x_1}^{x_2} \left[\frac{\partial f}{\partial y} - \frac{d}{dx}\frac{\partial f}{\partial y_x}\right]\eta(x)dx. \tag{3}$$

The first term vanishes by the assumption that $\eta(x) = 0$ at the end points. Since $\eta(x)$ is otherwise an arbitrary function, the condition $\delta J = 0$ can be fulfilled only if the integrand of the second term vanishes identically for $x_1 < x < x_2$; i.e.,

$$\frac{\partial f}{\partial y} - \frac{d}{dx}\frac{\partial f}{\partial y_x} = 0. \tag{4}$$

This is the basic Euler–Lagrange equation. For purposes of compactness, the functional

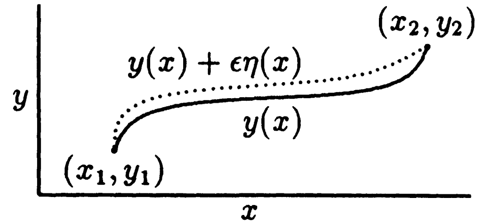

FIG. 1. Illustration of the actual path $y(x)$ and the varied path connecting fixed end points.

dependence of f on its various arguments is usually suppressed, as is done here.

Any solution to Eq. (4) satisfies the variational condition $\delta J = 0$. However, J itself could be a minimum, a maximum, or a point of inflection. One often knows from the geometrical nature of the problem being solved which case applies. Otherwise, it is necessary to extend the Taylor series expansion of $f(x,y,y_x)$ to terms of order ϵ^2 and determine the sign of the second-order variation $\delta^{(2)}J$ (see, e.g., Courant and Hilbert, 1966). If $\delta^{(2)}J < 0$, then J is a maximum; if $\delta^{(2)}J > 0$, then J is a minimum; if $\delta^{(2)}J = 0$, then J lies at a point of inflection.

If the end points are not fixed, then $\eta(x)$ does not vanish there. In this case, Eq. (4) still applies, subject to the condition that $\partial f/\partial y_x = 0$ at the end points (see Jeffreys and Jeffreys, 1972).

An important special case of Eq. (4) occurs if $f(x,y,y_x)$ does not depend explicitly on x because then the integrating factor is simply y_x. After multiplying Eq. (4) through by y_x and using

$$\frac{df}{dx} = \frac{\partial f}{\partial y} y_x + \frac{\partial f}{\partial y_x}\frac{dy_x}{dx} \tag{5}$$

(since $\partial f/\partial x = 0$ by assumption), the Euler–Lagrange equation becomes

$$\frac{d}{dx}\left(y_x \frac{\partial f}{\partial y_x} - f\right) = 0, \tag{6}$$

and so

$$y_x \frac{\partial f}{\partial y_x} - f = \text{const.} \tag{7}$$

A classic example is provided by the brachistochrone (shortest time) problem first propounded by John Bernoulli in 1696. It was solved by both him and his brother James, as well as by Newton and Leibnitz. Consider a bead sliding without friction on a wire of arbitrary length connecting two fixed points (x_1,y_1) and (x_2,y_2) in a vertical plane, as shown in Fig. 2. The problem is to find the shape that minimizes the travel time as the bead slides from rest under the force of gravity; i.e., to find the function $y = y(x)$ such that the integral

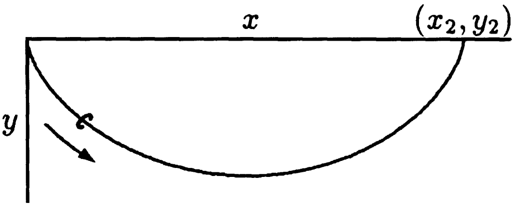

FIG. 2. The brachistochrone problem of a bead sliding without friction on a wire of arbitrary length in a vertical plane.

$$\tau = \int_{x_1}^{x_2} \frac{ds}{v} \tag{8}$$

for the travel time is a minimum. Here $ds = [(dy/dx)^2 + 1]^{1/2}dx$ is the element of arc length and v is the velocity. By conservation of energy, the velocity after falling a distance y (measured downward) is $v = \sqrt{2gy}$ (independent of x), where g is the acceleration due to gravity. The integral to be minimized is then

$$\tau = \int_{x_1}^{x_2} \frac{(y_x^2 + 1)^{1/2}}{(2gy)^{1/2}}\, dx. \tag{9}$$

With $f(x,y,y_x)$ defined by the above integrand, the Euler–Lagrange equation (7) then gives

$$\frac{y_x^2}{(y_x^2 + 1)^{1/2} y^{1/2}} - \frac{(y_x^2 + 1)^{1/2}}{y^{1/2}} = c^{1/2}, \tag{10}$$

and hence

$$y_x^{-1} \equiv \frac{dx}{dy} = \left(\frac{cy}{1 - cy}\right)^{1/2}, \tag{11}$$

where c is a constant of integration that determines the distance scale. Assuming that the bead starts from the origin, integration of this equation yields

$$cx = \sin^{-1}(cy)^{1/2} - (cy - c^2y^2)^{1/2}. \tag{12}$$

This is the equation of a cycloid symmetric about the minimum at $cy = 1$. The scale factor c is determined by the condition that the curve pass through the second terminus (x_2,y_2). If $y_2 = 0$ (as in Fig. 2), then $c = \pi/x_2$.

1.1 Variations with Constraints

There are many classes of problems where the functional J must be made an extremum subject to a subsidiary condition of the form

$$\int_{x_1}^{x_2} f_1(x,y,y_x)dx = \text{const.} \tag{13}$$

The example of a hanging chain of fixed length is discussed in the following paragraph. Such problems can be handled by applying the variational procedure to the functional

$$g(x,y,y_x) = f(x,y,y_x) + \lambda_1 f_1(x,y,x_y), \tag{14}$$

where λ_1 is called a *Lagrange undetermined multiplier.* The resulting Euler–Lagrange equation is

$$\frac{\partial f}{\partial y} - \frac{d}{dx}\frac{\partial f}{\partial y_x} = -\lambda_1\left(\frac{\partial f_1}{\partial y} - \frac{d}{dx}\frac{\partial f_1}{\partial y_x}\right), \tag{15}$$

or, if f and f_1 are independent of x, the first integral is [cf. Eq. (7)]

$$y_x\frac{\partial f}{\partial y_x} - f + \lambda_1\left(y_x\frac{\partial f_1}{\partial y_x} - f_1\right) = \text{const.} \tag{16}$$

The idea is to solve Eq. (15) or Eq. (16) for a fixed but arbitrary value of λ_1. The equation of constraint provides the additional condition to determine λ_1 at the end of the problem, together with the two constants of integration.

As an example, consider the problem of finding the shape of a uniform hanging chain with both ends fixed. The shape is such that the potential energy due to gravity is a minimum, and so the quantity to be minimized is

$$J = \int_{x_1}^{x_2} \mu g y(y_x^2 + 1)^{1/2}dx, \tag{17}$$

subject to the constraint

$$\int_0^L ds \equiv \int_{x_1}^{x_2} (y_x^2 + 1)^{1/2}dx = L, \tag{18}$$

where μ is the mass per unit length and L the length. Thus $f = \mu g y(y_x^2 + 1)^{1/2}$ and $f_1 = (y_x^2 + 1)^{1/2}$. After dividing by μg and defining $\lambda = \lambda_1/\mu g$, Eq. (16) gives

$$(y + \lambda)\left[\frac{y_x^2}{(y_x^2 + 1)^{1/2}} - (y_x^2 + 1)^{1/2}\right] = -\frac{1}{c}. \tag{19}$$

As for the brachistochrone problem, this equation can be solved for $y_x^{-1} \equiv dx/dy$ and the result integrated to obtain

$$cy = -c\lambda + \cosh[c(x - a)], \tag{20}$$

where a is the second constant of integration. The three parameters a, c, and λ are determined by the three conditions that the curve pass through the points (x_1,y_1) and (x_2,y_2) at the ends of the chain, together with the equation of constraint. For example, if the two points are $(0,0)$ and $(x_2,0)$, then $a = x_2/2$, $c\lambda = \cosh(cx_2/2)$, and the equation of constraint becomes

$$\begin{aligned} L &= \int_0^{x_2} \{\sinh^2[c(x - \tfrac{1}{2}x_2)] + 1\}^{1/2}dx \\ &= \frac{2}{c}\sinh(cx_2/2). \end{aligned} \tag{21}$$

Solving this transcendental equation determines the remaining constant c. The quantity $T_0 = \mu g/c$ is the force of tension in the chain at the lowest point, where $y_x = 0$.

1.2 Generalizations

In applications to mechanics (see Sec. 2.1), the time t plays the role of the independent variable x marking the evolution of the system, but there are typically several dependent generalized coordinates q_i and $\dot{q}_i \equiv dq_i/dt$, $i = 1, \ldots, N$, in place of y and y_x, respectively. With this change in notation, f becomes a function of all the q_i's, $\dot{q}_i$'s, and t, and the generalization of Eq. (4) is

$$\frac{\partial f}{\partial q_i} - \frac{d}{dt}\frac{\partial f}{\partial \dot{q}_i} = 0, \quad i = 1, \ldots, N. \tag{22}$$

There are thus N coupled Euler–Lagrange equations, one for each degree of freedom of the system.

If in addition there are several independent variables $t_1, t_2, \ldots, t_r$, then Eq. (22) is further generalized to read

$$\frac{\partial f}{\partial q_i} - \sum_{j=1}^{r} \frac{\partial}{\partial t_j} \frac{\partial f}{\partial(\partial q_i/\partial t_j)} = 0, \quad i = 1, \ldots, N. \tag{23}$$

There can also be several equations of constraint of the form of Eq. (13) with integrands $f_k(t_j,q_i,\dot{q}_i)$, $k = 1, \ldots, m$. In this case, m Lagrange undetermined multipliers λ_k are introduced, and the function f in Eq. (22) or (23) is replaced by

$$g(t_j,q_i,\dot{q}_i) = f(t_j,q_i,\dot{q}_i) + \sum_{k=0}^{m} \lambda_k f_k(t_j,q_i,\dot{q}_i). \tag{24}$$

Constraints that can be expressed in integrated form, such as Eq. (13), are said to be *holonomic* (wholly named or specified). However, problems often arise in mechanics involving *nonholonomic* constraints that can only be expressed in differential form, such as a relation between velocities. An example is the problem of a vertical disk of radius R rolling without slipping on a plane. Four coordinates are required—the (x,y) Cartesian coordinates of the point of contact between the disk and the plane, a spinning angle of rotation θ about a vertical axis, and a rolling angle ϕ about an axis perpendicular to the disk. If the plane of the disk is initially perpendicular to the x axis (i.e., $\theta = 0$), then the constraint of "not slipping" corresponds to the differential relations

$$dx = R \sin\theta \, d\phi, \tag{25}$$

$$dy = -R \cos\theta \, d\phi. \tag{26}$$

These equations cannot be integrated without knowing in advance θ and ϕ as a function of t. However, the method of Lagrange undetermined multipliers can still be applied. If the general form of the differential constraints is written as

$$\sum_{i=1}^{N} a_{k,i} dq_i + a_{k,t} dt = 0, \quad k = 1, \ldots, s, \tag{27}$$

where the coefficients $a_{k,i}$ are, in general, functions of the q_i's and $\dot{q}_i$'s, then the generalization of Eq. (22) for nonholonomic systems is

$$\frac{\partial f}{\partial q_i} - \frac{d}{dt}\frac{\partial f}{\partial \dot{q}_i} + \sum_{k=1}^{s} \lambda_k a_{k,i} = 0, \quad i = 1, \ldots, N. \tag{28}$$

This equation can still be used even if the constraints are in fact holonomic. The term $\Sigma_{k=1}^{s} \lambda_k a_{k,i}$ can be identified with the generalized forces of constraint. In general, the λ_k are now functions of the q_i's and $\dot{q}_i$'s. The term $a_{k,t} dt$ in Eq. (27) does not contribute to Eq. (28) because the variations δq_i from the actual path are considered to occur at a particular instant of time (see Sec. 2.1).

As a simple illustration of the versatility of the method, consider the problem of finding the function $u(x,y,z)$ such that the square of its gradient is a minimum in a given volume of space. The problem is then to minimize

$$J = \iiint f dx dy dz, \tag{29}$$

with

$$f = (\nabla u)^2 = \left(\frac{\partial u}{\partial x}\right)^2 + \left(\frac{\partial u}{\partial y}\right)^2 + \left(\frac{\partial u}{\partial z}\right)^2. \tag{30}$$

This can be regarded as an application of Eq. (23) with the three independent variables $t_1 = x$, $t_2 = y$, and $t_3 = z$, and a single degree of freedom ($N = 1$) with $q_1 = u$. Equation (23) then immediately gives

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} = 0, \tag{31}$$

which is Laplace's equation. The term $\partial f/\partial q_1 \equiv \partial f/\partial u$ does not contribute because f does not depend explicitly on u, only on the partial derivatives $\partial u/\partial x$, $\partial u/\partial y$, and $\partial u/\partial z$. This problem clearly illustrates the way in which functional derivatives are to be interpreted and should be carefully studied.

2. APPLICATIONS TO CLASSICAL MECHANICS

The elements and techniques of classical mechanics are covered under MECHANICS, CLASSICAL. This section draws together the connections with variational principles.

2.1 Introductory Concepts

Consider a classical system of n interacting particles having masses m_s located at positions $\mathbf{r}_s = (x_{s,1}, x_{s,2}, x_{s,3})$, and acted on by forces $\mathbf{F}_s = (F_{s,1},F_{s,2},F_{s,3})$ due to the other particles and any external forces, including forces of constraint. The evolution of the system is obtained by solving Newton's equations of motion

$$m_s\ddot{x}_{s,j} = F_{s,j}, \quad s = 1, \ldots, n; j = 1, 2, 3. \tag{32}$$

These equations are completely general. However, it is often more convenient to replace the $3n$ Cartesian coordinates $x_{s,j}$ by *generalized coordinates* q_i defined through a system of connection equations of the form

$$x_{s,j} = x_{s,j}(q_1,q_2, \ldots ,q_{3n}). \tag{33}$$

The use of generalized coordinates is particularly effective in problems involving constraints. If the generalized coordinates are chosen such that their variations δq_i do no *virtual work* against the forces of constraint (i.e., δq_i is perpendicular to the *instantaneous* forces of constraint), then the number of independent q_i needed is reduced from $3n$ to $3n - m$, where m is the number of constraints.

To make these ideas concrete, consider the example of a bead sliding on a vertical wire hoop of radius R that is itself constrained to rotate about the z axis with angular velocity ω. In terms of the polar angles θ and $\phi = \omega t$, the connection equations are

$$\begin{aligned} x &= \sin\theta \cos\omega t, \\ y &= \sin\theta \sin\omega t, \\ z &= \cos\theta. \end{aligned} \tag{34}$$

The constraint of sliding on the hoop has reduced the number of independent coordinates from three to a single azimuthal angle θ. A variation $\delta\theta$ generates a displacement of the bead consistent with the instantaneous orientation of the hoop, but not consistent with the actual time evolution of the system, which includes the rotation of the hoop. Such variations are said to do no virtual work, and are called *virtual displacements.* From the connection equations (34), the kinetic energy of the bead is

$$\begin{aligned} T &= \tfrac{1}{2}m(\dot{x}^2 + \dot{y}^2 + \dot{z}^2) \\ &= \tfrac{1}{2}m[(R\dot{\theta})^2 + (\omega R \sin\theta)^2]. \end{aligned} \tag{35}$$

If the system is conservative with a potential-energy function $V(x,y,z)$, then V can similarly be expressed in terms of θ.

2.2 Hamilton's Principle

In the absence of constraints, a direct transformation of Newton's equations of motion (32) from the $3n$ Cartesian coordinates $x_{s,j}$ to the $3n$ generalized coordinates q_i yields Lagrange's equations of motion

$$\frac{d}{dt}\frac{\partial T}{\partial \dot{q}_i} - \frac{\partial T}{\partial q_i} = Q_i, \tag{36}$$

where the Q_i are the generalized forces defined by

$$Q_i = \sum_{s=1}^{n} \mathbf{F}_s \cdot \frac{\partial \mathbf{r}_s}{\partial q_i}. \tag{37}$$

A comparison with Eqs. (3) and (22) shows immediately that with the identification $f = -T$, Lagrange's equations correspond to the variational condition

$$\int_{t_1}^{t_2} \left(\delta T + \sum_{i=1}^{3n} Q_i \delta q_i\right) dt = 0. \tag{38}$$

This is the most general form of Hamilton's principle in classical dynamics. The advantage gained is that $3n$ equations of motion have been consolidated into a single scalar variational condition that is invariant under coordinate transformation. In the absence of constraints, all the q_i can be varied independently so that each coefficient of δq_i must vanish separately, and Lagrange's equations are recovered. If m constraints are present, one need keep only $3n - m$ of the q_i whose virtual displacements δq_i are consistent with the instantaneous constraints, as in the rotating-hoop example of Sec. 2.1 where only a single parameter θ is required. One can still consider variations in the remaining q_i, even though they would violate the constraints. The only difference is that the corresponding Q_i are reinterpreted as the generalized forces required to maintain the constraints. They can be calculated by the method of Lagrange undetermined multipliers, as described in Sec. 1.2 [see especially Eq. (28)]. In this way, Lagrange's equations apply to the entire set, whether or not constraints are present. The invariance of Lagrange's equations and Hamilton's principle under coordinate transformation guarantees that if they are correct in Cartesian coordinates (as can easily be checked), they are correct in any other system of generalized coordinates.

2.2.1 Conservative Systems and First Integrals If the system is conservative, then the Q_i are derivable from a potential function $V(q_i)$ according to $Q_i = -\partial V/\partial q_i$, and Lagrange's equations reduce to

$$\frac{d}{dt}\frac{\partial L}{\partial \dot{q}_i} - \frac{\partial L}{\partial q_i} = 0, \tag{39}$$

where $L = T - V$ is the Lagrangian. It is then immediately evident from Eq. (4) that Hamilton's principle becomes

$$\delta \int_{t_1}^{t_2} L\, dt = 0. \tag{40}$$

This is the most useful form of Hamilton's principle for theoretical discussion.

If T and V do not involve time explicitly, then the first integral corresponding to Eq. (6) is

$$\sum_i \dot{q}_i \frac{\partial T}{\partial \dot{q}_i} - T + V = \text{const.} \tag{41}$$

If, further, T is a homogeneous quadratic function of the $\dot{q}_i$, then the above becomes

$$T + V = \text{const.}, \tag{42}$$

where the constant can now be identified with the conserved energy E of the system.

For the example of a bead on a rotating hoop discussed in Sec. 2.1, the first integral gives

$$\begin{aligned} &\tfrac{1}{2}m[(R\dot{\theta})^2 - (\omega R\sin\theta)^2] + V(\theta) \\ &\quad = T + V - m(\omega R\sin\theta)^2 = \text{const.} \end{aligned} \tag{43}$$

The constant of the motion here differs from $E = T + V$ because the time-dependent forces of constraint do work on the system. Overall conservation of energy is recovered only when the work required to keep the hoop rotating at a constant rate is included. If N_z is the required torque, then, with the use of Eq. (43), the rate at which it does work is

$$N_z\omega = \frac{d}{dt}(T + V) = \frac{d}{dt}m(\omega R\sin\theta)^2 = \omega\frac{dl_z}{dt}, \tag{44}$$

where $l_z = m\omega(R\sin\theta)^2$ is the angular momentum of the bead about the z axis. Thus $N_z = dl_z/dt$ as expected.

2.3 The Hamilton–Jacobi Equation

The variations considered thus far are taken between fixed end points t_1 and t_2 and, therefore, necessarily do not correspond to a possible dynamical evolution of the system. The actual evolution between fixed end points is uniquely defined, at least with respect to local variations, and so the varied path is unphysical. (But it is not necessarily so for nonlocal variations. For example, two points on a Kepler orbit are connected by two paths, depending on which way around the particle goes.)

The Hamilton–Jacobi equation comes from consideration of a different kind of variation Δq_i along a possible dynamical path between points allowed to vary in both space and time. In this case, it is necessary to keep the integrated term in Eq. (3) (or its generalizations). Suppose that t_1 and t_2 are replaced by $t_1 + \delta t_1$ and $t_2 + \delta t_2$. There is then a corresponding variation δt in the arrival time at each point along the path, so that $\Delta q_i(t) \equiv \delta q_i(t + \delta t)$ is the variation in path evaluated at the modified arrival time.

For definiteness, suppose that the paths are parameterized according to

$$q_i(\epsilon,t) = q_i(0,t) + \epsilon\eta_i(t), \tag{45}$$

where $q_i(0,t)$ is the actual path and $\eta_i(t)$ is an arbitrary differentiable function not assumed to vanish at the end points. Then $\delta q_i(t) = \epsilon\eta_i(t)$ and

$$\begin{aligned} \delta q_i(t + \delta t) &= q_i(\epsilon, t + \delta t) - q_i(0,t) \\ &\simeq q_i(0, t + \delta t) - q_i(0,t) + \epsilon\eta_i(t) \\ &= \dot{q}_i\delta t + \delta q_i(t) \end{aligned} \tag{46}$$

up to terms of first order in ϵ and δt. Application of the Δ variation to the integral in Hamilton's principle then yields

$$
\begin{aligned}
\Delta \int_{t_1}^{t_2} L\,dt
&= \int_{t_1+\delta t_1}^{t_2+\delta t_2} L\,dt - \int_{t_1}^{t_2} L\,dt + \int_{t_1}^{t_2} \delta L\,dt \\
&= L\delta t\Big|_{t_1+\delta t_1}^{t_2+\delta t_2} + \sum_i \frac{\partial L}{\partial \dot{q}_i}\,\delta q_i\Big|_{t_1}^{t_2} \\
&\quad + \int_{t_1}^{t_2} \sum_i \left(\frac{\partial L}{\partial q_i} - \frac{d}{dt}\frac{\partial L}{\partial \dot{q}_i}\right)\delta q_i dt. \qquad (47)
\end{aligned}
$$

The last term vanishes by the assumption that the varied path is a possible dynamical path, and so Lagrange's equations of motion are satisfied. Interest therefore centers on the integrated terms. The first term is simply $L(\delta t_2 - \delta t_1)$. Using Eq. (46) to replace $\delta q_i(t)$ by $\delta q_i(t + \delta t)$ in the second term, these terms become

$$
\Delta \int_{t_1}^{t_2} L\,dt = \left[\left(L - \sum_i \dot{q}_i \frac{\partial L}{\partial \dot{q}_i}\right)\delta t + \sum_i \frac{\partial L}{\partial \dot{q}_i}\,\delta q_i\right]_{t_1+\delta t_1}^{t_2+\delta t_2}. \qquad (48)
$$

With the definitions

$$
p_i = \frac{\partial L}{\partial \dot{q}_i}, \qquad (49)
$$

$$
H = \sum_i \dot{q}_i \frac{\partial L}{\partial \dot{q}_i} - L, \qquad (50)
$$

$$
S = \int_{t_1}^{t_2} L\,dt, \qquad (51)
$$

where the integral for S is taken along any dynamical path, Eq. (48) can be written in the form

$$
\Delta S = \left[-H\delta t + \sum_i p_i \delta q_i\right]_{t_1+\delta t_1}^{t_2+\delta t_2}. \qquad (52)
$$

H is called the *Hamiltonian* for the system, p_i is the *canonical momentum*, and S is called *Hamilton's principal function*. For an ordinary conservative system, $H = T + V$ is the total energy.

Equation (52) may be interpreted as follows. Since by assumption the system evolves along a possible dynamical path from an initial configuration $(q_i)_1$ at time t_1 to a final configuration $(q_i)_2$ at time t_2, there will in general be only a single set of initial velocities $(\dot{q}_i)_1$ that satisfy these requirements (at least with respect to small variations). The same applies to the initial momenta $(p_i)_1$ since they are connected to the $(\dot{q}_i)_1$ through Eq. (49), and hence the $(\dot{q}_i)_1$ can be eliminated from the problem. The p_i's as well as the q_i's are therefore uniquely determined from the initial conditions at time t_1. Since Eq. (52) remains true as t_2 is varied, it follows that

$$
\frac{\partial S}{\partial q_i} = p_i, \qquad (53)
$$

$$
\frac{\partial S}{\partial t} = -H(q_i,p_i,t) = -H\left(q_i,\frac{\partial S}{\partial q_i},t\right). \qquad (54)
$$

Equation (54) is called the *Hamilton–Jacobi* equation. It is a first-order partial differential equation in $N + 1$ variables and does not involve S explicitly. As it stands, a complete solution involving $N + 1$ constants of integration is determined from the initial conditions

$$
\left(\frac{\partial S}{\partial t}\right)_{t_1} = (H)_{t_1}, \quad \left(\frac{\partial S}{\partial q_i}\right)_{t_1} = -(p_i)_{t_1}. \qquad (55)
$$

The real significance of the Hamilton–Jacobi equation comes not from its practical utility in solving mechanical problems, but for the insight it gives into the structure of mechanics, and for applications involving the use of perturbation theory. The significance is further elaborated after a brief discussion of the principle of least action, Hamilton's equations of motion, and the theory of canonical transformations.

2.3.1 The Principle of Least Action

Assume that the system is conservative and holonomic so that H is a constant. The Maupertuis principle of least action follows by considering a restricted class of variations Δ_t that are identical to the Δ variations of Sec. 2.3, except that $\Delta_t q_i = \delta q_i(t + \delta t)$ is assumed to vanish at the end points; i.e., the system arrives at the same end point, but at the varied time $t + \delta t$, and H has the same constant value on the varied path. The varied path could be the same as the actual path except that it is traversed at a different rate. Under these conditions, Eq. (52) reduces immediately to

$$
\Delta_t S = -H(\delta t_2 - \delta t)_1. \qquad (56)
$$

However, with the use of Eq. (50) to replace L by H, a direct evaluation of $\Delta_t S$ from Eq. (51) yields

$$\Delta_t S = \Delta_t \int_{t_2}^{t_2} \sum_i p_i \dot{q}_i dt - H(\delta t_2 - \delta t_1), \qquad (57)$$

from which it follows that

$$\Delta_t \int_{t_1}^{t_2} \sum_i p_i \dot{q}_i dt = 0. \qquad (58)$$

The quantity

$$W = \int_{t_1}^{t_2} \sum_i p_i \dot{q}_i dt \qquad (59)$$

defines the classical action.

This is one of many possible ways of expressing the principle of least action. A purely geometrical form in which t is eliminated can be obtained as follows. If V is velocity-independent and T is a homogeneous quadratic function of the $\dot{q}_i$, then

$$\sum_i p_i \dot{q}_i = 2T = \sum_{j,k} M_{j,k}(q) \dot{q}_j \dot{q}_k, \qquad (60)$$

where the $M_{j,k}(q)$ are the coefficients appearing in the kinetic-energy expression. The $M_{j,k}(q)$ can be regarded as the elements of a metric tensor in a curvilinear coordinate space such that the element of path length is

$$(d\rho)^2 = \sum_{j,k} M_{j,k}(q) dq_j dq_k. \qquad (61)$$

The principle of least action can then be written in the form

$$\Delta_t \int_{t_1}^{t_2} T dt = 0 = \Delta \int_{\rho_1}^{\rho_2} \sqrt{T}\, d\rho, \qquad (62)$$

or equivalently,

$$\Delta \int_{\rho_1}^{\rho_2} \sqrt{H - V}\, d\rho = 0. \qquad (63)$$

For a single particle moving in a potential V, $d\rho$ is simply the element of arc length ds along the trajectory. In this form, the principle of least action is formally identical to Fermat's principle of geometrical optics. One need merely identify $\sqrt{H - V}$ with a variable index of refraction $n(s) = c_{\text{vac}}/c(s)$, which is inversely proportional to the velocity of light in the medium. The path taken by a beam of light is then such that the travel time given by

$$\tau = \frac{1}{c_{\text{vac}}} \int_{s_1}^{s_2} n(s) ds \qquad (64)$$

is a minimum (or, more strictly, an extremum). This justifies the solution to the brachistochrone problem in Sec. 1, and it demonstrates the formal equivalence between geometrical optics and the dynamics of conservative systems.

In a recent article, Gray *et al.* (1996) show that the Maupertuis principle of least action can be generalized to a form in which W is stationary with respect to varied paths on which H is held constant only *in the mean* and that there exists a reciprocal principle in which the mean value $\bar{H}$ is made stationary with respect to varied paths of constant W. They also show that the reciprocal principle can be derived directly from the classical limit of the Schrödinger variational principle of quantum mechanics (see Sec. 3.2). A similar reciprocity theorem for Hamilton's principle provides a set of four variational principles analogous to the four equilibrium principles of thermodynamics.

2.3.2 Hamilton's Equations of Motion

The basic approach in Lagrangian mechanics is to regard the N generalized coordinates $q_i(t)$ as the independent variables whose time dependence is determined by the N second-order Lagrangian equations of motion expressed by Eq. (39). The velocities $\dot{q}_i(t)$ enter only as derived quantities whose initial values, together with the initial $q_i(t)$, determine the required $2N$ constants of integration. The Hamiltonian approach differs in that the $\dot{q}_i(t)$ are eliminated in favor of the canonical momenta $p_i(t)$ defined by Eq. (49). The $p_i(t)$ are then elevated to an equal footing with the $q_i(t)$ so that the set $\{q_i, p_i | i = 1, \ldots, N\}$ forms a set of $2N$ independent variables satisfying a set of $2N$ coupled first-order differential equations called Hamilton's equations of motion. In what follows, we adopt the convention that a summation over repeated subscripts is implied, and q or p without a subscript stands for the entire set.

Hamilton's equations of motion can be

derived from Hamilton's principle if Eqs. (49) and (50) are first used to rewrite Eq. (51) in the form

$$S = \int [p_i\dot{q}_i - H(q,p,t)]dt. \tag{65}$$

With *fixed* end points t_1 and t_2, independent variations δp_i and δq_i then induce the variation

$$\begin{aligned}\delta S &= \int_{t_1}^{t_2} \left(p_i\delta\dot{q}_i + \dot{q}_i\delta p_i) + \frac{\partial H}{\partial q_i}\delta q_i + \frac{\partial H}{\partial p_i}\delta p_i\right)dt \\ &= p_i\delta q_i\Big|_{t_1}^{t_2} + \int_{t_1}^{t_2}\left(-\dot{p}_i\delta q_i + \dot{q}_i\delta p_i\right. \\ &\quad \left. + \frac{\partial H}{\partial q_i}\delta q_i + \frac{\partial H}{\partial p_i}\delta p_i\right)dt. \end{aligned} \tag{66}$$

The integrated term vanishes by assumption. Equating to zero the coefficients of δp_i and δq_i then yields the set of equations

$$\dot{q}_i = \frac{\partial H}{\partial p_i}, \quad \dot{p}_i = -\frac{\partial H}{\partial q_i}, \tag{67}$$

which are Hamilton's equations of motion. Thus, both Lagrangian and Hamiltonian mechanics are implied by Hamilton's principle, provided that the variations δp_i and δq_i can be regarded as independent. The latter assumption is important because it underlies the entire approach of Hamiltonian mechanics. It is justified by the fact that the Hamiltonian form can be obtained by a direct transformation of variables from the Lagrangian form.

2.3.3 Canonical Transformations

Transformations of the type (33) are called *point transformations* because they involve only the coordinates q_i. An advantage of Hamiltonian mechanics is that, with the q's and p's regarded as independent variables, more general types of transformation can be constructed that map the set $\{q,p\}$ to a new set $\{Q,P\}$ defined by connection equations of the form

$$Q_i = Q_i(q,p,t), \quad P_i = P_i(q,p,t). \tag{68}$$

Such a *contact transformation* is said to be *canonical* if the form of Hamilton's equations is left invariant; i.e., there exists a transformed Hamiltonian function $K(Q,P,t)$ such that

$$\dot{Q}_i = \frac{\partial K}{\partial P_i}, \quad \dot{P}_i = -\frac{\partial K}{\partial Q_i} \tag{69}$$

are the correct equations of motion for the transformed variables. This will be true if both sets of coordinates and momenta satisfy their respective variational principles

$$\delta \int [p_i\dot{q}_i - H(q,p,t)]dt = 0, \tag{70}$$

$$\delta \int [P_i\dot{Q}_i - K(Q,P,t)]dt = 0. \tag{71}$$

The integrands need not be equal, but they can differ by at most the total time derivative of a function F, called the *generating function* for the transformation. We can thus write

$$p_i\dot{q}_i - H(q,p,t) = \lambda\left[P_i\dot{Q}_i - K(Q,P,t) + \frac{dF}{dt}\right]. \tag{72}$$

Values of the constant $\lambda \neq 1$ just correspond to a scale transformation, and so without loss of generality, we can take $\lambda = 1$. With the choice $F = F_1(q,Q,t)$, the set $\{q,Q\}$ is regarded as the $2N$ separately independent variables, and the quantity dF/dt in Eq. (72) can be replaced by

$$\frac{dF_1}{dt} = \frac{\partial F_1}{\partial q_i}\dot{q}_i + \frac{\partial F_1}{\partial Q_i}\dot{Q}_i + \frac{\partial F_1}{\partial t}. \tag{73}$$

Equating to zero the coefficients of $\dot{q}_i$ and $\dot{Q}_i$ then yields

$$p_i = \frac{\partial F_1}{\partial q_i}, \quad P_i = -\frac{\partial F_1}{\partial Q_i}, \tag{74}$$

$$K = H + \frac{\partial F_1}{\partial t}. \tag{75}$$

For example, the choice $F_1 = q_iQ_i$ interchanges the roles of the q's and p's (except for a sign change), with the result

$$p_i = Q_i, \quad P_i = -q_i, \quad K = H. \tag{76}$$

This demonstrates explicitly that the q's and

p's stand on an equal footing as independent variables in Hamiltonian mechanics—their roles can be interchanged by a canonical transformation.

Other choices for the $2N$ independent variables can be achieved by application of one or more Legendre transformations (as is done in thermodynamics to change independent variables). Of particular relevance to the Hamilton–Jacobi equation is the choice $\{q,P\}$. One need merely replace $F_1(q,Q)$ by $F_2(q,P) = F_1 + Q_iP_i$. Then Eq. (72) becomes

$$p_i\dot{q}_i - H(q,p,t) = -Q_i\dot{P}_i - K(Q,P,t) + \frac{dF_2}{dt}, \tag{77}$$

with

$$\frac{dF_2}{dt} = \frac{\partial F_2}{\partial q_i}\dot{q}_i + \frac{\partial F_2}{\partial P_i}\dot{P}_i + \frac{\partial F_2}{\partial t}, \tag{78}$$

and so

$$P_i = \frac{\partial F_2}{\partial q_i}, \quad Q_i = \frac{\partial F_2}{\partial P_i}, \tag{79}$$

$$K = H + \frac{\partial F_2}{\partial t}. \tag{80}$$

For example, the choice $F_2 = q_iP_i$ generates the identity transformation with $Q_i = q_i$ and $P_i = p_i$.

2.3.4 Interpretation of the Hamilton–Jacobi Equation A comparison of Eq. (80) with Eq. (54) shows that the Hamilton–Jacobi equation can be regarded as a canonical transformation with $F_2 = S(q,P,t)$ such that the transformed Hamiltonian is $K = 0$. The transformed equations of motion are then

$$\frac{\partial K}{\partial P_i} = \dot{Q}_i = 0, \quad \frac{\partial K}{\partial Q_i} = -\dot{P}_i = 0. \tag{81}$$

Thus the transformed momenta $P_i = \alpha_i$ and the transformed coordinates $Q_i = \beta_i$ are all constants of the motion. The nature of the solution is now clear. Writing $S = S(q,\alpha,t)$, then the set of equations

$$p_i = \frac{\partial S(q,\alpha,t)}{\partial q_i}, \quad \beta_i = \frac{\partial S(q,\alpha,t)}{\partial \alpha_i} \tag{82}$$

evaluated at $t = t_1$ provides a set of $2N$ equations to determine $2N$ unknowns α_i and β_i in terms of the initial $(q_i)_1$ and $(p_i)_1$. For conservative systems, the remaining $(N + 1)$th constant of integration is the energy E of the system. For this case, the time variable is separable, and S can be written in the form

$$S(q,\alpha,t) = W(q,\alpha) - Et, \tag{83}$$

where $W(q,\alpha)$ is called *Hamilton's characteristic function.* The crucial point is that *any* complete integral to the Hamilton–Jacobi equation generates a possible dynamical motion of the system since it is the generating function for a canonical transformation. This result is called Jacobi's theorem.

As a consequence of Jacobi's theorem, any complete integral S contains within it all possible trajectories of the system as a function of the initial conditions, rather than one particular trajectory. In fact, surfaces of constant S move through configuration space like wave fronts of constant phase such that the particle trajectories follow the orthogonal set of curves. To see this, consider the example of a particle moving in a potential V, expressed in Cartesian coordinates. Equations (53) for $\{q_1,q_2,q_3\} = \{x,y,z\}$ can then be written as the single equation

$$\nabla S = \nabla W = \mathbf{p}, \tag{84}$$

which shows that the momentum $\mathbf{p} = m\mathbf{v}$ is everywhere perpendicular to surfaces of constant W, and the particle velocity is $v = |\nabla W|/m$. The Hamilton–Jacobi equation for W in this case is

$$(1/2m)(\nabla W)^2 + V = E, \tag{85}$$

so that

$$|\nabla W| = \sqrt{2m(E - V)}. \tag{86}$$

For the case of a freely falling particle, surfaces of constant W are just horizontal planes with the particle trajectories in the perpendicular direction. As time goes on, surfaces of constant S sweep through surfaces of constant W with a phase velocity given by

$$u = \frac{ds}{dt} = \frac{E}{|\nabla W|}, \tag{87}$$

where ds is a displacement in the direction normal to a surface of constant W. The above follows from the facts that the stationary phase condition $dS = 0$ corresponds to $dW = E\,dt$, and $dW = |\nabla W| ds$ is the change in W due to a displacement in the direction normal to the surface. Thus the phase velocity decreases as the particle velocity increases, just as is the case for the wave and particle pictures of light.

The above considerations in fact provide a wave picture of classical dynamics in the "geometrical optics" limit where the wavelength is infinitesimally small compared with the dimensions of the apparatus. The wave nature can then be ignored, and the trajectories determined by the principle of least action (or Fermat's principle in the case of geometrical optics).

2.4 Relativistic Generalization

For the case of a single particle acted on by forces derivable from a potential V, Hamilton's principle can be simply modified to incorporate the effects of special relativity. One need simply define

$$L = -mc^2\gamma - V, \tag{88}$$

where $\gamma = \sqrt{1 - v^2/c^2}$, and v is the velocity $|\dot{\mathbf{r}}|$ in a particularly chosen Lorentz frame. With this choice of L, Hamilton's principle and the Euler–Lagrange equations give the correct equations of motion

$$\frac{d}{dt}\left(\frac{m\dot{x}_i}{\gamma}\right) = -\frac{\partial V}{\partial x_i}. \tag{89}$$

The canonical momenta p_i and Hamiltonian H are given by

$$p_i = \frac{\partial L}{\partial \dot{x}_i} = \frac{m\dot{x}_i}{\gamma}, \tag{90}$$

$$H = p_i\dot{x}_i - L = T + V = E, \tag{91}$$

where $T = mc^2/\gamma$ is a relativistic generalization of the kinetic energy, including the rest-mass energy mc^2. After substituting for $\dot{x}_i$, H assumes the form

$$H = \sqrt{c^2p^2 + m^2c^4} + V. \tag{92}$$

2.4.1 Inclusion of Electromagnetic Fields In general, an electromagnetic field is derivable from a scalar potential $\phi(\mathbf{r},t)$ and a vector potential $\mathbf{A}(\mathbf{r},t)$ according to

$$\mathbf{E} = -\nabla\phi - \frac{1}{c}\frac{\partial \mathbf{A}}{\partial t}, \tag{93}$$

$$\mathbf{B} = \nabla \times \mathbf{A}, \tag{94}$$

where $\mathbf{E}$ and $\mathbf{B}$ are the electric and magnetic fields. The equation of motion for a particle of charge q is then

$$\frac{d}{dt}\left(\frac{m\dot{x}_i}{\gamma}\right) = qE_i + \frac{q}{c}(\mathbf{v} \times \mathbf{B})_i, \tag{95}$$

which now contains a velocity-dependent force term. This equation follows from the Lagrangian

$$L = -mc^2\gamma - q\phi + \frac{q}{c}\mathbf{A}\cdot\mathbf{v}, \tag{96}$$

or its nonrelativistic counterpart with the term $-mc^2\gamma$ replaced by T. The canonical momenta are then

$$p_i = \frac{\partial L}{\partial \dot{x}_i} = \frac{m\dot{x}_i}{\gamma} + \frac{q}{c}A_i. \tag{97}$$

A direct calculation shows that the Hamiltonian becomes [cf. Eq. (92)]

$$H = \sqrt{c^2[\mathbf{p} - (q/c)\mathbf{A}]^2 + m^2c^4} + V. \tag{98}$$

The same substitution $\mathbf{p} \to \mathbf{p} - (q/c)\mathbf{A}$ applies also in the nonrelativistic case. This simple prescription, together with $V = q\phi$, allows electromagnetic fields to be easily incorporated into the Lagrangian and Hamiltonian formulations of mechanics.

3. APPLICATIONS TO QUANTUM MECHANICS

3.1 Variational Derivation of the Schrödinger Equation

The considerations of Sec. 2.3.4 suggest that the Hamilton–Jacobi equation of classical dynamics expresses the short-wavelength limit of an underlying wave equation, with surfaces of constant S identified as surfaces of constant phase. In fact, Eq. (85) already bears a superficial resemblance to the time-independent Schrödinger equation, but it does not yet have the form of a wave equation. Following Schrödinger, a suitable wave equation can be obtained by first making the substitution

$$W = iC \ln \Psi \Rightarrow \Psi = e^{iW/C} \tag{99}$$

into the Hamilton–Jacobi equation

$$(1/2m)(\nabla W^* \cdot \nabla W) + V = E, \tag{100}$$

generalized for complex W, to obtain

$$(C^2/2m)(\nabla \Psi^* \cdot \nabla \Psi) + (V - E)\Psi^* \Psi = 0. \tag{101}$$

The left-hand side can be integrated over all space, provided that $\int \Psi^* \Psi d^3r$ remains finite. Application of the Euler–Lagrange equations to make the integral stationary with respect to arbitrary independent variations of Ψ and Ψ^* then yields the Schrödinger equation

$$-(C^2/2m)(\nabla^2 \Psi) + (V - E)\Psi = 0, \tag{102}$$

together with a similar equation for Ψ^*. The derivation is a simple extension of the one used to obtain Laplace's equation (31) in Sec. 1.2. The solution to Eq. (102) then determines the wave function $\Psi(\mathbf{r})$ for the system, subject to the constraint that $\int \Psi^* \Psi d^3r$ remain finite for bound systems; i.e., that Ψ is *normalizable.* Comparison with experiment shows that one should set $C = \hbar = h/2\pi$, where h is Planck's constant. Equation (102) can then be written in the form

$$H(q,p)\Psi = E\Psi, \tag{103}$$

where $H(q,p)$ is the Hamiltonian with the quantum-mechanical replacement $\mathbf{p} \rightarrow (\hbar/i)\nabla$. The constraint on $\int \Psi^* \Psi d^3r$ makes this an eigenvalue problem that determines the possible energies E of the system.

If there are n interacting particles, then the term $\nabla^2 \Psi$ is to be replaced by $\Sigma_i \nabla_i^2 \Psi$, and V includes all the interaction potentials. Also, the various integrals over $d\mathbf{r}$ are replaced by multiple integrals over $d^3r_1 d^3r_2 \cdots d^3r_n$.

3.2 The Rayleigh–Schrödinger Variational Principle

Consider a bound system, or one that is contained in a finite box. Under these conditions, Eq. (101) can be integrated over all space and the term $\nabla \Psi^* \cdot \nabla \Psi$ integrated by parts to obtain

$$\int \Psi^*(H - E)\Psi d^3r = 0. \tag{104}$$

The integrated term does not contribute under the assumed conditions because $\Psi(\mathbf{r}) \rightarrow 0$ sufficiently rapidly as $|\mathbf{r}| \rightarrow \infty$. The variational derivation of Sec. 3.1 guarantees that this integral is stationary with respect to arbitrary variations $\delta\Psi$ if Ψ satisfies the Schrödinger equation. However, the same variational condition can now be reinterpreted as the problem of making the integral $\int \Psi^* H \Psi d^3r$ stationary, subject to the constraint that

$$\int \Psi^* \Psi d^3r = \text{const.}, \tag{105}$$

with E playing the role of a Lagrange undetermined multiplier. In this guise, one can say that E obtained from the Rayleigh quotient

$$E = \frac{\int \Psi^* H \Psi d^3r}{\int \Psi^* \Psi d^3r} \tag{106}$$

is stationary. In fact, as discussed in the following section, E is a minimum under many circumstances.

3.3 The Rayleigh–Ritz Variational Method

The Schrödinger equation is a partial-differential equation that can be solved exactly only for certain special cases such as the Coulomb potential or the harmonic-oscillator potential. For arbitrary potentials, or for problems containing more than two bodies, the quantum-mechanical problem is no easier to solve than the corresponding classical one. In these cases, the Rayleigh–Schrödinger variational principle provides one of the most powerful methods for obtaining approximate eigenvalues E and wave functions Ψ.

Suppose one guesses by some means an approximate trial wave function $\Psi_{\rm tr}$ that conforms with the constraint of normalizability and approximates one of the exact solutions to

$$H\Psi_i = E_i\Psi_i, \quad i = 1, 2, \ldots. \tag{107}$$

The index i labels the spectrum of exact solutions. In general, the eigenvalue spectrum will have both discrete and continuous parts. In the latter case, summations over i include integrations over the continuous part. The crucial point is that even though the Ψ_i are not known, they form a complete basis set of functions in terms of which the trial function $\Psi_{\rm tr}$ can be expanded. In analogy with Fourier series, one can therefore write

$$\Psi_{\rm tr} = \sum_{i=1}^{\infty} c_i\Psi_i, \tag{108}$$

where the c_i are the expansion coefficients. Let the eigenvalue spectrum be ordered so that $E_1 < E_2 < E_3 < \cdots$, and assume that all the Ψ_i and $\Psi_{\rm tr}$ are normalized to unity; i.e., using Dirac bra-ket notation for integrals,

$$\begin{aligned}&\langle\Psi_{\rm tr}|H|\Psi_{\rm tr}\rangle \equiv \int \Psi^* H\Psi d^3r = E_{\rm tr},\\ &\langle\Psi_i|\Psi_j\rangle = \delta_{i,j},\\ &\langle\Psi_i|H|\Psi_j\rangle = E_i\delta_{i,j}.\end{aligned} \tag{109}$$

Substituting Eq. (108) into (106), and using Eqs. (109), one then obtains

$$E_{\rm tr} = |c_1|^2E_1 + |c_2|^2E_2 + |c_3|^2E_3 + \cdots \tag{110}$$

for the corresponding trial energy. Since, by assumption, $\langle\Psi_{\rm tr}|\Psi_{\rm tr}\rangle = 1$, it follows that

$$\sum_{i=1}^{\infty} |c_i|^2 = 1, \tag{111}$$

and so Eq. (110) can be rewritten in the form

$$\begin{aligned}E_{\rm tr} &= E_1 + |c_2|^2(E_2 - E_1)\\ &\quad + |c_3|^2(E_3 - E_1) + \cdots\\ &\geq E_1.\end{aligned} \tag{112}$$

Thus $E_{\rm tr}$ is an *upper bound* on the lowest eigenvalue E_1 for any normalizable $\Psi_{\rm tr}$.

The basic idea of variational calculations then is to write $\Psi_{\rm tr}$ in some arbitrarily chosen mathematical form with variational parameters (subject to normalizability and boundary conditions at the origin and infinity), and then adjust the parameters to obtain the minimum value of $E_{\rm tr}$. A lower $E_{\rm tr}$ is guaranteed to be closer to E_1. The power of the method stems both from this and the fact that, by the Rayleigh–Schrödinger variational principle, the error term linear in $\delta\Psi = \Psi_{\rm tr} - \Psi_1$ vanishes.

3.3.1 Algebraic Solution for Linear Variational Parameters

Suppose that $\Psi_{\rm tr}$ depends in some arbitrarily chosen way on a set of N variational parameters $a_1, a_2, \ldots, a_N$. [For example, in a one-dimensional case, one might choose $\Psi(r) = r^{a_1}e^{-a_2r}$ with a_1 and a_2 regarded as nonlinear variational parameters.] Then the variational condition corresponds to the system of equations

$$\frac{\partial E_{\rm tr}}{\partial a_p} = 0, \quad p = 1, \ldots, N. \tag{113}$$

In general, this is a set of transcendental algebraic equations that cannot be solved exactly.

However, the minimization problem for the case of *linear* variational coefficients can be solved exactly by matrix diagonalization. For example, let $\{\chi_p|p = 1, \ldots, N\}$ be a finite basis set of N arbitrarily chosen functions (subject to the boundary conditions and normalizability) that need have nothing to do with the exact Ψ_i, and write $\Psi_{\rm tr}$ in the form

$$\Psi_{\rm tr} = \sum_{p=1}^{N} a_p\chi_p. \tag{114}$$

Now the variational parameters a_p enter linearly, and the set of variational conditions (113) becomes exactly equivalent to the N-dimensional generalized eigenvalue problem

$$\mathbf{Ha} = \lambda\mathbf{Oa}, \tag{115}$$

where $\mathbf{a}$ is a column vector of coefficients a_p, and $\mathbf{H}$ and $\mathbf{O}$ have matrix elements $H_{pq} = \langle\chi_p|H|\chi_q\rangle$ and $O_{pq} = \langle\chi_p|\chi_q\rangle$. There are N eigenvalues $\lambda_1, \lambda_2, \ldots, \lambda_N$, of which the lowest is an upper bound to E_1.

Equation (115) is equivalent to the original Schrödinger equation (103) only if the basis set $\{\chi_p\}$ is complete, and in general this requires taking the limit $N \to \infty$. The significance of Eq. (115) is that it provides a computationally useful means of obtaining approximate solutions, even if the complete basis set of functions $\{\chi_p\}$ is truncated at some finite number N, and the lowest eigenvalue provides an upper bound that systematically decreases toward the exact E_1 as N is increased. As discussed in the following section, the bounds apply not just to the ground state but also to the lower-lying excited states.

3.3.2 Extension to Excited States By the Hylleraas–Undheim–MacDonald (HUM) theorem (see Hylleraas and Undheim, 1930; MacDonald, 1933), the remaining eigenvalues $\lambda_2, \lambda_3, \ldots$ are also upper bounds to the exact energies $E_2, E_3, \ldots$, provided that the spectrum is bounded from below. The HUM theorem is a consequence of the matrix eigenvalue interleaving theorem, which states that as the dimensions of **H** and **O** are progressively increased by adding an extra row and column, the N old eigenvalues λ_p fall between the $N + 1$ new ones. Consequently, as illustrated in Fig. 3, all eigenvalues numbered from the bottom up must move inexorably downward as N is increased. Since the exact spectrum of bound states is obtained in the limit $N \to \infty$, no λ_p can cross the corresponding exact E_p on its way down. Thus $\lambda_p \geq E_p$ for every finite N.

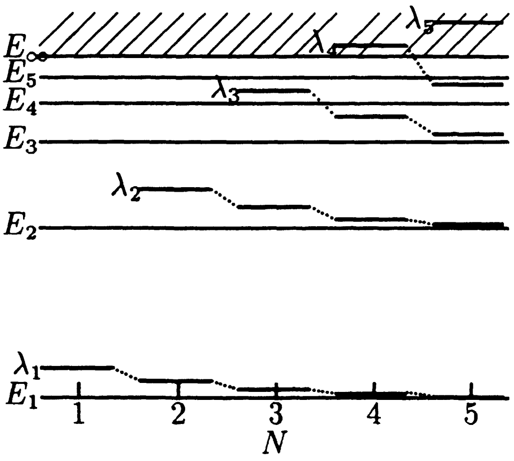

FIG. 3. Diagram illustrating the HUM theorem. The λ_p, $p = 1, \ldots, N$, are the variational eigenvalues for an N-dimensional basis set, and the E_i are the exact eigenvalues of H. The highest λ_p lie in the continuous spectrum of H.

If the exact Ψ_i can be formed from a linear combination of the χ_p included in the finite basis set, then the result of the variational calculation is the exact Ψ_i and E_i. Otherwise, one obtains the best variational approximation provided by the particular χ_p chosen. If the χ_p basis set becomes asymptotically complete as $p \to \infty$, then convergence to the correct answer is assured.

The HUM theorem no longer applies directly to the relativistic Dirac equation or similar problems because the spectrum is not bounded from below. However, finite basis-set methods can still be applied, provided that sufficient care is taken in their construction (see Drake and Goldman, 1988; Grant, 1996).

3.3.3 Variational Lower Bound If the Rayleigh–Ritz method is applied to the integral

$$\int \Psi^*(H - E)(H - E_2^<)d^3r, \tag{116}$$

then the quantity

$$E^< = \frac{\langle \Psi_{\rm tr}|H(H - E_2^<)|\Psi_{\rm tr}\rangle}{\langle \Psi_{\rm tr}|(H - E_2^<)|\Psi_{\rm tr}\rangle} \tag{117}$$

is made stationary. If the quantity $E_2^<$ is chosen to be a lower bound on the energy E_2 of the first excited state, then by an argument similar to that leading to Eq. (112), $E^<$ is a lower bound on the ground-state energy E_1, called the Temple lower bound (Temple, 1928) and denoted by $E_1^<$. In fact, if $\Psi_{\rm tr}$ is expanded as in Eq. (108), then after some algebra, $E^<$ from Eq. (117) becomes

$$E_1^< = E_1 + \frac{\sum_{i=2}^{\infty} |c_i|^2(E_i - E_1)(E_i - E_2^<)}{E_1 - E_2^< + D}, \tag{118}$$

where

$$D = \sum_{i=2}^{\infty} |c_i|^2(E_i - E_1) = E_1^> - E_1, \tag{119}$$

and $E_1^>$ is the variational upper bound on E_1. The numerator of the fraction in Eq. (118) is positive and the denominator is negative, provided that $E_1^> < E_2^<$, thus proving the bound. However, generally speaking, $E_1^<$ is much less accurate than $E_1^>$.

3.3.4 Illustrative Results for Helium

Application of the variational method to helium by Hylleraas (1928, 1929) played an important role in the early history of quantum mechanics because it provided the first test of the Schrödinger equation in a system more complicated than hydrogen. With its two electrons orbiting the nucleus, helium is the simplest atomic system that cannot be adequately described by the older Bohr–Sommerfeld quantum theory.

The Hamiltonian for helium (in the limit of infinite nuclear mass) is

$$H = -\sum_{i=1}^{2}\left(\frac{\hbar^2}{2m_e}\nabla_i^2 + \frac{e^2}{r_i}\right) + \frac{e^2}{r_{12}}, \tag{120}$$

where $r_{12} = |\mathbf{r}_1 - \mathbf{r}_2|$ is the electron–electron separation and Ze is the nuclear charge. The e^2/r_{12} term represents the Coulomb repulsion between the two electrons. Without this term, the Schrödinger equation would be separable, and the exact solution (including permutational symmetry) would be of the form

$$\Psi(\mathbf{r}_1,\mathbf{r}_2) = \psi_1(\mathbf{r}_1)\psi_2(\mathbf{r}_2) \pm \psi_1(\mathbf{r}_2)\psi_2(\mathbf{r}_1), \tag{121}$$

where $\psi_1(\mathbf{r})$ and $\psi_2(\mathbf{r})$ are exactly known hydrogenic wave functions, depending on the state in question. The Hartree–Fock approximation corresponds to the best variational representation that can be written in the form of a separable product with $\psi_1(\mathbf{r})$ and $\psi_2(\mathbf{r})$ regarded as arbitrary functions of r. However, even this is in error for the ground-state energy of $-2.903\,724$ a.u. [the atomic unit (a.u.) of energy is $e^2/a_0 = 27.211\,396$ eV, where a_0 is the Bohr radius] by 0.0247 a.u., or 0.673 eV. This difference, called the *correlation energy*, is much larger than typical chemical energies.

To obtain a better representation, Hylleraas suggested constructing a trial solution of the form

$$\Psi_{\text{tr}} = \sum_{i,j,k} a_{ijk} r_1^i r_2^j r_{12}^k \exp(-\alpha r_1 - \beta r_2), \tag{122}$$

which is of the form of a hydrogenic product $\psi_1(\mathbf{r}_1)\psi_2(\mathbf{r}_2)$, except that it contains explicit powers of r_{12} and is therefore not separable. The a_{ijk} are the linear variational parameters, and α and β are additional nonlinear parameters that can be separately varied to optimize the energy. Detailed formulas for the necessary matrix elements are given by Drake (1996). This basis set is provably complete in the limit of large $i_{\max}$, $j_{\max}$, and $k_{\max}$ (Klahn and Bingel, 1977). Typically, all combinations of powers are included in the basis set such that, for electrons with angular momenta l_1 and l_2,

$$i + j + k - l_1 - l_2 \le \Omega, \tag{123}$$

where Ω is an integer that is progressively increased until adequate convergence is obtained. Without further truncation, the number of terms obtained in this way is

$$N = \tfrac{1}{6}(\Omega + 1)(\Omega + 2)(\Omega + 3). \tag{124}$$

The effect of including powers of r_{12} is dramatic and immediate. The Hartree–Fock approximation corresponds to the limit of large $i_{\max}$ and $j_{\max}$ with $k_{\max} = 0$. As shown in Table 1, an increase of $k_{\max}$ to 1 reduces the error in E to only 0.006 20 eV, thereby accounting for 99% of the correlation energy. The results in Table 1 also demonstrate that the odd powers of r_{12} are much more effective than the even powers. This can be understood from the fact that r_{12}^2 can be written in the form

$$r_{12}^2 = r_1^2 + r_2^2 - 2r_1r_2\cos\theta_{12}, \tag{125}$$

where θ_{12} is the angle between the vectors $\mathbf{r}_1$ and $\mathbf{r}_2$. Thus r_{12}^2 is only linear in $\cos\theta_{12}$, while an expansion of $r_{12} = (r_{12}^2)^{1/2}$ contains all powers of $\cos\theta_{12}$.

Table 1. Energies for the ground state of helium obtained with various powers of r_{12} in the basis set.

r_{12} Terms	Energy (a.u.)	Error (eV)
No r_{12}	−2.879 029	0.672

Calculations of this type have been performed by many authors (see Drake, 1993a, for a review), and they have reached a high degree of sophistication. Problems typical of all variational calculations are a dramatic and progressive loss of accuracy for the more highly excited states, and numerical linear dependence in the basis set as it is enlarged. These problems can be avoided by doubling the basis set so that it contains a second set of terms with the same powers but different scale factors α and β. A complete optimization with respect to the α's and β's then leads to a natural partition of the basis set into two sectors with one representing the asymptotic form of the wave function and the other representing complex inner correlation effects. The results obtained by this method are essentially exact for all practical purposes. The nonrelativistic energies are known to better than one part in 10^{16} for the entire singly excited spectrum. A sample of results for the low-lying states is given in Table 2. The indicated convergence was obtained by progressively increasing Ω up to 17, corresponding to about 1700 terms in the doubled basis set. Table 3 shows an example of the convergence for the ground state. [For the case of S states, the basis-set sizes are smaller than indicated by Eq. (124) because terms with $i > j$ can be omitted by symmetry.] The ratios of successive differences in the last column provide a convenient method to monitor the convergence of the eigenvalue. They show that the differences themselves decrease in a fairly smooth and uniform fashion with increasing Ω. These high-precision results provide a benchmark for comparison with other less accurate methods of calculation such as Hartree–Fock and configuration interaction. Results for many other states are given by Drake (1993b, 1994).

Table 2. Nonrelativistic energies for several states of helium in the limit of infinite nuclear mass.

[a] $R(\Omega) = [E(\Omega - 1) - E(\Omega - 2)]/[E(\Omega) - E(\Omega - 1)]$.

A comparison of the results in Table 2 with experiment is meaningful only after corrections for finite nuclear mass, special relativity, and quantum-electrodynamic (QED) effects (such as electron self-energy and vacuum polarization) are taken into account. A detailed discussion of these corrections can be found in Drake (1993b, 1994). When they are included, the calculated transition frequencies agree to within the estimated accuracy of the QED shift. If the measurements are expressed in terms of ionization energies for the various states, then their accuracies range from ±30 MHz ($\pm 5 \times 10^{-9}$ a.u.) for the ground state to ±0.1 MHz ($\pm 1.5 \times 10^{-11}$ a.u.) for the higher-lying P and D states. Since the nonrelativistic energies in Table 2 are much more accurate than this, the comparison with experiment is primarily a test of higher-order contributions to the QED shift (two-electron Lamb shift), which is the dominant source of uncertainty in the calculations.

As one example, the calculated ionization energy of the $1s2s\ ^1S$ state is (Drake *et al.*, 1993)

960 332 039.4 ± 1 MHz.

Of this total, −2808.5 ± 1 MHz comes from the calculated QED shift. For comparison, the two experimental values are

960 332 041.52 ± 0.21 MHz,
960 332 040.87 ± 0.15 MHz.

The first is obtained from an extrapolation of the $1s2s\ ^1S$–$1snp\ ^1P$ transition frequencies to the series limit (Sansonetti and Gillaspy, 1992), and the second from the $1s2s\ ^1S$–$1snd\ ^1D$ two-photon transition frequencies (Lichten *et al.*, 1991). Although the measurements do not quite agree with each other, taken together they determine the QED shift of the $1s2s\ ^1S$ state to an accuracy of about 100 parts per million and verify the calculated value to better than 0.1%. For the ground state, the calculated QED shift in the ionization energy has the much larger value $-(41\,233 \pm 35)$ MHz. This has recently been verified to an accuracy of ±45 MHz (±0.1%) from the total $1s^2\ ^1S$–$1s2p\ ^1P$ transition frequency (Eikema *et al.*, 1996).

In summary, the results in Table 2 provide a firm foundation of nonrelativistic energies upon which higher-order corrections can be built and compared with experiment. Further improvements in the QED part of the theory remain an important challenge for the future.

3.3.5 Extensions to More Complex Systems Fully correlated variational calculations of the type described in the previous section are difficult to extend to systems more complex than helium because of the rapid increase in the number of terms required. For an atom containing K electrons, there are K single-particle radial distances r_s and $K(K-1)/2$ interparticle distances r_{st} for a total of $P = K(K+1)/2$ radial coordinates. If all combinations of powers of the r_s and r_{st} are included in the basis set such that the sum of powers is $\leq \Omega$ [cf. Eq. (123)], then the generalization of Eq. (124) for the number of terms is

$$N = \frac{(\Omega+1)(\Omega+2)\cdots(\Omega+P)}{P!}. \tag{126}$$

Since the time required to calculate a single eigenvector increases in proportion to N^3, the overall complexity of the calculation increases roughly in proportion to

$$\left[\frac{6(\Omega+P)!}{P!(\Omega+3)!}\right]^3 \tag{127}$$

relative to helium with the same Ω.

As an example, from Table 3, an accuracy of 10^{-10} a.u. for the ground state of helium requires $\Omega = 8$. A similar accuracy for lithium with $K = 3$ and $P = 6$ therefore requires about 6000 times the computer resources, and for beryllium with $K = 4$ and $P = 10$, the factor from expression (127) becomes 1.4×10^{13}.

Because of this rapid increase of complexity with the number of electrons, fully correlated calculations of spectroscopic accuracy have only been extended as far as lithium (see Yan and Drake, 1995; Yan *et al.*, 1996; and earlier references therein). The pattern of convergence for the ground state is similar to that shown in Table 3. The results up to $\Omega = 8$ yield the extrapolated nonrelativistic eigenvalue

$$E(1s^2 2s^2\ S) = -7.478\,060\,323\,10(31) \text{ a.u.} \tag{128}$$

The uncertainty of $\pm 3 \times 10^{-10}$ is about what one would expect from Table 3 for $\Omega = 8$.

For systems more complex than lithium, one must resort to other methods of calculation that can be extended to arbitrarily complex systems, but typically having much lower accuracy ($\pm 10^{-6}$ a.u. or more). These methods include multiconfiguration Hartree–Fock (MCHF), configuration-interaction (CI), many-body perturbation-theory, finite-element, diffusion Monte Carlo (DMC), and variational Monte Carlo (VMC) techniques. The MCHF and CI methods are similar in concept to the fully correlated variational method described in Sec. 3.3.4, except that the members of the basis set χ_p are constructed from antisymmetrized products of one-electron orbitals corresponding to definite electronic configurations. The effect is analogous to including only the *even* powers of r_{12} as shown in Table 1, and so convergence with increasing angular momentum of the individual electrons is slow. Recently, Goldman (1994) has devised a modified CI method involving extrapolation procedures to overcome this problem, at least for simple systems. For recent work on finite-element and many-body perturbation-theory methods, see Ackermann (1995) and Plante *et al.* (1994), respectively.

The DMC and VMC Monte Carlo methods attempt to reduce the complexity problem for more complex systems by the use of random-sampling techniques. The DMC method takes advantage of the fact that the time-dependent Schrödinger equation is formally identical to the diffusion equation in imaginary time, and for large imaginary time, an arbitrary starting solution quickly decays to the ground state (see, e.g., Moskowitz *et al.*, 1982; Barnett *et al.*, 1995; and earlier references therein). A random sampling of initial configurations is then propagated forward in time to construct the wave function. The VMC method is more closely related to the standard variational techniques discussed in Sec. 3.3.4. The idea is to define a trial wave function Ψ_{tr} in terms of variational parameters, as in Sec. 3.3.4, and then to optimize them over a statistical distribution of sample points $\mathbf{r}_i$ by minimizing an expression for the variance such as

$$\frac{\sum_i (H\Psi_i - E_{\mathrm{ref}}\Psi_i)^2/w_i}{\sum_i \Psi_i^2/w_i}, \tag{129}$$

or the energy variance given by

$$\frac{\sum_i (H\Psi_i - E_{\mathrm{ref}}\Psi_i)^2\Psi_i^2/w_i^2}{\left[\sum_i \Psi_i^2/w_i\right]^2}. \tag{130}$$

Here, $\Psi_i = \Psi_{\mathrm{tr}}(\mathbf{r}_i)$ is the trial wave function evaluated at some particular set of values for the electronic coordinates collectively denoted by $\mathbf{r}_i$, and the weight function $w_i = w(\mathbf{r}_i)$ is the probability of choosing $\mathbf{r}_i$ if the sampling is nonuniform. The optimum strategy is to bias the sampling according to the value of a guiding function $g(\mathbf{r}_i)$ that resembles the actual Ψ^2 as closely as possible and to choose the reference energy E_{ref} as close as possible to the desired eigenvalue. Although the method could be applied to a direct optimization of $\langle H\rangle$, the advantage gained by optimizing the variance is that the sample space required for a given accuracy is much smaller. Several sample problems and illustrative examples are discussed by Alexander *et al.* (1991).

3.4 Variation–Perturbation Methods

For many problems, it is advantageous to split the Hamiltonian into two parts according to

$$H = H^{(0)} + gV, \tag{131}$$

where the eigenvalue problem for $H^{(0)}$ can be solved exactly (or to high precision), and V is a perturbation whose strength is controlled by the parameter g. If the wave functions and energies are similarly expanded,

$$\Psi = \Psi^{(0)} + g\Psi^{(1)} + g^2\Psi^{(2)} + \cdots, \tag{132}$$

$$E = E^{(0)} + gE^{(1)} + g^2E^{(2)} + \cdots, \tag{133}$$

and substituted into the Rayleigh–Ritz quotient (106), then the terms linear in g give

$$E^{(1)} = \frac{1}{\langle\Psi^{(0)}|\Psi^{(0)}\rangle}\Big[\langle\Psi^{(0)}|V|\Psi^{(0)}\rangle + 2\langle\Psi^{(0)}|H^{(0)} - E^{(0)}|\Psi^{(1)}\rangle\Big]. \tag{134}$$

This is stationary with respect to variations $\delta\Psi^{(0)}$ if $\Psi^{(1)}$ satisfies the first-order perturbation equation

$$(H^{(0)} - E^{(0)})|\Psi^{(1)}\rangle + (V - E^{(1)})|\Psi^{(0)}\rangle = 0. \tag{135}$$

Since by assumption

$$H^{(0)}|\Psi^{(0)}\rangle = E^{(0)}|\Psi^{(0)}\rangle, \tag{136}$$

it follows from Eq. (134) that

$$E^{(1)} = \langle\Psi^{(0)}|V|\Psi^{(0)}\rangle/\langle\Psi^{(0)}|\Psi^{(0)}\rangle. \tag{137}$$

The entire series of perturbation equations to all orders can be similarly generated from the Rayleigh–Ritz variational principle. Computational methods based on these results were first developed by Slater and Kirkwood (1931), and by Dalgarno and Lewis (1955, 1956) (see also Dalgarno and Stewart, 1956; Sternheimer, 1951, 1954, 1957; Schwartz, 1959). They have since been employed by numerous other authors for a wide variety of problems.

3.4.1 Variational Bounds A particular advantage of the variational derivation of the perturbation equations is its use in establishing bounds (see, e.g., Glover and Weinhold, 1976). For example, consider the second-order energy

$$E^{(2)} = \frac{1}{\langle \Psi^{(0)}|\Psi^{(0)}\rangle}\Big[2\langle \Psi^{(0)}|V|\Psi^{(1)}\rangle + 2\langle \Psi^{(0)}|H^{(0)} - E^{(0)}|\Psi^{(2)}\rangle + \langle \Psi^{(1)}|H^{(0)} - E^{(0)}|\Psi^{(1)}\rangle\Big], \qquad (138)$$

from terms quadratic in g. $E^{(2)}$ is stable with respect to variations $\delta\Psi^{(0)}$ if $\Psi^{(2)}$ satisfies the second-order perturbation equation

$$(H^{(0)} - E^{(0)})|\Psi^{(2)}\rangle + (V - E^{(1)})|\Psi^{(1)}\rangle = E^{(2)}|\Psi^{(0)}\rangle, \qquad (139)$$

from which it follows that

$$E^{(2)} = \frac{\langle \Psi^{(0)}|V - E^{(1)}|\Psi^{(1)}\rangle}{\langle \Psi^{(0)}|\Psi^{(0)}\rangle}. \qquad (140)$$

However, $\Psi^{(1)}$ is typically not known exactly and must be approximated in some way. From Eq. (138), $E^{(2)}$ is stable with respect to variations $\delta\Psi^{(1)}$ if $\Psi^{(1)}$ satisfies the first-order equation (135). Since the total $E = E^{(0)} + gE^{(1)} + g^2E^{(2)} + \cdots$ is an upper bound for sufficiently small g, and $E^{(0)}$ and $E^{(1)}$ are known exactly (by assumption), it follows that the value of $E^{(2)}$ calculated from Eq. (138) with some approximate $\Psi_{\mathrm{tr}}^{(1)}$ must be an upper bound.

In particular, if $\Psi_{\mathrm{tr}}^{(1)}$ is expanded in a finite basis set of functions χ_p, as in Eq. (114), then the variational condition $\partial E^{(2)}/\partial b_p = 0$ for the expansion coefficients b_p yields the set of N linear algebraic equations [cf. Eq. (115)]

$$(\mathbf{H}^{(0)} - E^{(0)}\mathbf{O})\mathbf{b} + \mathbf{V}^E = 0, \qquad (141)$$

where $\mathbf{V}^E$ is a column vector with elements $V_p^E = \langle \chi_p|V - E^{(1)}|\Psi^{(0)}\rangle$. [This works correctly if $\langle \chi_p|\Psi^{(0)}\rangle = 0$ by symmetry. However, if $\Psi^{(0)}$ can be expressed as a linear combination of the χ_p, then these equations are singular. In that case, it is sufficient just to delete one of the equations to obtain a nonsingular set.] It then follows that

$$\langle \Psi^{(1)}|(H^{(0)} - E^{(0)})|\Psi^{(1)}\rangle = -\langle \Psi^{(1)}|(V - E^{(1)})|\Psi^{(0)}\rangle \qquad (142)$$

within the finite basis set, and Eq. (138) for $E^{(2)}$ reduces to Eq. (140).

3.4.2 Spectral Representations and Pseudostates Although computationally less efficient, it is instructive and sometimes useful to transform the χ_p basis set to a new basis $\tilde{\chi}_p$ that diagonalizes $\mathbf{H}$. The matrix elements in the transformed basis are then

$$\langle \tilde{\chi}_p|H|\tilde{\chi}_q\rangle = \tilde{E}_p\delta_{p,q}, \qquad (143)$$

$$\langle \tilde{\chi}_p|\tilde{\chi}_q\rangle = \delta_{p,q}. \qquad (144)$$

The eigenvectors $\tilde{\chi}_p$ with eigenvalues $\tilde{E}_p$ are called *pseudostates* that form a discrete variational representation of the actual spectrum of the system (including the continuous spectrum of $H^{(0)}$; see Fig. 3). Although the diagonalization step is computationally slow, the advantage gained is that the system of equations (141) is brought into diagonal form with the immediate solutions

$$\tilde{b}_p = \frac{\langle \tilde{\chi}_p|V - E^{(1)}|\Psi^{(0)}\rangle}{E^{(0)} - \tilde{E}_p}, \quad p = 1, 2, \ldots, N. \qquad (145)$$

A term with $\tilde{E}_p = E^{(0)}$, if present, is simply omitted. Without loss of generality, one can then assume that $\langle \tilde{\chi}_p|\Psi^{(0)}\rangle = 0$ for the remaining $\tilde{\chi}_p$. Equation (140) then becomes

$$E^{(2)} = \sum_{p=1}^{N}{}' \frac{|\langle \tilde{\chi}_p|V - E^{(1)}|\Psi^{(0)}\rangle|^2}{E^{(0)} - \tilde{E}_p}, \qquad (146)$$

where the prime denotes that terms with $\tilde{E}_p = E^{(0)}$ are to be omitted. This expression for $E^{(2)}$ is formally identical to the standard second-order perturbation expression, except that the summation over the actual spectrum of $H^{(0)}$ (including an integration over the continuum) is replaced by a summation over the discrete variational pseudostates. The results are completely equivalent to those obtained by solving Eqs. (141) directly. A similar formal identity can be extended to all orders of perturbation theory.

From a more general point of view, the above results correspond to a discrete variational representation for the Green's function of complex variable z, defined by

$$(H^{(0)} - z)G^{(0)}(\mathbf{r},\mathbf{r}') = \delta(\mathbf{r} - \mathbf{r}'). \qquad (147)$$

Then

$$G^{(0)}(\mathbf{r},\mathbf{r}') \approx \sum_{p=1}^{N} \frac{|\tilde{\chi}(\mathbf{r})\rangle\langle\tilde{\chi}(\mathbf{r}')|}{\tilde{E}_p - z}. \tag{148}$$

The great advantage is that often a small number of appropriately chosen pseudostates can replace the infinite summation over bound states plus an integration over the continuous spectrum of $H^{(0)}$.

The pseudostate method has important applications in scattering theory as an alternative way to represent the scattering continuum. For example, the convergent close-coupling method of Bray and Stelbovics (1992) has yielded essentially exact solutions to the electron–hydrogen scattering problem.

3.4.3 Example: The Polarizability of Hydrogen Consider the problem of a hydrogen atom in its 1*s* ground state subjected to a static electric field of strength F pointing in the z direction. The total Hamiltonian in polar coordinates is then

$$H = H^{(0)} + eFr\cos\theta. \tag{149}$$

With $V = eFr\cos\theta$ as the perturbation, the first-order equation (135) can be solved analytically with the result

$$\Psi^{(1)} = -(1/\sqrt{3})(2r + r^2)e^{-r}Y_1^0(\hat{\mathbf{r}}). \tag{150}$$

Since V is of odd parity, $E^{(1)} = 0$, and, from Eq. (140), $E^{(2)} = -\frac{9}{4}a_0^3$, where $E^{(2)}$ is the coefficient of F^2 in the energy expansion. By definition, the dipole polarizability is

$$\alpha_{\mathrm{d}} \equiv -2E^{(2)} = \tfrac{9}{2}a_0^3. \tag{151}$$

If $E^{(2)}$ is written in the form of Eq. (146), summed over the actual spectrum of hydrogen, then nearly half of α_{d} comes from virtual transitions to the continuum.

Suppose now that a variational solution is constructed of the form

$$\Psi_{\mathrm{tr}}^{(1)} = -(1/\sqrt{3})(b_1 r + b_2 r^2)e^{-\lambda r}Y_1^0(\hat{\mathbf{r}}), \tag{152}$$

where b_1 and b_2 are linear variational parameters, and λ is an additional nonlinear variational parameter. This provides a two-dimensional basis set, with the exact solution being recovered for the case $\lambda = 1$. For $\lambda \neq 1$, the basis set provides the best variational representation of $\Psi^{(1)}$. After solving Eq. (141) for b_1 and b_2, the expression for α_{d} as a function of λ becomes

$$\alpha_{\mathrm{d}}(\lambda) = 6\lambda^5\left(\frac{2}{\lambda + 1}\right)^{12} \times \frac{9\lambda^4 - 12\lambda^3 + 14\lambda^2 - 10\lambda + 5}{5\lambda^4 - 10\lambda^3 + 18\lambda^2 - 10\lambda + 5}. \tag{153}$$

A graph of this function near its peak is displayed in Fig. 4. Since $E^{(2)}$ is an upper bound, α_{d} is a lower bound for any λ. It is clear that the exact value of $4.5a_0^3$ is recovered at $\lambda = 1$, where there is an absolute maximum. But what is also significant is the broad region of stability for $0.6 \leq \lambda \leq 1.1$, with a second local maximum near $\lambda = 0.657$. For any λ in this region, α_{d} is in error by no more than 0.6%, even with a basis set containing only two terms. In other words, the entire spectrum of hydrogen is being well represented by just two pseudostates, neither of which corresponds to a physical state of hydrogen. In fact, the accuracy is considerably worse at $\lambda = \frac{1}{2}$, corresponding to the physical 2*p* state. As higher powers of r are added to the basis set, the region of stability rapidly becomes broader and flatter.

3.4.4 Time-Dependent Perturbations Similar methods can be used to treat the case where the perturbation V is time depen-

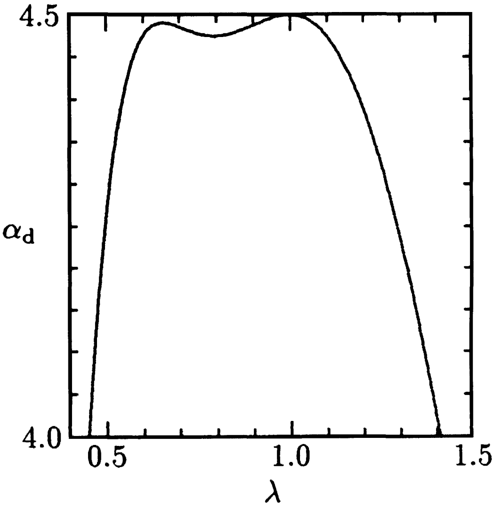

FIG. 4. Variational polarizability α_d of hydrogen, in units of a_0^3. The exact value at $\lambda = 1$ is $\alpha_d = 4.5\ a_0^3$.

dent. For example, with the replacement $E^{(0)} \rightarrow i\hbar\partial/\partial t$, the variational condition

$$\delta\left[\left\langle \Psi^{(1)}(t)\middle| H^{(0)} - i\hbar\frac{\partial}{\partial t}\middle|\Psi^{(1)}(t)\right\rangle + 2\langle\Psi^{(1)}(t)|V(t)|\Psi^{(0)}(t)\rangle\right] = 0 \qquad (154)$$

with respect to $\Psi^{(1)}(t)$ leads to the first-order time-dependent perturbation equation

$$\left(H^{(0)} - i\hbar\frac{\partial}{\partial t}\right)|\Psi^{(1)}(t)\rangle + V(t)|\Psi^{(0)}(t)\rangle = 0. \qquad (155)$$

This can be solved by Dirac's method of variation of constants. Many other techniques have been developed, but these will not be further pursued here. See, for example, Dalgarno (1966).

4. THE GENERAL STURM–LIOUVILLE PROBLEM

Many of the variational techniques discussed in Sec. 3 were developed long before the invention of quantum mechanics, in connection with boundary-value problems in classical physics such as vibrating membranes. Any linear second-order differential equation (of which the radial Schrödinger equation is just one example) can be written in the Sturm–Liouville form

$$\frac{d}{dx}\left[K(x)\frac{dy}{dx}\right] - G(x)y = 0, \qquad (156)$$

defined over some closed interval $[a,b]$, together with suitable boundary conditions. By application of the Euler–Lagrange equation with fixed end points, this equation follows from the variational condition

$$\delta\int_a^b\left[K(x)\left(\frac{dy}{dx}\right)^2 + G(x)y^2\right]dx, \qquad (157)$$

and so all the techniques discussed thus far can be applied. With the choice

$$G(x) = -\lambda g(x) + l(x), \qquad (158)$$

the Sturm–Liouville problem becomes an eigenvalue problem with λ adjusted to satisfy the boundary conditions.

4.1 The Oscillation Theorem

A great many theorems have been proven concerning the solutions to Sturm–Liouville problems (see, e.g., Ince, 1956). Of particular importance for physical applications is the oscillation theorem. Suppose that $K(x)$, $g(x)$, and $l(x)$ are all continuous, real, positive, monotonic decreasing functions of x in the interval $[a,b]$. It can then be proved that the two-point eigenvalue problem

$$\frac{d}{dx}\left[K(x)\frac{dy}{dx}\right] + [\lambda g(x) - l(x)]y = 0 \qquad (159)$$

has an infinite sequence of increasing eigenvalues $\lambda_1, \lambda_2, \ldots$, with corresponding eigenvectors $y_1(x), y_2(x), \ldots$ such that $y_m(x)$ has exactly $m - 1$ zeros in the open interval $[a,b]$. The eigenvalues are entirely discrete. If $g(x)$ changes sign in the interval, then the sequence of eigenvalues becomes doubly infinite with both an increasing $(\lambda_m^{(+)})$ and a decreasing $(\lambda_m^{(-)})$ set. In either case, the solutions are orthogonal with respect to the weight function $g(x)$.

The importance of this theorem (and its extensions) is that the $y_m(x)$ form the basis for a generalized Fourier series in terms of which an arbitrary function $f(x)$ can be expanded in the form

$$f(x) = \sum_{m=1}^{\infty} c_m y_m(x) \qquad (160)$$

with

$$c_m = \int_a^b f(x)g(x)dx. \qquad (161)$$

Since the eigenvalues are entirely discrete, there is no integration over a continuum in Eq. (160). Such a basis is called a *Sturmian* basis set. Most of the mathematical apparatus developed for Fourier analysis can be carried over directly. In fact, a Fourier series just corresponds to the choices $K(x) = 1$, $g(x) = 1$, $l(x) = 0$.

4.2 Example: The Coulomb Problem

Consider the radial Schrödinger equation

$$\left[-\frac{1}{2r^2}\frac{d}{dr}r^2\frac{d}{dr}+\frac{l(l+1)}{2r^2}-\frac{Z}{r}\right]R(r)=ER(r) \tag{162}$$

for an electron moving in the field of a nucleus with charge Z. The quantum-mechanical eigenvalue problem is solved on the interval $[0,\infty]$ by holding Z fixed and varying E such that the boundary conditions

$$\lim_{r\to 0} rR(r)=0,\quad \lim_{r\to\infty} R(r)=0, \tag{163}$$

are satisfied for the infinity of bound states with $E < 0$. There is in addition a continuum of scattering solutions with $E > 0$.

The Sturmian eigenvalue problem differs in that E is held fixed at some negative value $-\epsilon$ with $\epsilon > 0$, and Z is varied so as to satisfy the boundary conditions. Since the eigenvalues to the Coulomb problem are

$$E_n(Z) = -Z^2/2n^2, \tag{164}$$

it is clear that the Sturmian eigenvalue condition $E_n(Z) = -\epsilon$ can be satisfied infinitely many times by progressively increasing both n and Z. As Z increases, one eigenvalue after another from the original problem is pulled down through the value $-\epsilon$. The Sturmian eigenvalues are thus $Z_n = n\sqrt{\epsilon}$ and the corresponding eigenfunctions are

$$\begin{aligned} R_{nl}(r) = {} & \frac{1}{(2l+1)!}\left(\frac{(n+l)!}{(n-l-1)!2n}\right)^{1/2} \\ & \times (2\alpha)^{3/2}(2\alpha r)^l e^{-\alpha r} \\ & \times F(-n+l+1, 2l+2; 2\alpha r), \end{aligned} \tag{165}$$

where $\alpha = \sqrt{2\epsilon}$ and $F(a,b;z)$ is a confluent hypergeometric function. The $R_{nl}(r)$ form a complete set of finite Sturmian polynomials for $n \geq l+1$ that are orthogonal with respect to the potential $1/r$; i.e.

$$\int_0^\infty R_{n'l}(r)\frac{1}{r}R_{nl}(r)r^2dr = \epsilon\delta_{n',n}. \tag{166}$$

The Sturmian functions $R_{nl}(r)$ closely resemble the bound-state Coulomb wave functions. The main distinguishing feature is that α is a constant in the exponential factor instead of decreasing as $1/n$. The first N of them differ only by a transformation of the basis set from the functions used to construct a finite variational representation of $\Psi_{\mathrm{tr}}^{(1)}$ in Sec. 3.4.3. The theory of Sturmian functions therefore provides a rigorous foundation for the choice of basis functions in variational calculations, and their property of completeness ensures convergence to the correct answer as N increases.

5. APPLICATIONS TO ELECTRODYNAMICS

Consider an electromagnetic field propagating through a medium with a charge density $\rho(\mathbf{r})$ moving with velocity $\mathbf{v}(\mathbf{r})$. It follows from Maxwell's equations that the scalar and vector potentials introduced in Sec. 2.4.1 satisfy the equations

$$\nabla^2\mathbf{A} - \frac{1}{c^2}\frac{\partial^2\mathbf{A}}{\partial t^2} = -4\pi\rho\frac{\mathbf{v}}{\mathbf{c}}, \tag{167a}$$

$$\nabla^2\phi - \frac{1}{c^2}\frac{\partial^2\phi}{\partial t^2} = -4\pi\rho, \tag{167b}$$

provided that the Lorentz gauge condition

$$\nabla\cdot\mathbf{A} + \frac{1}{c}\frac{\partial\phi}{\partial t} = 0 \tag{168}$$

is imposed. Many other gauge choices can be made that leave the physical fields **E** and **B** invariant, but this one is simplest for the present discussion.

Unlike problems involving point particles, we are now dealing with fields that vary continuously in space. Equations (167a) and (167b) can be derived from a variational principle if a Lagrangian density $\mathcal{L}$ is first defined such that

$$L = \int \mathcal{L}dxdydz. \tag{169}$$

The action integral in Hamilton's principle then assumes the four-dimensional form

$$J = \int \mathcal{L}dxdydzdt. \tag{170}$$

The condition $\delta J = 0$ is obtained in a manner similar to that leading to Laplace's equation (31). The present case is an application of Eq. (23) with $f = \mathcal{L}$ and four independent variables $t_1 = x$, $t_2 = y$, $t_3 = z$, $t_4 = t$. There will be four equations corresponding to $q_1 = A_1$, $q_2 = A_2$, $q_3 = A_3$, and $q_4 = \phi$. The choice of $\mathcal{L}$ is severely restricted for fields *in vacuo* by the requirement that it be quadratic in the field components (since the field equations are linear), and relativistically invariant. The only quantity satisfying both requirements is a term proportional to $E^2 - B^2$. The inhomogeneous interaction terms on the right-hand sides of Eqs. (167a) are also included with the definition

$$\mathcal{L} = \frac{1}{8\pi}\left[\left(-\nabla\phi - \frac{1}{c}\frac{\partial \mathbf{A}}{\partial t}\right)^2 - (\nabla \times \mathbf{A})^2 - \left(\nabla\cdot\mathbf{A} + \frac{1}{c}\frac{\partial\phi}{\partial t}\right)^2\right] + \rho\left(\mathbf{A}\cdot\frac{\mathbf{v}}{c} - \phi\right), \tag{171}$$

where the first two squared terms correspond to E^2 and $-B^2$, respectively, and the third term generates the Lorentz gauge condition (168). The last term is the interaction term. A straightforward application of Eq. (23) with the terms identified as described following Eq. (170) then yields Eqs. (167a) and (167b).

The Lagrangian density $\mathcal{L}$ gives the equations of motion for the fields in the presence of a predefined matter distribution $\rho(\mathbf{r},t)$. For comparison, the Lagrangian L defined by Eq. (96) gives the converse equations of motion for particles in the presence of predefined fields $\mathbf{A}$ and ϕ. The remarkable point emerging from a comparison of $\mathcal{L}$ and L is that the matter-field interaction term $\rho(\mathbf{A}\cdot\mathbf{v}/c - \phi)$ in $\mathcal{L}$ is very similar in form to the second and third terms in L. In fact, the terms become identical with the choice $\rho(\mathbf{r}) = q\delta(\mathbf{r} - \mathbf{r}')$, corresponding to a point particle of charge q at position $\mathbf{r}'$. This suggests that the two Lagrangians can be combined into a single Lagrangian

$$L_{\text{tot}} = L_0 + \int \mathcal{L}_0 dxdydz + L_{\text{int}}, \tag{172}$$

where L_0 and $\mathcal{L}_0$ are the Lagrangians for free particles and free fields, respectively, and L_{int} is the remaining interaction term common to both L and $\int \mathcal{L}\, d\mathbf{r}$. Hamilton's principle and the Euler–Lagrange equations then give the equations of motion for the combined system of interacting particles and fields.

The above is of course not a proof that the resulting equations of motion provide an exact description of nature. The derivation is based on the supposition that something like Hamilton's principle remains valid for the combined system of interacting particles and fields, and it ignores the quantum nature of both matter and fields. However, Eq. (172) provides a basis for combining a quantized description of matter fields and electromagnetic fields into a single theory called *quantum electrodynamics*, whose predictions have been verified to an extremely high degree of precision (see, e.g., Kinoshita and Yennie, 1990). It can safely be described as the most successful theory ever invented. However, further discussion of this topic would take us beyond the scope of this article (see Further Reading and the article QUANTUM ELECTRODYNAMICS).

6. FEYNMAN'S PATH INTEGRAL

This article would not be complete without at least a passing reference to Feynman's path integral because of the way in which it provides an underlying coherent formalism unifying classical mechanics, quantum mechanics, and optics.

Consider for simplicity the x coordinate of a particle moving in a potential. The aim is to construct a path integral giving the quantum-mechanical transition amplitude for the particle to move from position x_0 at time t_0 to position x_f at time t_f. Let the state vector corresponding to a particle at position x be denoted by $|x\rangle$. In the coordinate representation

$$\langle x'|x\rangle = \delta(x - x'), \tag{173}$$

and by closure,

$$\int |x\rangle\langle x| = \mathbf{1}, \tag{174}$$

where $\mathbf{1}$ is the identity operator. In the momentum representation,

$$\langle p|x\rangle = (2\pi\hbar)^{-1/2}e^{-px/\hbar} = \langle x|p\rangle^*. \tag{175}$$

The remaining ingredient is the time-evolution operator $e^{-iHt/\hbar}$. Its inverse defines states $|x,t\rangle$ in the Heisenberg representation such that

$$|x,t\rangle = e^{iHt/\hbar}|x\rangle. \tag{176}$$

With these preliminaries, an initial expression for the desired transition amplitude is

$$\begin{aligned} K(x_f,t_f;x_0,t_0) &= \langle x_f,t_f|x_0,t_0\rangle \\ &= \langle x_f|\exp[-iH(t_f - t_0)/\hbar]|x_0\rangle. \end{aligned} \tag{177}$$

The key idea in constructing a path integral is to suppose that the system passes through a large number N of intermediate states $|x_k,t_k\rangle$ in making the above transition from $|x_0,t_0\rangle$ to $|x_f,t_f\rangle$ such that $t_{k+1} = t_k + \epsilon$, with $\epsilon = (t_f - t_0)/(N + 1)$. This can be formally achieved by making repeated use of the closure relation (174) to write

$$\begin{aligned} &K(x_f,t_f;x_0,t_0) \\ &\quad = \int dx_1\cdots dx_N\langle x_f,t_f|x_N,t_N\rangle \\ &\quad\quad \times \langle x_N,t_N|x_{N-1},t_{N-1}\rangle\cdots\langle x_1,t_1|x_0,t_0\rangle. \end{aligned} \tag{178}$$

Then for each intermediate step, the inner product is

$$\begin{aligned} &\langle x_k,t_k|x_{k-1},t_{k-1}\rangle \\ &\quad = \langle x_k|\exp[-i(t_k - t_{k-1})H/\hbar]|x_{k-1}\rangle \\ &\quad = \langle x_k|e^{-i\epsilon H/\hbar}|x_{k-1}\rangle. \end{aligned} \tag{179}$$

Using Eq. (175), this can be evaluated in the momentum representation to obtain (with symmetric or Weyl operator ordering)

$$\begin{aligned} &\langle x_k,t_k|x_{k-1},t_{k-1}\rangle \\ &\quad = \int \frac{dp_k}{2\pi\hbar}\exp\{i[p_k\Delta x_k - i\epsilon H(\bar{x}_k,p_k)]/\hbar\}, \end{aligned} \tag{180}$$

where $\Delta x_k = x_k - x_{k-1}$ and $\bar{x}_k = (x_k + x_{k-1})/2$. Substitution of this form into Eq. (178) then yields

$$K(x_f,t_f;x_0,t_0) = \int dx_1\cdots dx_N\frac{dp_1}{2\pi\hbar}\cdots\frac{dp_{N+1}}{2\pi\hbar}e^{iS_N}, \tag{181}$$

where

$$S_N = \frac{\epsilon}{\hbar}\sum_{k=1}^{N+1}\left[\frac{p_k\Delta x_k}{\epsilon} - H(\bar{x}_k,p_k)\right]. \tag{182}$$

Consider now the limit $N \to \infty$, $\epsilon \to 0$. Although each x_k separately ranges over all possible values due to the integrations in Eq. (181) (see Fig. 5), the quantity $\Delta x_k/\epsilon \equiv (x_k - x_{k-1})/\epsilon$ contributes a large and rapidly varying phase that averages to zero unless $x_k \approx x_{k-1}$. We can therefore identify $\Delta x_k/\epsilon$ with $\dot{x}$ in the limit $\epsilon \to 0$ and write

$$\lim_{\epsilon\to 0} S_N = \frac{1}{\hbar}\int_{t_0}^{t_f}[p\dot{x} - H(x,p)]dt = \frac{1}{\hbar}\int_{t_0}^{t_f} L\,dt. \tag{183}$$

This result provides a version of the Feynman path integral with the path integrated over all possibilities (including discontinuous ones) in phase space. However, the result can be carried a step further by performing the momentum integrations in Eq. (181). For example, if H has the form

$$H(x,p) = p^2/2m + V(x), \tag{184}$$

then a typical momentum integral has the Gaussian form

$$\begin{aligned} &\int_{-\infty}^{\infty}\frac{dp_k}{2\pi\hbar}\exp\left\{-\frac{i\epsilon}{\hbar}\left[\frac{p_k^2}{2m} - \frac{p_k\Delta x_k}{\epsilon}\right]\right\} \\ &\quad = \left(\frac{m}{2\pi\hbar i\epsilon}\right)^{1/2}\exp\left[\frac{im\epsilon}{2\hbar}\left(\frac{\Delta x_k}{\epsilon}\right)^2\right]. \end{aligned} \tag{185}$$

Using this in Eq. (181) gives

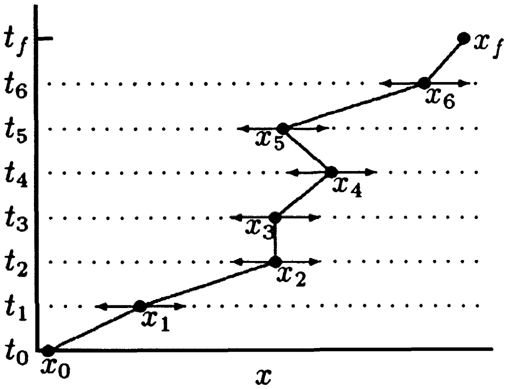

FIG. 5. A possible path for the Feynman integral with six intermediate states. Each of x_1 through x_6 varies independently over all possible values.

$$K(x_f,t_f;x_0,t_0) = \left(\frac{m}{2\pi\hbar i\epsilon}\right)^{(N+1)/2} \int dx_1 \cdots dx_N e^{iS_N}, \tag{186}$$

where now

$$S_N = \frac{\epsilon}{\hbar} \sum_{k=1}^{N+1} \left[\frac{m\Delta x_k}{2\epsilon} - V(\bar{x}_k)\right]. \tag{187}$$

Taking the limit $N \to \infty$, $\epsilon \to 0$ as in Eq. (183) leads to the final result

$$K(x_f,t_f;x_0,t_0) = A \int \mathcal{D}x \exp\left(\frac{i}{\hbar}\int_{t_0}^{t_f} L\,dt\right), \tag{188}$$

where A is a constant independent of the path, and $\mathcal{D}x$ is a shorthand notation for the infinitely nested integrals in Eq. (186). Since this structure is mathematically not well defined, any practical calculation must be done with a finite subdivision and the limit $\epsilon \to 0$ taken at the end.

An explicit calculation of K is possible only for certain special cases such as the free particle or harmonic oscillator. In the free-particle case ($V = 0$), K becomes

$$K(x_f,t_f;x_0,t_0) = \left(\frac{m}{2\pi i\hbar\Delta t}\right)^{1/2} \exp\left[-\frac{m(\Delta x)^2}{2i\hbar\Delta t}\right], \tag{189}$$

where $\Delta t = t_f - t_0$ and $\Delta x = x_f - x_0$. This is the known nonrelativistic kernel or Green's-function propagator for a free particle (see, e.g., Merzbacher, 1970). It controls the time evolution of the wave function according to

$$\Psi(x_f,t_f) = \int_{-\infty}^{\infty} K(x_f,t_f;x,t_0)\Psi(x,t_0)dx. \tag{190}$$

6.1 Relation to Classical Dynamics

As it stands, the Feynman path integral is not strictly a variational principle. However, in the limit $\hbar \to 0$, the exponential term

$$\frac{i}{\hbar}\int_{t_0}^{t_f} L\,dt \tag{191}$$

in general gives a large phase that varies rapidly with slight variations in the path, except very near the particular path where the integral is stationary; i.e., by Hamilton's principle, the classical trajectory. For any other path, the rapid phase variations cause the contributions to the integral to cancel. All possible paths contribute with equal weight, but the phase cancellation singles out the classical path. It similarly singles out the path of a light ray in geometrical optics by Fermat's principle. The connection between variational principles in classical and quantum mechanics is discussed from a different point of view by Gray *et al.* (1996), who show that the reciprocal form of the Maupertuis principle of least action (see Sec. 2.3.1) can be obtained from the classical limit of the Schrödinger variational principle without the use of the Feynman path integral.

On the other hand, the path integral embodies quantum mechanics, and, with the use of the Lagrangian density, electrodynamics. It therefore provides a powerful underlying formalism that unifies all of these diverse branches of physics. It provides a general starting point for the construction of quantum field theories and the description of new phenomena. These topics may be further pursued through some of the books in the reading list.

ACKNOWLEDGMENTS

GLOSSARY

Brachistochrone Problem: The problem of finding the curve giving the shortest travel time for a bead constrained to slide on a wire of arbitrary shape.

Calculus of Variations: A mathematical technique for finding the extrema (maxima, minima, or stationary points) with respect to variations in the function defining the path for an integration.

Canonical Momentum: The momentum p_i conjugate to a generalized coordinate q_i, defined by $p_i = \partial L/\partial \dot{q}_i$, where $\dot{q}_i = dq/dt$ and L is the Lagrangian.

Canonical Transformation: A transformation from one set of generalized coordinates and momenta to another such that the form of Hamilton's equations of motion is preserved.

Conservative System: A mechanical system for which the Hamiltonian is a constant of the motion.

Constraint: An equation that must be satisfied by the solution to a variational problem.

Correlation Energy: The difference between the exact and Hartree–Fock energies of a many-particle quantum-mechanical system.

Electrodynamics: The study of electromagnetic fields and their interactions with charged particles, treated as a single dynamical system.

Euler–Lagrange Equation: A second-order differential equation whose solutions determine the function that makes a path integral an extremum.

Fermat's Principle: A principle from geometrical optics stating that the path of a light beam through a medium of varying index of refraction is such that the travel time is a minimum.

Feynman Path Integral: An integral over all possible paths (both continuous and discontinuous ones) connecting the initial and final states of a system, with each path weighted by a phase factor of the form $\exp(iS/\hbar)$, where S is the path integral over the Lagrangian appearing in Hamilton's principle, and $\hbar$ is Planck's constant.

Functional: A function $F[y(x)]$ that depends on the functional form chosen for $y(x)$. For example, $y(x)$ might determine the path of an integration between fixed end points in a plane.

Generalized Coordinate: Any function of the Cartesian coordinates used to describe the evolution of a mechanical system, or its dynamical analogues involving continuous fields.

Generalized Force: The component of the work done by the actual force acting on a particle due to a change of a generalized coordinate.

Generalized Momentum: The momentum conjugate to a generalized coordinate—see **Canonical Momentum.**

Hamiltonian: A constant of the motion for time-independent systems, which for ordinary conservative systems becomes the sum $T + V$ of the kinetic energy T and the potential energy V.

Hamilton's Characteristic Function: The time-independent part of Hamilton's principal function.

Hamilton's Equations of Motion: A set of $2N$ first-order differential equations linking directly the N generalized coordinates and N generalized momenta through their time derivatives.

Hamilton's Principal Function: The function represented formally by the indefinite integral of the Lagrangian with respect to time. It corresponds to the general solution to the Hamilton–Jacobi equation.

Hamilton's Principle: A variational condition, involving a path integral over the Lagrangian with respect to time, that determines the equations of motion for the system under consideration.

Hartree–Fock Approximation: The best possible approximation to the wave function for a many-particle quantum-mechanical system that can be written in the form of a separable product of independent functions, with a separate function for each particle. The coupled differential equations to be solved follow from the Rayleigh–Schrödinger variational principle.

Holonomic Constraint: An equation of constraint involving the generalized coordinates that can be expressed in integrated form, as opposed to a relation among differential quantities.

Hylleraas–Undheim–MacDonald Theorem: A theorem establishing variational upper bounds for the energies of excited states of a quantum-mechanical system as well as for the ground state.

Lagrange Undetermined Multiplier: A mathematical technique for the introduction of constraints into variational problems.

Lagrange's Equations of Motion: A system of N second-order partial differential equations that determine the equations of motion for the generalized coordinates $q_i = q_i(t)$.

Lagrangian: For ordinary conservative systems, the Lagrangian L is the quantity $T - V$, expressed as a function of the N generalized coordinates q_i and their time derivatives $\dot{q}_i$.

Lagrangian Density: A generalization of the Lagrangian to continuous systems and fields in which the continuous system is first conceived as consisting of discrete elements.

Oscillation Theorem: A theorem applicable to two-point boundary-value problems of the Sturm–Liouville type. The theorem establishes that there is an infinite sequence of eigenvalues whose eigenfunctions have progressively more zeros between the boundary points, and hence progressively more oscillations.

Path Integral: The integral of a function $f(y(x))$ between given points in an xy plane (or its higher-dimensional generalizations) along a path specified by the function $y(x)$.

Perturbation Theory: A technique for the progressive approximation of more difficult problems involving the solution of differential equations (for example), starting from an exactly soluble simpler one. The difference between the two equations is called the perturbation term.

Principle of Least Action: A variational principle in classical dynamics, closely related to Hamilton's principle, which establishes a direct connection with Fermat's principle in geometrical optics.

Pseudostate: A member of a set of states obtained by diagonalization of the Hamiltonian matrix in a discrete variational basis set.

Quantum Electrodynamics: A quantized field theory describing the dynamical interactions of charged particles with electromagnetic fields.

Rayleigh–Ritz Variational Method: A method for the construction of an approximate wave function Ψ by expansion in a finite basis set of functions with expansion coefficients determined by the Rayleigh–Schrödinger variational principle.

Rayleigh–Schrödinger Variational Principle: A principle stating that the ratio $\langle\Psi|H|\Psi\rangle/\langle\Psi|\Psi\rangle$ is an upper bound to the lowest eigenvalue of H for any arbitrary (but normalizable) choice for the wave function Ψ.

Schrödinger Equation: A second-order partial differential wave equation that forms the basis of nonrelativistic quantum mechanics.

Sturmian Basis Set: The set of discrete eigenvalues and corresponding eigenfunctions obtained by solving a two-point eigenvalue problem of the Sturm–Liouville type.

Sturm–Liouville Problem: A class of second-order differential equations of the form $(d/dx)[K(x)dy/dx] - G(x)y = 0$, together with suitable boundary conditions.

Spectral Representation: A representation of the Green's function, or the terms in a perturbation series, in terms of explicit summations over the eigenvalue spectrum of the unperturbed problem.

Temple Bound: A method for constructing variational lower bounds to the energy based on the square of the Hamiltonian.

Variational Bound: An upper or lower bound on the energy or some other quantity obtained by means of a trial solution to the underlying differential equation, typically with parameters in the trial solution that can be adjusted to obtain the best possible solution.

Further Reading

Techniques of the calculus of variations are covered in great detail by Courant and Hilbert (1966), and by Morse, P. M., and Feshbach, H. (1953), *Methods of Theoretical Physics,* New York: McGraw-Hill, along with most other books on the techniques of theoretical physics. The book by Yourgrau, W., and Mandelstam, S. (1968), *Variational Principles in Dynamics and Quantum Theory,* 3rd ed., Philadelphia: Saunders (Dover reprint 1979) provides an interesting and informative historical perspective.

Applications of variational principles to classical mechanics are covered in a very thorough, detailed, and readable manner by Goldstein, H. (1980), *Classical Mechanics,* 2nd ed., Reading, MA: Addison-Wesley. This book also contains a good pedagogical introduction to variational principles for continuous systems and fields. See also Lanczos, C. (1970), *The Variational Principles of Mechanics,* Toronto: University of Toronto Press (Dover reprint 1986).

The development of field theory from variational principles is covered in many recent books such as Ramond, P. (1981), *Field Theory, a Modern Primer,* Menlo Park, CA: Benjamin/Cummings; and Itzykson, C., and Zuber, J.-B. (1980), *Quantum Field Theory,* New York: McGraw-Hill. A good introduction to the Feynman path integral approach is given by Das, A. (1993), *Field Theory, a Path Integral Approach,* Singapore: World Scientific, and more detailed developments are contained in Rivers, R. J. (1987), *Path Integral Methods in Quantum Field Theory,* Cambridge, U.K.: Cambridge Univ. Press. The original development in Feynman, R. P., and Hibbs, A. R. (1965), *Quantum Mechanics and Path Integrals,* New York: McGraw-Hill, remains an authoritative source.

A wide variety of applications of variational principles in quantum-mechanical calculations can be found in numerous articles throughout Drake, G. W. F. (Ed.) (1996), *Atomic, Molecular, and Optical Physics Handbook,* New York: American Institute of Physics. In addition, the Kohn and Schwinger variational methods for scattering problems are covered in most books on scattering theory, such as Taylor, J. R. (1972), *Scattering Theory: The Quantum Theory on Nonrelativistic Collisions,* New York: Wiley. All of the above contain numerous other references to the literature and are intended only as a guide.

INTRODUCTION

The purpose of this article is to survey the history and the state of the art of the relationship between computation and physics. Traditionally, this topic has been divided into three major areas of study: *Physical computation* is the study of the use of physical systems, from simple mechanical devices to modern very large-scale integrated circuitry, to perform computation. *The theory of computation* is the mathematical specification of exactly what we mean by "computation" and of what computers can do and what they cannot do. *Computational physics* is then the study of how to use computers to simulate physical systems.

Recent developments in this field make it clear that all of these areas of study are closely related and that their relationship will only strengthen in the coming decades. The smallest electronic circuitry is already at the point where quantum-mechanical effects play a significant role. The consequences of the fact that certain physical systems are capable of computation have had a subtle but profound impact on physics, from the study of dynamical systems to the second law of thermodynamics. Finally, the recent realization that quantum computers may be able to do things that classical computers cannot (or at least do them much faster) reminds us that paradigms of computing are not unique mathematical abstractions but are rather dependent upon an underlying physical model. The observation that *computation is physical* is very analogous to—and every bit as profound as—the 19th century realization that

Euclidean geometry is not a unique mathematical abstraction and the early 20th century addendum that the geometry of our physical world is in fact non-Euclidean.

This is a vast field, and so this article is necessarily in the nature of a very cursory survey. The object has been to give the reader many different and varied perspectives on how physicists use and think about computers, rather than a complete account of any one of them. Nevertheless, it is hoped that it will give the interested reader some appreciation of how and why people use physical systems to compute, of the nature of the computational process, of the implications of the theory of computation to physics, of the use of computation to study physics, and of the future of this entire enterprise.

1. COMPUTATION AND ITS RELATIONSHIP TO PHYSICS

1.1 The History of Computation

Since the first shepherds tied knots in strings to keep track of their flocks, mankind has employed physical systems to tabulate numerical data and perform computations. The reason then was the same as it is now: Physical devices can be used quite effectively to reduce the tedium of storing, manipulating, and retrieving large amounts of data. Other ancient calculational procedures may have involved the use of pebbles (indeed, the word "calculate" is derived from the Latin word for pebble), or marks on papyrus or clay to keep track of data. It is likely that early counters recognized that they could deal with data far more efficiently by employing representations for groups of objects, and then groups of groups of objects, etc. This observation gave rise to the *digital* representation of numbers (Schwartzman, 1996) and to computing machinery that stored and manipulated numeric data in this format. The *abacus* was developed in the Middle East at least 2500 years ago and uses wooden beads on a wire to add and subtract numbers in a digital representation.

Mechanical aids for multiplication and division are a much more recent development. In early 17th century Scotland, John Napier carved logarithmically spaced divisions on ivory sticks called *Napier's bones.* These could be used for multiplication and division and soon gave rise to the *slide rule,* which had both linearly and logarithmically spaced divisions and could be used to add, subtract, multiply, and divide. Slide rules remained in widespread use until the 1970s.

Meanwhile, the automation of tedious and difficult mechanical tasks in the Industrial Revolution gave rise to the idea that tedious and difficult calculations could likewise be performed by "computational engines." Thus, in Napoleonic France, Joseph Marie Jacquard developed a loom with an automatic card reader, so that information about desired patterns of colors on fabric could be easily encoded on punched cards. In Cambridge, England, in the mid-1800s, the mathematician Charles Babbage worked on the construction of a *difference engine,* and later an *analytical engine;* these would accept input from Jacquard-style punched cards and, by means of a complicated system of gears and cogs, compute and automatically print tables of numerical data. Though Babbage never finished these projects, he can be credited with designing the first general-purpose computer with data storage and printed output. Moreover, his collaboration with the mathematician Ada Augusta Lovelace gave rise to the first *computer programs,* including the *loop* construct, *subprograms,* and *conditional jumping.* By 1890, Herman Hollerith had convinced the United States Census Bureau to store information on punched cards, so that they could be processed by an electrical device.

The 20th century has seen spectacular advances—both quantitative and qualitative—in the field of computing. Between 1937 and 1944, Howard Aiken of Harvard University built a gigantic electrical computer called the Mark I, which could read and write punched cards and manipulate data by means of electrical switches and relays. It could add and subtract numbers in about 0.3 s, multiply them in less than 6 s, and divide them in less than 16 s. Meanwhile, at the University of Pennsylvania, Dr. John Mauchly and Dr. J. Presper Eckert developed the first electronic computer, called ENIAC, which used 18 800 vacuum tubes to perform computations. This represented a great advance in speed, as it could perform hundreds of multiplications and/or additions in 1 s; its memory, however, was limited to 20 ten-digit numbers. By 1949, the EDSAC (Electronic Delay Storage Automatic Calculator), built at Cambridge University in England, could perform both addition and multiplication in times on the order of a millisecond.

Thus was begun the exponential growth of computational speed and efficiency that, fueled by the microelectronics revolution of the late 20th century, continues to the present day. Currently, several figures of merit of modern computers seem to maintain an exponential rate of growth: At the time of this writing, modern processors can add and/or multiply hundreds of millions of *floating-point numbers* per second. (This figure of merit is sometimes called "FLOPS.") Clock rates are on the order of a nanosecond, and processor speed seems to double every 1.5 years or so. Figure 1 shows the amount of physical area required to store one *bit* of information as a function of time, beginning with relays as they were used in the Mark I and ending with modern integrated circuitry; the exponential rate of decrease of this quantity is apparent.

This stunning increase in computing capability has already had a profound impact on physics. First, and most clearly, it has elevated computation to a status on a par with that of theory and experimentation as a means of acquiring scientific knowledge. For example, though analytic methods were often able to discern the overall behavior of the *linear* equations of classical mathematical physics, such as the Maxwell equations, computation has made it possible to solve such equations in a much wider variety of geometries, with inhomogeneities, and irregular boundary and/or initial conditions. Moreover, certain *nonlinear* equations of mathematical physics, such as the Navier–Stokes equations of viscous fluid dynamics, have been known for more than a century but have only a very restricted set of known, nontrivial analytic solutions; the overall behavior of these equations is safely said to be unknown, as even the most elementary sta-

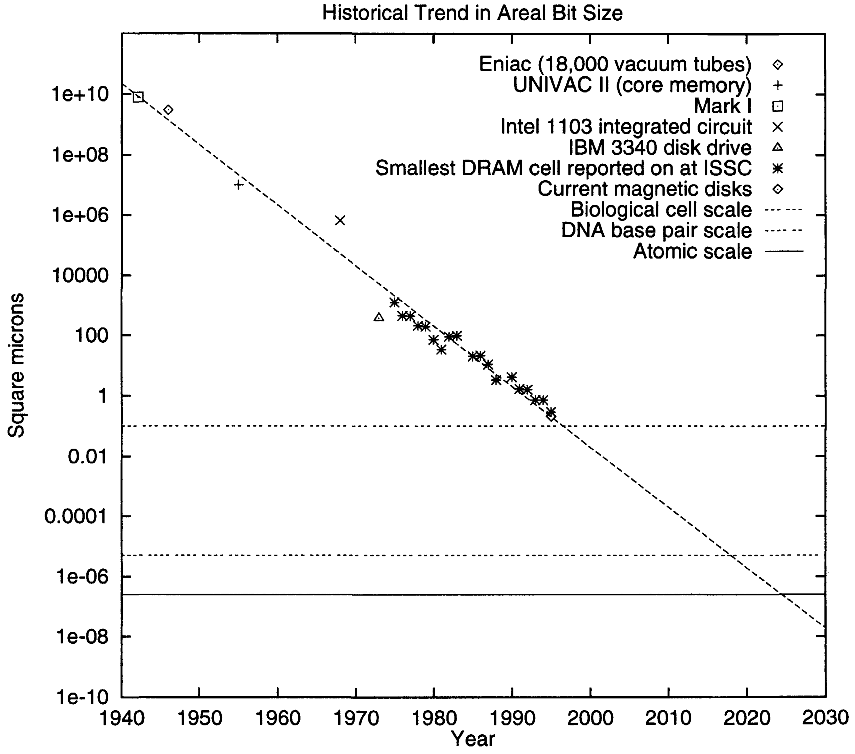

FIG. 1. Areal size required to store 1 bit of information, as a function of time (courtesy of Norman Margolus, MIT Laboratory for Computer Science).

tistical properties of high–Reynolds-number Navier–Stokes flow are analytically intractable. Computation has thus made it possible to examine the behavior of a much wider class of solutions to these equations and compare these to experiment, thereby enhancing our ability to test the laws of physics. Much of this article is devoted to outlining how computers are used for this purpose.

1.2 The Theory of Computation

Computers can simulate physical systems, but, at the same time, they are themselves physical systems. The computer simulation of physics can thus be viewed as the representation of one physical system by another. This observation has profound and surprising consequences. To begin to appreciate some of these, let us return to Fig. 1. In the physical world, no exponential rate of increase can go on forever, and the figure points to serious problems that will be faced by the computer industry in the coming decades. At the time of this writing, the physical area required to store 1 bit of information is seen to be on the order of the size of a biological cell. If the exponential rate of decrease were to continue unchecked, this size would be down to atomic scales before the year 2020. Such considerations have fueled new thinking about the relationship of computation to physics, and of possible physical limits to computation. The results of such thinking may ultimately be viewed as the second great contribution of the 20th century to the science of computation.

Though the underpinnings of the theory of computation date back to the 19th century, it was the mathematicians Alan Turing and John von Neumann who, in the 1930s and 1940s, developed the modern theory of computation that guided the first 50 years of electronic computer evolution. Turing provided a mathematical model of the computational process, known as a *Turing machine.* Conceptually, this can be imagined as a linear strip of paper tape, infinite in both directions and imprinted with symbols chosen from some finite set, passing through a machine with some finite number of internal states. At each time step, the machine can read a symbol from the paper tape and, on the basis of that symbol and the internal state of the machine at that moment, take one or more of four actions: (1) change the internal state, (2) print something on the tape, (3) advance the tape in one direction or the other, and (4) halt the machine. Note that the Turing machine can be thought of as a dynamical system with Markovian evolution. In spite of its conceptual simplicity, Turing showed that his "machine" was capable of performing all of the arithmetic operations of number theory, such as addition, subtraction, multiplication, division, and exponentiation, by initializing the paper tape with the proper (finite) "program." It is also possible to make the Turing machine perform more complex algorithmic procedures, such as looping and conditionally jumping.

More interestingly, it is even possible to make any Turing machine simulate any other Turing machine. That is, it is possible to write a program for a Turing machine *A* which accepts as input *both* the rules and input of another Turing machine *B*, and produces the same output that *B* would have produced. Because the Turing machine has this ability, we say that it is capable of *universal computation.* It therefore seemed eminently reasonable to regard the universal Turing machine as a complete mathematical paradigm of exactly what a computer is and does.

To be sure, the Turing machine is not the only possible computational paradigm that can be demonstrated capable of universal computation. One might imagine other schemes, with more tapes, more symbols, more internal state, etc. A particularly interesting computational paradigm, advanced by von Neumann just after World War II, is called a *cellular automaton.* This consists of an infinite Cartesian grid with some (usually small) number of states at each site, which are updated according to a rule that depends on the states of neighboring sites. As demonstrated later, this paradigm is also computationally universal, in that it is capable of simulating a Turing machine; thus, we say that it is *Turing equivalent.* Of course, this raises the question of whether some other digital computational paradigm might be found to be *super-Turing*—that is, capable of performing a computation that a Turing machine cannot perform. [Note that *analog computers,* such as analog recurrent neural nets, are often said to be super-Turing; for the moment, however, we limit our discussion to digital computing paradigms.] Turing's name, along with that of the American logician Alonzo Church, is attached to the hypothesis that the answer to this question is "no." The *Church–Turing hypothesis* states that any computer capable of universal computation may simulate any other computer capable of universal computation. That is, outside of quantitative considerations such as memory and speed, no universal computer is more powerful than another. There is no problem that one can do that another cannot also do, given sufficient time and memory. Thus, computer manufacturers may argue about whose product is faster and larger, but none can claim to perform any computation that their competitors cannot.

In addition to establishing the concept of universal computers and outlining what they could do, Turing addressed the even more interesting question of what they could *not* do. Strongly influenced by the contemporary work of Kurt Gödel who showed that there existed truths of number theory that could not be proven from its axioms, Turing recognized the close analogy between computation and the axiomatic systems of mathematics and demonstrated that there were some functions that could never be calculated by a universal computer. To see this, imagine that we would like to construct a Turing machine to accept a number x as input, compute a function $f(x)$, write it as output, and then come to a halt; such a procedure is called an *algorithm.* Since such programs must consist of a finite number of symbols chosen from a finite set, they can be enumerated; that is, they have the cardinality of the integers. It is therefore possible to create an (infinite) "alphabetized" list of *all* such algorithms. (We agree to discard from this list algorithms that are syntactically incorrect.) The question then reduces to whether or not every function that can be specified has an algorithm appearing on the list. Let us denote by $f_i(x)$ the result of applying the ith algorithm on the list to the numerical input value x; that is, f_i is the function corresponding to the ith algorithm on the list. From this, we can construct the function $g(x) \equiv f_x(x) + 1$. We can now prove that the function $g(x)$ cannot be on the list. If it were, there would be some j for which $f_j(x) = g(x)$ for all x; but this cannot be the case because when $x = j$ we would have $f_j(j) = f_j(j) + 1$, a contradiction. Thus, we have found a function that cannot be computed by any algorithm. This result is all the more odd because it *seems* straightforward to describe an algorithm for computing the function $g(x)$: Simply write a program that, given an input value x, causes the Turing machine to enumerate legal algorithms until it finds the xth such algorithm, apply this algorithm to the number x, output the result, and halt. Turing noted that the problem with this putative procedure is that it assumes that there is an algorithm for determining whether or not a given string of symbols is indeed a legitimate algorithm—that is, one that eventually produces output and halts. The conclusion is that no such "algorithm-verifying algorithm" can possibly exist.

The similarity of this line of reasoning to Gödel's theorem for axiomatic systems in mathematics should be evident. To see this, note that we can reduce any question about number theory to the computation of a mathematical function. For example, by knowing the value of

$$\min_{\substack{n>2,\\ i,j,k>0,}} (i^n + j^n - k^n)^2, \tag{1}$$

we can discern the truth or falsity of Fermat's last theorem (FLT). Why is it not always possible to specify an algorithm for the computation of such a function? After all, to pursue the foregoing example, it seems quite straightforward to write a computer program that will perform an open-ended search for a counterexample of Fermat's last theorem. One could simply loop over all possible i, j, k, and $n > 2$, evaluating expression (1), and stopping if it were ever found to be zero. Clearly, we can restrict the search to $i \geq j$ without loss of generality, so j can be taken from the finite set $\{1, \ldots, i\}$; likewise, it is easy to see that $k \in \{i + 1, \ldots, 2i\}$. This leaves infinite loops over two integer variables, i and n; these can be done by conducting a single open-ended loop over their sum $m \equiv i + n \geq 4$, restricting i to the finite set $\{1, \ldots, m - 3\}$, and taking $n = m - i$. (Of course, much better bounds are available, but these serve to illustrate the idea.) The problem with this grand scheme is that there is no *a priori* way of knowing if this program will ever halt (unless, of course, FLT is proven, as may be the case at the time of this writing). If it does not halt, then it is not a valid algorithm for computing the function in Eq. (1), since it does not provide a result in a finite number of steps. Thus, our result on uncomputable functions is related to the impossibility of solving what is often called the *halting problem*—the problem of making an *a priori* determination of whether or not a given computer program will ever halt.

The impossibility of solving the halting problem has profound implications for the simulation of dynamical systems on a computer and may indeed have profound implications for physics itself. To see this, let us return to von Neumann's idea of computing by means of *cellular automata.* One very heavily studied cellular automaton, developed by the mathematician John Horton Conway, is called the *Game of Life.* It is a dynamical system on a two-dimensional Cartesian grid, with only 1 bit of information (0 or 1) at every site, that is synchronously updated in discrete time steps according to rules that are easy to describe: Consider a site whose bit is b, and let the sum of the bits of that site's eight neighbors (at distances 1 and $\sqrt{2}$) be called S. The site then "updates" its bit to the value b', where

$$b' = \begin{cases} 1 & \text{if } (b,S) \in \{(1,2),(0,3),(1,3)\}, \\ 0 & \text{otherwise.} \end{cases} \tag{2}$$

It is to be emphasized that this rule is to be applied *simultaneously* to all of the sites on the lattice.

If this rule is applied to a lattice with randomized initial conditions, a wide variety of interesting emergent behavior is observed. Figure 2(a) shows configurations that are locally stable; that is, they are invariant under the action of the rule. Figure 2(b) shows configurations that oscillate in time, returning to their initial configurations after a definite period of time. In the language of dynamical systems theory, we might say that these kinds of patterns are *fixed points* and *limit cycles,* respectively. It is also possible to find patterns that are reminiscent of solitons or nonlinear waves; Fig. 2(c) shows examples of patterns that return to their original shape—but translated in space—after some finite period. The first of these translating patterns is often called a "glider." Figure 2(d) then shows a "glider gun"—that is, a pattern that oscillates (with period 24), emitting one glider at every oscillation.

Gliders are somewhat reminiscent of "bits" of information traveling along a wire in a computer. In this analogy, the glider gun plays the role of a "clock," emitting these bits at a set rate. It is also possible to show by construction that one can create the analog of *logic gates* for gliders—for example, a "NOT" gate, which emits gliders at the clock frequency unless another glider is inci-

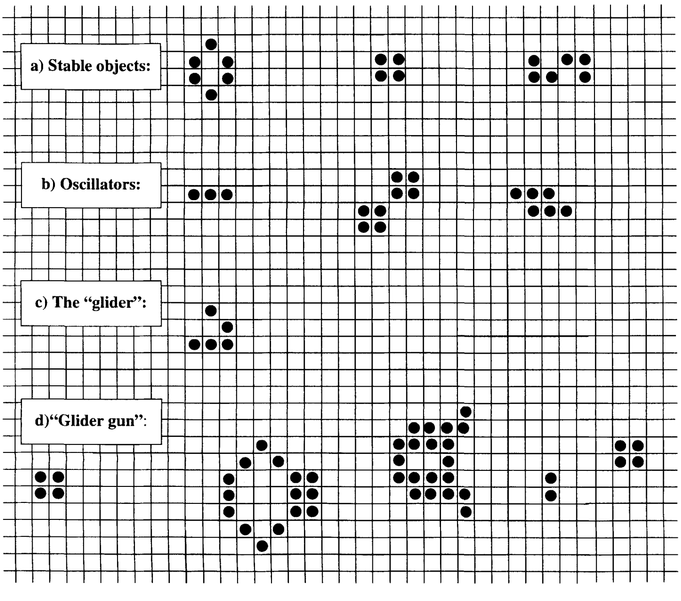

FIG. 2. Coherent structures of the Game of Life: (a) stable patterns, (b) oscillatory patterns, (c) translating patterns, and (d) the "glider gun."

dent, and an "AND" gate, which emits one glider if and only if gliders are present on both of two incoming channels. Since these logic gates are the basic building blocks of a digital computer, one could, in principle, use the patterns formed by the Game of Life to set up a universal computer on the lattice. This exercise may seem academic—indeed, almost frivolous—but it contains a very important lesson: It shows that the Game of Life is *Turing equivalent*—that is, its dynamics are capable of universal computation. It is highly significant that a simple dynamical system, defined by nearest-neighbor rules on a lattice, can function as a universal computer. Among other things, it means that it is *provably impossible* to know the asymptotic behavior of the Game of Life for every initial condition, since this would be tantamount to solving the halting problem. Note that there are many physical models, such as the heat equation, the asymptotic behavior of whose solutions can be determined by elementary methods of analysis. We have just demonstrated that the Game of Life is one dynamical system that *cannot* possibly admit such a simple, general asymptotic treatment.

Now there are many other dynamical systems in physics—such as the driven pendulum—that have thus far resisted a general asymptotic treatment. Could this be because they somehow set up structures that are capable of computation? A partial answer to this question is provided by the work of Moore (1990, 1991), who showed that bundles of trajectories in simple classical dynamical systems, as can be identified on a Poincaré surface of section ("puncture plot" in phase space), can shuffle about in successive time steps in a manner that is Turing equivalent. Moore demonstrated this by construction for a system consisting of an ideal classical particle in three dimensions, with a finite number of planar and parabolic reflectors. The asymptotic state of such a system is therefore unknowable for general initial conditions. Note that this *uncomputability* is a much stronger result than the demonstration of "chaos" for such a system. Certain dynamical systems, such as the logistic map with maximum multiplicative parameter [$x_{n+1} = 4x_n(1 - x_n)$, where $x_n \in [0,1]$], are certainly chaotic, in the sense that they have positive Liapunov exponents, but at the same time admit a simple asymptotic treatment. [The substitution $x_n = \sin(2\pi\theta_n)$ reduces this map to $\theta_{n+1} = (2\theta_n)_{\text{mod}1}$, which has the effect of chopping off the leading digit of the binary representation of the number at each time step. Thus, given the initial condition to infinite precision, one can immediately specify the result after iteration n.] Much less can be said about the time asymptotics of an *uncomputable* dynamical system.

1.3 Physical Computation

These mathematical limitations to computation are undeniably fascinating, but one might well wonder if they are simply academic exercises. After all, the proven existence of mathematical functions that cannot be described algorithmically certainly did not stop people from making good use of computers in the simulation of physical systems. At the same time, however, it should be kept in mind that real-world computers *are* themselves physical systems. Thus, as the power of real computers increased dramatically in the latter half of the 20th century, it was natural for people to begin to wonder if there were any *physical* limitation to their size and speed, in addition to the mathematical limitations studied by Turing. As we shall see, this issue remains an important topic of study to this day, and in addressing it we shall find that many of the issues raised by Turing reappear in a slightly different form.

Turing machines are mathematical idealizations of computers. How fast and how small may we make a computer in the real world? In the drive to make computers more powerful, one of the fundamental engineering constraints is due to the heat released by its components. As these components are packed ever more tightly together in three dimensions, the dissipation of this heat becomes an important problem. This leads to the question: Must computation always release heat? As late as the 1960s, it was widely believed that the answer to this question must be "yes." The reasoning was predicated on an ingenious argument due to Landauer (1961) that erasure of information in a computer—a process that goes on all the time in modern computers—must be accompanied by the dissipation of heat. This argument went as follows: Consider a microscopically reversible physical system that is capable of representing N macroscopically observable bits of information. Since each bit can take on one of two values, the system of N bits can be in any one of 2^N macroscopic states. Corresponding to each of these macroscopic states, let us say that there are Ω_0 microscopic states of the underlying physical structure, so that the full state-space volume can be written as $\Omega = 2^N\Omega_0$. Note that the volume associated with the *computational degrees of freedom* is 2^N, while that associated with the *noncomputational degrees of freedom* is Ω_0, and that these volumes are multiplicative since they correspond to independently specifiable degrees of freedom. Since the entropy of a system is Boltzmann's constant times the natural logarithm of its state-space volume, the entropy associated with our physical system is then $S = k_B \ln \Omega = k_B \ln(2^N\Omega_0) = k_B \ln \Omega_0 + Nk_B \ln 2$. Since we have assumed that the underlying physical system is reversible, this entropy must be constant. Now suppose that our physical system "erases" a bit of information at the macroscopic level; that is, suppose that it forces one of its bits to take on a specific value, regardless of its previous value. This constraint has the effect of contracting the state-space volume of the computational degrees of freedom by a factor of 2, since it can now be in one of only 2^{N-1} states; equivalently, we see that this has the effect of decreasing the entropy of the computational degrees of freedom by $\Delta S = k_B \ln 2$. Since the entropy of the system as a whole must be constant, we see that this lost computational entropy must be dumped into the noncomputational degrees of freedom. If the underlying physical structure corresponding to the noncomputational degrees of freedom is maintained at a temperature T, the increase in its entropy by ΔS corresponds to the appearance of an amount $T\Delta S = k_BT \ln 2$ of dissipated heat energy. Moreover, the full force of the second law of thermodynamics precludes the possibility of this heat energy ever being recovered as useful macroscopic information.

Landauer's argument indicates a close connection between the process of computation and thermodynamics. In particular, it indicates that any computer that erases bits of information must necessarily release heat. The trouble is that all of the familiar logic gates from which modern computers are built do this all the time. AND and OR gates, for example, are irreversible because their input cannot be deduced from their output. This is illustrated in Fig. 3(a). Since 1 bit of information is lost each time either of these gates is used, heat energy $T\Delta S = k_BT \ln 2$ must be dissipated. While this amount is many orders of magnitude smaller than the amount of heat released by the operation of a real computer gate, the result was considered interesting since it seemed to indicate that computation was fundamentally and necessarily irreversible.

In passing we note that this observation was used by Bennett (1987) and others to explain finally and convincingly the "Maxwell's demon" paradox that had plagued kinetic theory for a century. The issue has to do with the apparent ability of a "demon," poised at a small opening in a partition between chambers of high- and low-pressure gas, to violate the second law of thermodynamics by allowing molecules from the low-pressure side to enter the high-pressure side, but not vice versa. Such a demon effectively exploits the thermal energy of the molecules to create a pressure difference that could

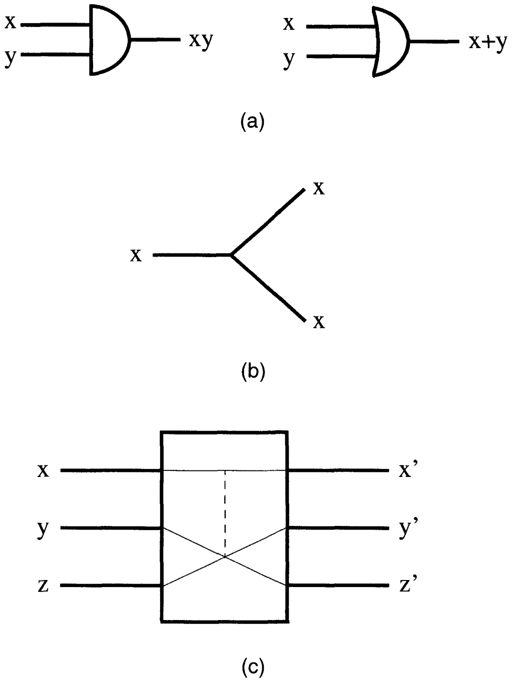

FIG. 3. Irreversible and reversible logic gates: (a) AND and OR gates (arithmetic shown is understood to be Boolean), (b) FANOUT gate, and (c) reversible, universal gate.

then be employed to do useful work—an egregious violation of the second law. A number of explanations of the demon have been put forth over the past century, but the issue was finally resolved only in the 1980s. Bennett observed that such a demon must perform what is essentially a computation in order to decide whether or not to allow a molecule through the partition. Indeed, Bennett was able to demonstrate this most clearly using a variant of the Maxwell demon argument due to Szilard. Requiring that the demon be able to perform computation is not, in and of itself, a fatal flaw, but the fact that the demon must *erase* his computational memory after each molecule is processed, in preparation for the next one, is the real explanation of why he is unable to violate the second law.

Returning to the lost information and concomitant heat generation inherent in computation, we note that one might try to retain the lost bits of information by considering two-input/two-output gates. Even then, however, one must restrict one's attention to those gates for which the input can be reconstructed from the output. It is not difficult to see that there are $2^8 = 256$ gates that accept 2 bits of input and yield 2 bits of output. Of these, $4! = 24$ are reversible, in that the 2-bit output states are a permutation of the 2-bit input states. Unfortunately, these gates are insufficient to construct a universal computer. It should be noted that, in addition to the usual gates necessary for this purpose (e.g., AND and NOT), it is necessary to worry about such things as the "FANOUT" function that is implicit every time one wire splits into two within a circuit, as in Fig. 3(b); though FANOUT is reversible given a legal output state, not all possible output states are legal, and the operation does seem to change the number of bits and hence the entropy of the computational degrees of freedom.

The observation that 2-bit reversible gates are insufficient to construct a universal computer, and the realization of the problematic nature of operations such as FANOUT long taken for granted by computer designers, tended to support the argument that universal computation is necessarily irreversible. In the 1970s, however, it was realized (Bennett, 1973; Fredkin and Toffoli, 1982) that this argument is specious. Figure 3(c) shows a three-input/three-output gate, known as the *Fredkin gate*, that is fully reversible and quite sufficient to construct a universal computer. It has three inputs (b_1, b_2, and b_3) and three outputs (b'_1, b'_2, and b'_3). If the first input is zero, then the other two outputs are exchanged; otherwise the outputs are the same as the inputs. The truth table for this gate is thus

b_1	b_2	b_3	b'_1	b'_2	b'_3
0	0	0	0	0	0
0	0	1	0	1	0
0	1	0	0	0	1
0	1	1	0	1	1
1	0	0	1	0	0
1	0	1	1	0	1
1	1	0	1	1	0
1	1	1	1	1	1

Note that if $b_3 = 0$, then $b'_2 = b_1 \times b_2$. (Here we identify 0 with *false* and 1 with *true*, as is customary.) This means that the gate captures all the functionality of the AND gate. If we fix $b_2 = 1$ and $b_3 = 0$, then $b'_3 = \sim b_1$ giving us the functionality of the NOT gate, and $b'_2 = b_1$ giving us FANOUT. These functions are sufficient to create a universal computer.

One can therefore imagine a universal computer that accepts input bits on the left, passes them through circuitry consisting entirely of Fredkin gates, and yields output on the right. There is, however, one remaining problem: In addition to the desired output, numerous "garbage" bits will have accumulated in the course of the calculation. For example, as we have seen, it is possible to arrange for the Fredkin gate to output the AND of two of its input bits, but it also produces other output bits when it does so. That other output, inessential for our calculation, cannot be simply thrown away because that would generate heat and violate reversibility. It seems possible that we have just postponed the problem of heat generation to the stage at which we read the computer's output and reset it for a new computation. As soon as we read the portion of the output that we want and unceremoniously erase the rest of it, heat will be generated in proportion to the number of garbage bits destroyed. It is therefore necessary to bound the number of garbage bits created.

Thanks to an ingenious argument of Bennett (Bennett, 1982), this is easy to do and necessitates only a factor of 2 or so more circuitry. Suppose that we set up a reversible circuit of Fredkin gates as above, with input on the left and both output and garbage bits on the right. Since the Fredkin gate is its own inverse, it is possible to recover the input from the output using a mirror image of the very same reversible circuit. Adding this on the right, we recover the original input bits that can then be channeled back to the left-hand side of the circuit and reused. At this point the circuit is fully reversible, and all of the garbage bits have been recycled. Recall, however, that the desired output resides somewhere in the middle of all this circuitry. By extracting it with FANOUT operations, we arrive at a perfectly reversible circuit that produces no garbage bits.

This discovery was quickly followed by that of a reversible cellular automaton that is capable of universal computation (Margolus, 1984), and by Fredkin's observation (Benioff, 1982) that a system of ideal billiard balls and reflectors could perform reversible logic. Figure 4(a) shows the paths taken by two billiard balls with perpendicular trajectories in the event that both balls are present and that either ball is absent. If the presence of a ball is regarded as a "bit" of information, examination of the final trajectories allows us to perform the AND operation on these bits. Given a steady supply of balls, emerging at the clock rate, the NOT operation is also easy to arrange: Simply collide the input balls with the stream balls in such a way that the former knock the latter (and themselves) out of the stream. The stream balls that do get through will then be the NOT of the incoming signal. Once again, AND and NOT are sufficient to attain universal computation.

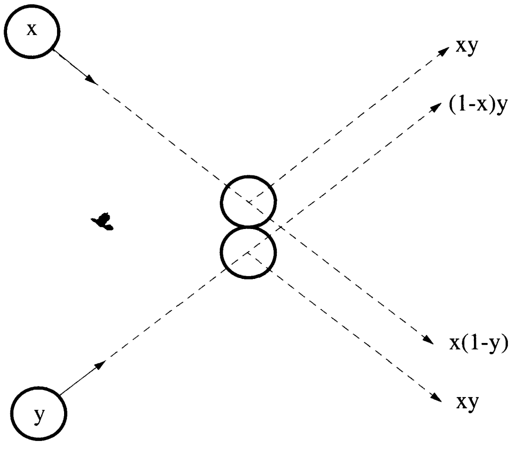

FIG. 4. Billiard-ball model of computation. The presence or absence of the two balls encodes the bits *x* and *y*, respectively. Note that the outgoing, post-collision trajectories yield the logical functions *xy*, *x*(1 − *y*), and (1 − *x*)*y* (arithmetic is understood to be Boolean).

One critique of billiard-ball computational paradigms is that they are inordinately error prone. The slightest deviation of any of the balls from their intended trajectories will tend to propagate and amplify in time according to the Liapunov exponent of the dynamics. It therefore seems that reversible computation could not be achieved experimentally. It turns out to be possible, however, to implement a simple and effective *error correction* scheme. Indeed, note that the NOT gate described above does precisely this. The output ball of the NOT gate is likely to be much more accurately aimed than the input, since the output balls have just emerged from their source. Thus, by passing a signal through two NOT gates, we can remove any errors that may have accumulated in their trajectories.

Thus, bits of information do not have to be destroyed in order to perform universal computation, and heat dissipation is not an unavoidable side effect of computation. Moreover, reversible computation can be achieved reliably, with error correction. The notion that computation can be reversible and robust is central to the idea of quantum computation, which is discussed later on in this article.

2. LANGUAGES FOR SCIENTIFIC COMPUTATION

We now descend abruptly from the lofty heights of ideal computational models to the ignominious realities of performing useful computation on contemporary computers. As noted above, the realization that computers could not compute everything did not stop people from trying to compute as many things as possible. In order for computers to become a practical tool for scientific computation, however, it was necessary that they become easy to program. At the very lowest level, computers accept instructions in *machine language,* which is really nothing more than a sequence of elemental instructions in the binary format expected by the processor. In fact, the very first computer programs input this binary data by setting hardware switches on the computer's front panel. This approach is obviously inappropriate for all but the smallest sets of instructions.

At the next level, *assembly language* uses mnemonic abbreviations for certain of these elemental operations and groups thereof. In the late 1950s, researchers at IBM developed the first *high-level language,* designed to simplify the programming of a computer for solving scientific problems. A high-level language typically employs a program called a *compiler* (or perhaps an *interpreter*) to translate instructions written according to a carefully defined language syntax into assembly language. This first high-level language was called *Fortran* (an abbreviation of "FORmula TRANslation"), and it quickly came to be the predominant high-level language for scientific computation—a status that it retains to this day.

Since its invention, Fortran has had three principal stages of evolution: In the early 1960s many divergent varieties of the language existed. To combat this tendency, computer users and vendors cooperated on the development and publication of a language standard. The result, called Fortran 66, was the first standardized computer language (in that programs written in this language could be compiled and executed on different computer platforms), and this stability contributed to its popularity among scientific programmers. Though powerful, this language was very undisciplined. It allowed for control to jump about from one part of the code to another in arbitrary ways, by means of a GOTO statement, leading some programmers to refer to it facetiously as "spaghetti code." Unless great care was taken in its use, it could be very difficult to read and understand an existing Fortran 66 code. For this reason, programs of more than 10 000 lines of instructions were very difficult to write, debug, maintain, and modify.

The desire to impose some structure on the language led to the next major leap in computer programming, called *structured programming,* in the late 1960s and early 1970s. The idea was that control in a computer code should have a definite and more or less unidirectional flow to it; the GOTO statement should be avoided. Frequently reused groups of instructions should be broken up into succinct and easily invoked *subroutines* or *function subprograms.* These subprograms should have the ability to declare and use *local variables,* and they should be capable of calling themselves in a recursive fashion. A number of new languages, including Pascal, Algol, PL1, and C, were invented to support this new paradigm. Eventually, however, most of these ideas found their way into the next major Fortran language standard, called *Fortran 77.* This was adopted by the International Standards Organization in 1980, and remains the dominant dialect of the language in use to this day. Using Fortran 77 or C, programmers routinely write and maintain computer codes with tens of thousands of lines. As larger and more complex software was developed, however, it soon became clear that codes larger than about 100 000 lines would be very difficult to develop and maintain.

At the time of this writing, the newest and most fashionable structuring paradigm for computer software is called *object-oriented programming.* It is defined by the following principal characteristics:

- **Encapsulation, persistency of state, and data hiding:** The notion of subprograms should be strengthened to allow the creation of "black box" software with local data that is completely protected from outside interference, and may be persistent in that it does not disappear when the subprogram completes execution. This allows for the development and maintainance of software libraries in complete isolation from the application programs that utilize them. This should be contrasted with more conventional software libraries, which often require the internal state to be passed back and forth to the calling routine.
- **Data abstraction:** In structured programming languages, users could specify if a given variable represented, e.g., a logical value, an integer, a real number, or a complex number. In object-oriented programming, the user should have the ability to create his/her own data structures and representations out of more fundamental

ones and to declare variables in them. For example, one might imagine creating a data structure for quaternions, representing them by four real numbers; a user could then declare variables of quaternionic type.

- **Polymorphism:** Since object-oriented computer languages allow for many new and varied data types, one might well worry about the management of the plethora of new operations necessary to manipulate them. Of course, mathematicians use the same symbol "+" to denote addition of integers, reals, complex numbers, and quaternions. Likewise, object-oriented languages allow for *operator overloading* so that the same operation may be applied to variables of different type. The compiler is able to determine the type of the arguments and arrange for the appropriate operations to be performed when the code is executed.
- **Inheritance and extensibility:** Object-oriented programs should be modular and should allow for data to acquire or inherit certain properties of other data. For example, if a program has data structures for cats, mammals, and animals, it ought to be possible for objects of type cat to inherit all properties of objects of type mammal, and for these to in turn inherit all properties of objects of type animal. This greatly facilitates hierarchical code development.

At the time of this writing, the most popular object-oriented computer languages are C++ (an extension of the C language) and Java. Nevertheless, Fortran has incorporated many of these ideas in its latest standard, called *Fortran 90*. Other languages developed for scientific programming, such as Ada, allow for some, but not all, object-oriented features. Most of the software examples used in the remainder of this article will be presented in Fortran 90, using an object-oriented style.

3. DATA STRUCTURES AND ALGORITHMS

3.1 Algorithms and Computational Complexity

The concept of a computer *algorithm* was described earlier, in reference to Turing machines. While modern algorithm development has become a science unto itself, the basic idea remains much the same: An algorithm is a sequence of basic instructions, or "recipe," for solving a given problem on a computer. Often the same problem will allow for several different algorithms, and it becomes important to be able to compare them to see which is better. One way that this comparison can be achieved is to compare the algorithms' *computational complexity*. This is simply a count of the number of elemental operations required to solve the problem; it can be more mathematically defined as the number of steps required for a standardized Turing machine to implement the algorithm.

Consider the procedure known as *Gaussian elimination* for the solution for x of

$$Ax = b, \tag{3}$$

where A is a dense $N \times N$ matrix, and x and b are N-vectors. Assuming that nothing is singular, we begin by dividing each element of the first row by the first element in that row (a total of N divisions, excluding that of the first matrix element since we know that will yield 1, but including that of the first element of b). We then multiply this row by the first element of each of the remaining rows, and subtract it from those rows, so that only the first row has a nonzero entry in the first column, and that entry is 1 (a total of $(N - 1)(N - 1)$ multiplications and subtractions for the nonzero matrix elements). To get to this point, we have performed a total of $2N^2 - 3N + 2$ operations (subtractions, multiplications, or divisions). We can now repeat this process on the lower right-hand $n \times n$ submatrices, where n ranges from $N - 1$ down to 1. At that point, we will have performed a total of

$$\sum_{n=1}^{N} (2n^2 - 3n + 2) = \frac{N}{6}(4N^2 - 3N + 5) \tag{4}$$

operations, and the problem will be solved. We say that the computational complexity of this algorithm is $O(N^3)$; that is, if the number of unknowns is increased by a factor of z, the number of operations required to solve the problem will increase by z^3 in the limit of large problem size.

Oftentimes, clever algorithmic design can drastically reduce the computational complexity required to solve a given problem. For example, the *optimal wedding problem* is well known in combinatorics: Given N men and N women who state quantitative preferences for each other, say as a number from 1 to 10, how can they be paired so as to maximize the sum of the preferences? At first glance, it would seem that all possible pairings of men and women must be considered in turn, leading to an algorithm with complexity $O(N!)$. In fact, an algorithm with $O(N^3)$ complexity is known for solving this problem (Khuller *et al.*, 1991).

Perhaps more pertinent to scientific computation is the example of the discrete Fourier transform of N data elements, f_j, where $j \in \{0, \ldots, N-1\}$. Since the definition of this transform,

$$\tilde{F}_k \equiv \sum_{j=0}^{N-1} e^{2\pi ijk/N} f_j, \tag{5}$$

involves a sum over N elements to obtain each of N results, it would appear that the transform requires a minimum of $O(N^2)$ elemental operations to compute. In 1965, however, Cooley and Tukey (1965) showed that it is possible to develop an algorithm, called the *fast Fourier transform*, with computational complexity of order $O(N \log N)$.

3.2 Parallel Computers

Since computers perform elemental operations at some rate fixed by an internal "clock," it follows that a single processor will perform a calculation in a time proportional to that calculation's computational complexity. A reduction of computational complexity therefore translates directly into faster execution time. Another way to decrease execution time is to apply more than one processor to a problem; this is called *parallel computing.*

Since the 1980s, parallel computers, containing anywhere from a few to thousands of processors, have been extensively applied to problems of computational science. There are several reasons for this trend. First, as has been noted, *very large-scale integration* (VLSI) of electronic components is approaching some fundamental physical limitations of size and speed (see Fig. 1). By the mid-1980s, the fastest processors had clock rates measured in nanoseconds. It was therefore natural that people would begin to investigate increasing computational power through the cooperative use of many such processors as an alternative to making them faster. Second, as processors and memory components became faster, and as memories became much larger, people began to worry that the classic computer architecture, in which a single processor reads a few words of data from memory and then writes a result back to memory, was becoming a bottleneck to speed. Since only those words of memory actually accessed by the processor were in use at any one moment, most of memory remains idle. Such an architecture was first advocated by von Neumann (not to be confused with his advocacy of cellular automata as a computational paradigm) and is therefore called a *von Neumann architecture.* This problem is therefore sometimes called the *von Neumann bottleneck.* Third, as processors became cheaper in the 1980s, so that processor and memory prices (per unit area of silicon) became comparable, it made sense to try to combat the von Neumann bottleneck by spreading more processing power out to the memory, so to speak.

In spite of these rather compelling arguments, parallel computers took some time to find applications to computational science because of an initial fear that they would be difficult to program. When it turned out that the regular structure of many scientific programs was quite amenable to parallelization and that most major parallel algorithmic paradigms could be easily captured in high-level languages, parallel computing exploded in popularity. At the time of this writing, virtually all major high-performance computer vendors offer one or more parallel computer platforms.

Early scenarios imagined *massively parallel* or *data parallel* computers, in which the number of processors available was comparable to the amount of data in a problem (Hillis and Boghosian, 1993). While computers with tens of thousands of processors have been built (Hillis, 1985), the current market seems to favor a coarser, more modest, "granularity" in which anywhere from a few to a few hundred processors, with sophistication comparable to that of modern workstations, can communicate as if they

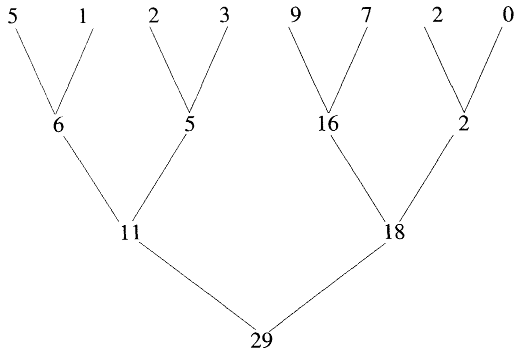

FIG. 5. Tree algorithm for parallelizing summation. Numbers are added together in a "tree" data structure, so that eight of them can be combined in only three parallelizable stages.

are connected to a very fast *local-area network*. Nevertheless, if we imagine spreading an algorithm with N data elements over M processors, it is interesting to try to determine the asymptotic behavior of the time required to execute the algorithm as a function of N and M; of course, as $M \rightarrow 1$ this result must approach the computational complexity of the algorithm. To demonstrate this idea, we can consider a few simple examples.

Suppose that we have an *array* of N numerical data elements, D_i, where $i = 1, \ldots, N$, and we wish to find its sum, $\Sigma_{i=1}^{N} D_i$. Clearly, this has computational complexity of order N, since $N - 1$ additions are required. We could, however, distribute N/M data elements in each of M processors. These processors would then require a time of order N/M to sum their elements, but they could all do this simultaneously. Once they each had their subtotal, the M data elements would need to be combined into one total, but this could be carried out in the "tree" structure shown in Fig. 5, in which all the operations at each level of the tree are performed in parallel. For a binary tree, the combination requires only $\log_2 M$ parallel steps to complete, and the time required to execute the algorithm scales like

$$T(M,N) \sim c_1 \frac{N}{M} + c_2 \log_2 M + c_3, \tag{6}$$

where c_1, c_2, and c_3 are architecture-dependent constants. Specifically, c_1 is the time required to add two numbers in the same processor, c_2 is the time required to communicate a number from one processor to another, and c_3 is whatever constant "overhead" or *latency* time is required to orchestrate the calculation. In Fig. 6 we plot the *speedup* due to parallelism, defined as

$$S(M,N) \equiv \frac{T(1,N)}{T(M,N)}, \tag{7}$$

as a function of the number of processors M, for $N = 100$ and $c_2/c_1 = c_3/c_1 = 5$. Note that this initially increases with M, due to the parallelism, but quickly reaches a point of diminishing returns, as the latency and interprocessor communication begin to dominate the performance. It is not difficult to see that a maximum speedup of

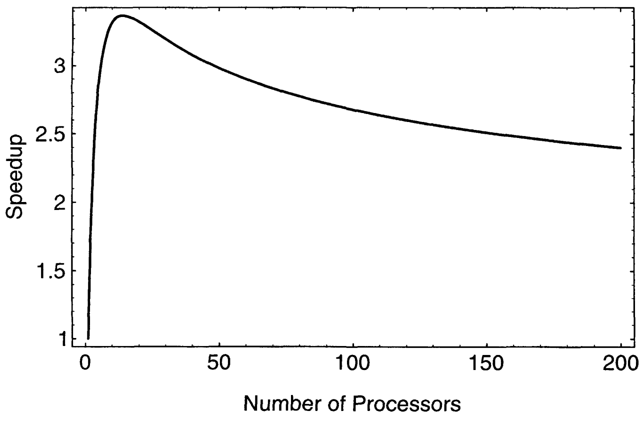

FIG. 6. Speedup versus number of processors, illustrating Amdahl's law, for $N = 100$ and $c_2/c_1 = c_3/c_1 = 5$.

$$S_{\max}(N) = \frac{c_1N + c_3}{c_2 \log_2(2c_1N/c_2) + c_3} \tag{8}$$

is obtained for M equal to

$$M_{\max} \equiv c_1N/c_2, \tag{9}$$

which is 20 for our example. For $M > M_{\max}$ the speedup actually begins to *decrease* with increasing M! This rather pessimistic assessment of the benefits of parallelism is a special case of what is known as *Amdahl's law*. This is the observation that, as the parallelism reduces the time required for the parallel portion of the computation toward zero, the latency (and interprocessor communication) will always end up dominating the speedup, which therefore must have an upper bound.

Though Amdahl's law seems compelling, in recent years researchers have very successfully applied parallel computers with thousands of processors to scientific problems. This seems like a contradiction and has been the source of much confusion, but the reason is simple: Amdahl's law considers the application of parallel computers to problems of a fixed size N. As problems become ever larger, however, note that both the maximum speedup, given by Eq. (8), and the number of processors for which it is obtained, given by Eq. (9), can become arbitrarily large. Thus, parallel computers are naturally most useful for the largest and most data-intensive problems of computational science. As we shall see, there is no shortage of such problems, and so parallel computers are here to stay.

Before leaving the topic of parallelism and the scaling of execution time with the number of processors, we note that different parallel data structures can result in quite different time scalings. To illustrate this, we consider the problem of multiplying a pair of dense $N \times N$ matrices, A and B, to obtain their product C. Since

$$C_{i,j} = \sum_{k=1}^{N} A_{i,k}B_{k,j} \tag{10}$$

are N^2 quantities, each of which requires N multiplications and additions to compute, it is clear that the problem has $O(N^3)$ computational complexity and thus requires a time proportional to N^3 to complete on a single processor. By contrast, on a parallel computer of N^2 processors, this problem can be done in $O(N)$ time. The algorithm used is the systolic or Cannon algorithm (Cannon, 1969), and it is naturally parallel. Both operands, call them A and B, are stored as parallel variables. We begin by cyclically shifting the ith row of A by $i - 1$ entries for all $i \in \{1, \ldots, N\}$, and the jth column of B by $j - 1$ entries for all $j \in \{1, \ldots, N\}$. This puts $A_{i,j+i-1}$ and $B_{j+i-1,j}$ in array element (i,j) (where all subscripts are taken modulo N). We then multiply these and accumulate into the product parallel variable $C_{i,j}$. These N^2 multiplications and accumulations can be done in fixed time, since we have assumed that our parallel computer has $O(N^2)$ processors. Continuing, we cyclically shift all the rows of A and all the columns of B by one, and then multiply and accumulate into C. We repeat this step a total of N times. After the kth such step, array element (i,j) contains $A_{i,k+j+i-1}$ and $B_{k+j+i-1,j}$, so that the N multiplications and accumulations into array element (i,j) are equivalent to a sum over the dummy index. Thus, after N steps, the result for $C_{i,j}$ is correct and in place. The algorithm takes $O(N)$ time because N steps are required. The Fortran 90 implementation of the Cannon algorithm is

```
SUBROUTINE CANNON(A, B, C)

 INTEGER :: i, n
 REAL, DIMENSION(:, :) :: A, B, C

 n = SIZE(A, 1)

 ! Initial skewing of operands:
 A = CSHIFT(A, DIM = 2, SHIFT =
   (/(i, i = 0, n-1)/))
 B = CSHIFT(B, DIM = 1, SHIFT =
   (/(i, i = 0, n-1)/))

 ! Multiplication of matrices:
 C = 0.0
 DO i = 1, n
  C = C + A*B
  A = CSHIFT(A, DIM = 2, SHIFT
  = 1)
  B = CSHIFT(B, DIM = 1, SHIFT
  = 1)
 END DO
 ! Restore operands:
  A = CSHIFT(A, DIM = 2, SHIFT =
    -(/(i, i = 0, n-1)/))
  B = CSHIFT(B, DIM = 1, SHIFT =
    -(/(i, i = 0, n-1)/))

END SUBROUTINE CANNON
```

Note that the `CSHIFT` command performs the cyclic shifts of either rows or columns; its first argument is the array to be shifted, and the other two keyword arguments are the dimension in which to shift it, and the amount of the shift. Also, we have added a step to restore the operands to their input values.

To take this one step further, suppose that we have a parallel computer with $O(N^3)$ processors. We can then allocate arrays `D`, `E`, and `F` of size $N \times N \times N$, and *spread* array `A` over the third dimension of array `D` so that $A_{i,k}$ is stored in $D_{i,k,j}$ for all j, and *spread* array `B` over the first dimension of array `E` so that $B_{k,j}$ is stored in $E_{i,k,j}$ for all i. We can then perform all N^3 multiplications of $D_{i,k,j} = A_{i,k}$ by $E_{i,k,j} = B_{k,j}$ in fixed time, since we have assumed a parallel computer with $O(N^3)$ processors. The answer for array `C` is then obtained by summing array $F_{i,k,j} = D_{i,k,j}E_{i,k,j}$ over its second (dummy) dimension. The Fortran 90 implementation of this algorithm is as follows:

```
SUBROUTINE FAST_MATMUL(A, B, C)

  INTEGER :: n
  REAL, DIMENSION(:, :) :: A, B, C
  REAL, DIMENSION(:, :, :),
    ALLOCATABLE :: D, E

  n = SIZE(A, 1)
  ALLOCATE(D(n, n, n), E(n, n, n))

  D = SPREAD(SOURCE = A, DIM = 3,
    NCOPIES = n)
  E = SPREAD(SOURCE = B, DIM = 1,
    NCOPIES = n)
  C = SUM(D*E, DIM = 2)
  DEALLOCATE(D, E)

END SUBROUTINE FAST_MATMUL
```

Note that there was no need actually to declare the array `F`. Note also that the most expensive operations were the *spreads* of array elements over a new array dimension, and the summation or *reduction* of array elements over an existing array dimension. Both of these operations, however, can be carried out in time of $O(\log_2 N)$, by the same arguments that we used to parallelize summation, illustrated in Fig. 5. Thus, on $O(N^3)$ processors, the multiplication of two $N \times N$ matrices takes $O(\log_2 N)$ time.

3.3 The Computer Representation of Real-Valued Data

Most physical models are formulated in terms of quantities that can take on a continuous range of values. Many physical models are described in terms of *fields* (either classical or quantum), for which the number of degrees of freedom itself is infinite. By contrast, digital computers can manipulate only a finite amount of finite-precision data. Thus, one of the principal challenges of computational physics is to reformulate physical laws in terms of finite and discrete mathematical models.

Real-valued quantities can be represented as finite-precision *floating-point numbers* in most all high-level languages available today. There is a standard for the storage of such numbers, adopted by the Institute of Electrical and Electronics Engineers (IEEE), whereby *single-precision* floating-point data is represented as

$$\sigma(1 + m)2^e, \qquad (11)$$

where the *mantissa* $m \in [0,1)$ is represented by 23 bits of data, the exponent $e \in \{-127, \ldots, 128\}$ is represented by 8 bits of data, and the sign of the number $\sigma \in \{-1, +1\}$ is represented by 1 bit, for a total of 32 bits. *Double-precision* floating-point numbers are also available in which the mantissa is represented by 52 bits, the exponent by 11 bits, and the sign by 1 bit, for a total of 64 bits. Thus, both single- and double-precision floating-point data take their values in a finite range, and the computer user must be ever vigilant not to *overflow* or *underflow* this range. There are many subtleties involved in this truncation; for some nice examples, see Kahan (1996).

Should we expect the truncation of real-valued data into finite-precision floating-point numbers to cause problems in physical simulations? Obviously, this finiteness circumvents the *computability* problem noticed by Turing and discussed earlier. Recall that Turing machines are idealized models of computers with infinite storage capacity. Real computers have finite storage capacity, and all finite strings of bits are computable, so that any number represented on a real computer is finite precision and computable. Thus, the issue of computability would seem to be an esoteric problem, wrapped up in infinities, that plagues idealized models of computing but not real computers. This sidestepping of the issue is satisfactory so long as the real world can be described in terms of computable numbers alone. Interestingly, Pour-El and Richards (1982) have proven that even simple linear physical models, such as the wave equation, when given computable initial conditions and evolved for a computable length of time, can give rise to uncomputable values of the dependent variable. Should this be a cause for concern? The real answer is that almost nobody worries about it. Nevertheless, we shall soon discuss some situations in which truncation of continuum data plays a very detrimental role in physical simulations, and so this issue is important at least to keep in mind.

4. GRID-BASED ALGORITHMS

4.1 Finite-Difference Methods

The most obvious way to discretize classical fields is simply to store their values on a fine spatial grid and to update those values in discrete time steps. Historically, this was the first approach adopted, and it is still in widespread use today. In this subsection, we consider this *finite-difference* method as applied to the heat equation in order to illustrate the various tradeoffs involved. We shall see that there are three main considerations when discretizing partial differential equations on grids: First, there is the *consistency* of the difference approximation—the question of whether or not it is really an approximation to the desired partial differential equation in some well-posed limit. Second, there is the *accuracy* of the difference approximation to the continuum equation—the question of how large an error may be expected for a given discretization. Third, there is the *stability* of the difference approximation—the question of whether or not its error remains bounded as the algorithm is applied.

Consider the heat equation,

$$\frac{\partial u(\mathbf{x},t)}{\partial t} = D\nabla^2 u(\mathbf{x},t) \tag{12}$$

in a d-dimensional box of side L, so that $\mathbf{x} \in [0,L]^d$, with periodic boundary conditions. We represent the spatial domain by a regular Cartesian grid with N points in each dimension, with points $\mathbf{x_j} = \mathbf{j}\Delta x$, where $\Delta x \equiv L/N$, indexed by $\mathbf{j} \in \{0, \ldots, N - 1\}^d$. Likewise, we consider the system at discrete times $t_k = k\Delta t$, where $k \in \{0,1,2,\ldots\}$ and Δt is the time step. We denote the dependent variable at the gridpoint indexed by j and time step k by $u_{\mathbf{j},k} \equiv u(\mathbf{x_j},t_k)$.

We can use the *centered* finite-difference approximation of the Laplacian operator,

$$\nabla^2 u(\mathbf{x_j},t_k) \approx \sum_{l=1}^{d} \frac{(u_{\mathbf{j}-\hat{e}_l,k} - 2u_{\mathbf{j},k} + u_{\mathbf{j}+\hat{e}_l,k})}{(\Delta x)^2}, \tag{13}$$

where $\hat{e}_l$ is the unit vector in dimension l. As the spatial grid spacing Δx goes to zero, this approximation is readily seen to become exact; hence the difference approximation is *consistent.* In fact, by Taylor expanding the right-hand side, we see that it is $\nabla^2 + O((\Delta x)^2)$, demonstrating both consistency and accuracy to $O((\Delta x)^2)$.

Likewise, a *two-point* finite-difference approximation of the time derivative is

$$\frac{\partial u(\mathbf{x_j},t_k)}{\partial t} \approx \frac{u_{\mathbf{j},k+1} - u_{\mathbf{j},k}}{\Delta t}. \tag{14}$$

This becomes exact as the time step Δt goes to zero. By Taylor expanding $u_{\mathbf{j},k+1}$ about $t = t_k$, we see that this approximation is accurate to $O(\Delta t)$.

The full finite-difference approximation to the heat equation is then

$$\frac{u_{\mathbf{j},k+1} - u_{\mathbf{j},k}}{\Delta t} = D \sum_{l=1}^{d} \frac{(u_{\mathbf{j}-\hat{e}_l,k} - 2u_{\mathbf{j},k} + u_{\mathbf{j}+\hat{e}_l,k})}{(\Delta x)^2}. \tag{15}$$

This is called an *explicit* finite-difference scheme, since it may be explicitly solved for the new dependent variable at each point on the grid $u_{\mathbf{j},k+1}$,

$$u_{\mathbf{j},k+1} = u_{\mathbf{j},k} + \alpha \sum_{l=1}^{d} (u_{\mathbf{j}-\hat{e}_l,k} - 2u_{\mathbf{j},k} + u_{\mathbf{j}+\hat{e}_l,k}), \tag{16}$$

where $\alpha \equiv D\Delta t/(\Delta x)^2$. By iterating this equation, beginning with some specified initial conditions on the grid, we can evolve the difference approximation forward in time to obtain an approximation to the solution of the heat equation. We have demonstrated that this approximation is consistent and accurate to $O((\Delta x)^2)$ and $O(\Delta t)$. We must next assess the *stability* properties of this algorithm. Since all arithmetic done on a computer is of finite precision, a certain amount of error will naturally be introduced into these calculations. If this error tends to grow exponentially in time, the algorithm will be unstable. We can determine this by applying a classical linear stability argument to the difference equation. Let

$$u_{\mathbf{j},k} = U_{\mathbf{j},k} + \xi_{\mathbf{j},k}, \tag{17}$$

where U is the exact solution to the difference equation and ξ is error. Since the difference equation is linear and homogeneous, it is clear that ξ will satisfy it,

$$\xi_{\mathbf{j},k+1} = \xi_{\mathbf{j},k} + \alpha \sum_{l=1}^{d} (\xi_{\mathbf{j}-\hat{e}_l,k} - 2\xi_{\mathbf{j},k} + \xi_{\mathbf{j}+\hat{e}_l,k}), \tag{18}$$

and that we can solve it by Fourier analysis. Letting

$$\tilde{\xi}_{\mathbf{m},k} = \sum_{\mathbf{j}} \xi_{\mathbf{j},k} \exp\left(-\frac{2\pi i \mathbf{j}\cdot\mathbf{m}}{N}\right), \tag{19}$$

so that

$$\xi_{\mathbf{j},k} = \frac{1}{N}\sum_{\mathbf{m}} \tilde{\xi}_{\mathbf{m},k} \exp\left(+\frac{2\pi i \mathbf{m}\cdot\mathbf{j}}{N}\right), \tag{20}$$

we substitute this into our difference equation to find the evolution equation of the **m**th mode,

$$\tilde{\xi}_{\mathbf{m},k+1} = \left[1 - 2d\alpha + 2\alpha \sum_{l=1}^{d} \cos\left(\frac{2\pi m_l}{N}\right)\right]\tilde{\xi}_{\mathbf{m},k}. \tag{21}$$

Clearly, this iteration will be stable for

$$-1 \leq 1 - 2d\alpha + 2\alpha \sum_{l=1}^{d} \cos\left(\frac{2\pi m_l}{N}\right) \leq +1. \tag{22}$$

The right inequality is easily seen to always be satisfied; the left requirement is most stringent for the $m_l = N/2$ mode, for which it demands that $2d\alpha \leq 1$, or

$$\Delta t \leq \frac{(\Delta x)^2}{2dD}. \tag{23}$$

This is called the *Courant condition* for the explicit finite-difference approximation to the heat equation. It states that the time step must scale as the square of the spatial grid size. This is a stringent requirement. It means that if one halves the grid spacing and doubles the number of grid points, presumably in an effort to increase accuracy, one must also decrease the time step by a factor of 4 and iterate for four times as many time steps.

The scaling of Δt with the square of Δx is characteristic of parabolic differential equations. As another physically relevant example, we consider the Navier–Stokes equations for a three-dimensional, viscous, incompressible fluid,

$$\nabla\cdot\mathbf{v}(\mathbf{x},t) = 0, \tag{24}$$

$$\frac{\partial\mathbf{v}(\mathbf{x},t)}{\partial t} + \mathbf{v}(\mathbf{x},t)\cdot\nabla\mathbf{v}(\mathbf{x},t) = -\nabla P(\mathbf{x},t) + \frac{1}{Re}\nabla^2\mathbf{v}(\mathbf{x},t), \tag{25}$$

where Re is the Reynolds number. Though a rigorous stability analysis for a nonlinear equation is generally much more difficult, since the equation is parabolic we might expect a Courant condition similar to that of the heat equation. Since the inverse of the Reynolds number plays the role of the diffusivity, we have

$$\Delta t \sim Re(\Delta x)^2, \tag{26}$$

so that the number of time steps needed to integrate one unit of physical time is

$$N_t \sim \frac{1}{\Delta t} \sim \frac{1}{Re(\Delta x)^2}, \tag{27}$$

and the number of grid points in one unit of physical spatial distance is

$$N_x \sim \frac{1}{\Delta x}. \tag{28}$$

The computational complexity of updating the entire three-dimensional lattice one unit of physical time is then

$$C \sim N_t N_x^3 \sim \frac{1}{Re(\Delta x)^5}. \tag{29}$$

We must then decide how large Δx needs to be according to accuracy considerations. Since the length scale of the smallest eddies in three-dimensional Navier–Stokes flow scale as $Re^{-3/4}$ (see Landau and Lifschitz, 1982 for details), to resolve these we must take $\Delta x \sim Re^{-3/4}$ so that

$$C \sim Re^{11/4}. \tag{30}$$

Thus, computational complexity scales very strongly with Reynolds number. At the time of this writing, the very highest Reynolds numbers that have been simulated are in the vicinity of 10^4 or 10^5. To increase this by an order of magnitude will require nearly three orders of magnitude more computing power. Since Reynolds numbers of interest to, for example, aircraft manufacturers are in the vicinity of 10^7, direct simulations of the Navier–Stokes equations are not an option anytime in the foreseeable future; instead, various approximations are used to avoid having to track the smallest eddies.

It is clear that there is much incentive to try to circumvent the Courant condition. One way of doing this is to use *implicit* finite-differencing schemes, as opposed to the explicit method just described. To pursue our foregoing example, suppose that we replace the finite difference in Eq. (16) by the following, in which the right-hand side is averaged over its values at t_k and t_{k+1}; one may think of this as an estimate of the rate of change at $t_{k+1/2}$. We get

$$\begin{aligned} u_{\mathbf{j},k+1} = u_{\mathbf{j},k} &+ \frac{\alpha}{2} \sum_{l=1}^{d} [(u_{\mathbf{j}-\hat{e}_l,k} - 2u_{\mathbf{j},k} + u_{\mathbf{j}+\hat{e}_l,k}) \\ &+ (u_{\mathbf{j}-\hat{e}_l,k+1} - 2u_{\mathbf{j},k+1} + u_{\mathbf{j}+\hat{e}_l,k+1})]. \end{aligned} \tag{31}$$

This is called the Crank–Nicholson differencing scheme for the heat equation. By arguments similar to those presented above, it can be shown to be *unconditionally stable.* The limitation on the time step Δt is therefore set by *accuracy,* rather than *stability,* considerations. The drawback to implicit schemes is that it is impossible to solve explicitly for the updated dependent variable at each site. Rather, one typically obtains a *banded-matrix* equation for the updated dependent variable. For example, specializing to one spatial dimension for simplicity, Eq. (31) may be written

$$\begin{aligned} -\frac{\alpha}{2} u_{j-1,k+1} &+ (1+\alpha) u_{j,k+1} - \frac{\alpha}{2} u_{j+1,k+1} \\ &= \frac{\alpha}{2} u_{j-1,k} + (1-\alpha) u_{j,k} + \frac{\alpha}{2} u_{j+1,k}, \end{aligned} \tag{32}$$

which makes it clear that $u_{j,k+1}$, for $j \in \{0, \ldots, N-1\}$, is the solution to a *tridiagonal-matrix* equation. (In two spatial dimensions this would be *pentadiagonal,* etc.) The gain of using a larger time step must thus be weighed against the expense of solving this type of equation. Methods for solution of banded-matrix problems are discussed in the next subsection.

4.2 Banded-Matrix Equations

The general tridiagonal system can be written

$$L_i X_{i-1} + D_i X_i + U_i X_{i+1} = R_i, \tag{33}$$

for $i \in \{1, \ldots, N\}$, with L_1 and U_N understood to be zero. Numerous methods for solving such systems of equations are known and are in widespread use. These tend to fall in one of three categories: *Direct solvers* provide an algorithm whereby the solution to the matrix equation is obtained in a finite number of steps, carried out in a prescribed sequence; *recursive solvers* break down the problem into two or more smaller problems, which are in turn broken down, in recursive fashion, until the resulting system is small enough to solve explicitly; *iterative solvers* provide an iteration for updating the unknown that converges to the correct answer. We consider each of these in turn.

A *direct tridiagonal solver* may be derived by rewriting Eq. (33) as follows:

$$L_i\left(X_{i-1} + \frac{D_i - P_i}{L_i} X_i\right) + P_i\left(X_i + \frac{U_i}{P_i} X_{i+1}\right) = R_i, \tag{34}$$

where the P_i are as yet unspecified. We define

$$Y_i \equiv X_i + (U_i/P_i)X_{i+1} \tag{35}$$

and determine the P_i by demanding that

$$U_{i-1}/P_{i-1} = (D_i - P_i)/L_i, \tag{36}$$

so that

$$L_iY_{i-1} + P_iY_i = R_i. \tag{37}$$

Thus, Eqs. (36) and (37) yield recursions for the P_i and Y_i,

$$P_i = D_i - L_iU_{i-1}/P_{i-1} \tag{38}$$

and

$$Y_i = (R_i - L_iY_{i-1})/P_i. \tag{39}$$

These may be recursed forward in i from the initial condition $P_1 = D_1$ (and remembering that $L_1 = 0$) to obtain all the P's and Y's. Once these are known, Eq. (35) yields a *backward* recursion in i for the desired unknowns,

$$X_i = Y_i - (U_i/P_i)X_{i+1}. \tag{40}$$

Since two recursive sweeps of N steps are required, note that this algorithm has computational complexity of $O(N)$. A Fortran 90 implementation of the above-described algorithm might be

```
SUBROUTINE TRIDIAGONAL_SOLVE(X, L,
 D, U, R)

 IMPLICIT NONE
 INTEGER :: j, n
 REAL :: p
 REAL, DIMENSION(:) :: X, L, D, U, R
 REAL, ALLOCATABLE, DIMENSION(:)
  :: Y

 n = SIZE(D)
 ALLOCATE(Y(n))

 p = D(1)
 IF(p == 0.0) THEN
  PRINT *, ™Error: Ill-conditioned
   matrix. Pivot: 1
  STOP
 END IF
 X(1) = R(1)/p

 DO j = 2, n
  Y(j) = U(j - 1)/p
  p = D(j) - L(j)*Y(j)
  IF(p == 0.0) THEN
   PRINT *, ™Error: Ill-conditioned
    matrix. Pivot: , j
   STOP
  END IF
  X(j) = (R(j) - L(j)*X(j - 1))/p
 END DO
 DO j = n - 1, 1, -1
  X(j) = X(j) - Y(j + 1)*X(j + 1)
 END DO

 DEALLOCATE(Y)

END SUBROUTINE TRIDIAGONAL_SOLVE
```

One problem with the above routine is that the recursions are inherently serial. If parallelism is desired, a different strategy must be adopted. One such strategy is that of a *recursive solver* in which the problem is successively broken down into smaller pieces. Consider, for example, the following three rows of the matrix relationship in Eq. (33):

$$\begin{aligned} L_{i-1}X_{i-2} + D_{i-1}X_{i-1} + U_{i-1}X_i \qquad\qquad\qquad\qquad &= R_{i-1}, \\ L_iX_{i-1} + \quad D_iX_i + \quad U_iX_{i+1} \qquad\qquad &= R_i, \\ L_{i+1}X_i + D_{i+1}X_{i+1} + U_{i+1}X_{i+2} &= R_{i+1}. \end{aligned} \tag{41}$$

Eliminating X_{i-1} using the first of these, and X_{i+1} using the last, the middle equation becomes

$$\left(-\frac{L_iL_{i-1}}{D_{i-1}}\right)X_{i-2} + \left(D_i - \frac{L_iU_{i-1}}{D_{i-1}} - \frac{U_iL_{i+1}}{D_{i+1}}\right)X_i + \left(-\frac{U_iU_{i+1}}{D_{i+1}}\right)X_{i+2} = \left(R_i - \frac{L_iR_{i-1}}{D_{i-1}} - \frac{U_iR_{i+1}}{D_{i+1}}\right). \tag{42}$$

Since this equation couples X_i only to X_{i-2} and X_{i+2}, this has had the effect of breaking the tridiagonal system of N equations into two tridiagonal systems of $N/2$ equations each. If N is a power of two, this process can be continued recursively, until a two-by-two system is obtained, for which the general solution is simple to write down. Since modern languages, such as Fortran 90, support recursion—subroutines that can call themselves—it is a simple matter to capture the above in code:

```
RECURSIVE SUBROUTINE
  NESTED_BISECTION(X, L, D, U, R)

  DH(2:nh) = D(3:n-1:2) -
   L(3:n-1:2)*U(2:n-2:2)/
   D(2:n-2:2) - & & U(3:n-1:2)*
   L(4:n:2)/D(4:n:2)
  UH(1:nh-1) = -U(1:n-1:2)*
   U(2:n:2)/D(2:n:2)
  RH(1) = R(1) - U(1)*R(2)/D(2)
  RH(2:nh) = R(3:n-1:2) -
L(3:n-1:2)*
   R(2:n-2:2)/D(2:n-2:2) - &
   & U(3:n-1:2)*R(4:n:2)/D(4:n:2)
  CALL NESTED_BISECTION(X(1::2), LH,
   DH, UH, RH)

  DEALLOCATE(LH, DH, UH, XH, RH)

 ELSE
  PRINT *, ™Error: Problem size
   contains prime factors other than
   2.
  STOP

 ENDIF

END SUBROUTINE NESTED_BISECTION
```

Note that the above routine treats $N = 1$ and $N = 2$ as special cases. For even $N > 2$ it divides up the problem into two smaller ones as indicated above and calls itself for each of those two smaller problems. If an odd $N > 2$ is ever encountered, it means that the initial problem size was not a power of 2.

Note also that if N contains factors of 3 as well as 2 it is straightforward to work out a variant of the above algorithm that divides the system into three subsystems of size $N/3$, and to add that to the above recursive subroutine, with the test that `MOD(N, 3) == 0`. By working out this treatment for the first several prime numbers, a routine can be created that works for any N containing only those prime factors.

This routine is more amenable to parallel computation than the direct tridiagonal solver described above, since the arithmetic operations needed to compute the matrix coefficients of the smaller systems can be performed in parallel.

4.3 The Galerkin Approximation and Finite-Element Methods

Representing a function by its values at discrete grid points is, of course, only one way of approximating it. More generally, we might consider expanding a function in a series of (not necessarily orthogonal) basis functions, $\psi_\alpha(\mathbf{x})$. These may be a complete set if α is allowed to range over an infinite (discrete and/or continuous) set of values. We can then approximate the dependent variable $u(\mathbf{x},t)$ by restricting α to a finite subset $\mathcal{A}$ of its possible values. Thus, we write

$$u(\mathbf{x},t) \approx U(\mathbf{x},t) \equiv \sum_{\alpha\in\mathcal{A}} U_\alpha(t)\psi_\alpha(\mathbf{x}). \tag{43}$$

An error will generally be incurred if we substitute the approximate dependent variable $U(\mathbf{x},t)$ in any given dynamical equation for the field $u(\mathbf{x},t)$. Returning to our example of the heat equation, this error may be defined,

$$E(\mathbf{x},t) \equiv \frac{\partial U(\mathbf{x},t)}{\partial t} - D\nabla^2 U(\mathbf{x},t). \tag{44}$$

The *Galerkin approximation* fixes the coefficients $U_\alpha(t)$ by demanding that this error be orthogonal to all of the basis functions in the set α, and hence orthogonal to the entire subspace spanned by them. In order to have some notion of orthogonality, an inner product must be defined; this is most often taken to be an integral of the product of the functions,

$$\langle f|g\rangle = \int d^3x W(\mathbf{x}) f(\mathbf{x}) g(\mathbf{x}), \tag{45}$$

where $W(\mathbf{x})$ is a judiciously chosen weighting factor. Thus, we demand that

$$0 = \langle\psi_\alpha|E\rangle = \left\langle\psi_\alpha\left|\frac{\partial U}{\partial t} - D\nabla^2 U\right.\right\rangle \tag{46}$$

for all $\alpha \in \mathcal{A}$. Substituting Eq. (43), we quickly obtain

$$A_{\alpha\beta}\frac{dU_\beta(t)}{dt} = B_{\alpha\beta}U_\beta(t), \tag{47}$$

where there are understood summations over the repeated index $\beta \in \mathcal{A}$, and where we have defined the matrix A with elements

$$A_{\alpha\beta} \equiv \langle\psi_\alpha|\psi_\beta\rangle \tag{48}$$

and B with elements

$$B_{\alpha\beta} \equiv \langle\psi_\alpha|\nabla^2\psi_\beta\rangle. \tag{49}$$

As long as A is nonsingular, this can be solved for the $dU_\beta(t)/dt$, which can then be integrated by any one of a number of different numerical integration schemes. Fed back into Eq. (43), this gives the finite-element approximation to the solution $u(\mathbf{x},t)$.

As a concrete example, let us consider one spatial dimension and suppose that the functions $\psi_\alpha(\mathbf{x})$ are the linear basis splines,

$$\psi_\alpha(x) \equiv \begin{cases} (x - x_{\alpha-1})/(x_\alpha - x_{\alpha-1}), & x_{\alpha-1} \le x < x_\alpha, \\ (x_{\alpha+1} - x)/(x_{\alpha+1} - x_\alpha), & x_\alpha \le x < x_{\alpha+1}, \\ 0 & \text{otherwise,} \end{cases} \tag{50}$$

illustrated in Fig. 7. For the case of equally spaced grid points, $x_\alpha = \alpha\Delta x$ for $\alpha \in \{0, \ldots, N-1\}$, and if the weight function $W(x)$ is taken to be unity, we find that A and B are the tridiagonal matrices with elements

$$A_{\alpha\beta} = \begin{cases} 2\Delta x/3, & \alpha = \beta, \\ \Delta x/6, & |\alpha - \beta| = 1, \\ 0 & \text{otherwise,} \end{cases} \tag{51}$$

and

$$B_{\alpha\beta} = \begin{cases} 2/\Delta x, & \alpha = \beta, \\ -1/\Delta x, & |\alpha - \beta| = 1, \\ 0 & \text{otherwise.} \end{cases} \tag{52}$$

Thus, Eq. (47) can be solved using one of the previously discussed tridiagonal algorithms, and the system can be integrated forward in time. Note that this system is quite similar to that of Eq. (15), except that the matrix $A_{\alpha\beta}$

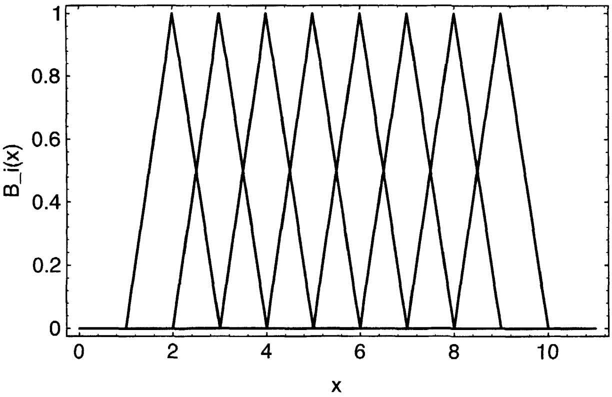

FIG. 7. Linear basis splines for finite-element method in one dimension. Function $B_j(x)$ increases linearly from 0 at $x = x_{j-1}$ to 1 at $x = x_j$, and then decreases back to zero at $x = x_{j+1}$. Functions $B_2(x)$ through $B_9(x)$ are shown for equally spaced grid points, $x_j = j$. These span the space of piecewise linear functions.

has the effect of smoothing the time differencing scheme a bit.

Because the dependent variable is represented as a sum of the linear splines illustrated in Fig. 7, it is clear that the function subspace that we are considering is that of all piecewise linear functions. It is also clear that we would still get a tridiagonal system if the grid points were spaced irregularly. Thus, finite-element methods can be easily applied to situations in which one needs more grid refinement in one part of a spatial domain than another. Moreover, the method could be used with a smoother set of basis splines than the linear splines used above. Cubic basis splines, assuring continuity of first and second derivatives at the gridpoints, are commonly used; in this situation, the resulting matrix equation will still be banded, though it will be pentadiagonal, rather than tridiagonal.

The method assumes great importance in more than one spatial dimension and for problems with irregular boundary conditions, such as are often encountered in engineering applications. In two dimensions, for example, it is possible to break up a domain into triangular or other polygonal regions and define spline functions on them with the appropriate continuity properties. Tensor products of one-dimensional basis splines can be used to create multidimensional basis splines, and the Galerkin approximation can still be employed to derive a finite-element method. In such situations, the matrix A is generally no longer neatly banded, though it is still likely to be *sparse* for problems involving purely local differential operators; a number of efficient schemes exist for storing and inverting such sparse matrices. Finally, we note that the method is also sometimes used for the solution of integrodifferential equations for which the matrix A is dense.

5. SPECTRAL METHODS

5.1 Spectral Representation of Data

In the applications of the Galerkin method that we examined in the previous section, we chose basis functions that were *local*—i.e., had compact support. This restriction is unnecessary. One might consider, for example, expanding a function on a periodic domain in a discrete Fourier series and representing it on a computer by the coefficients of this series. For problems in other geometries, or with other linear operators, other basis functions may be more appropriate. While Fourier representations diagonalize the ubiquitous del operator (and hence the gradient, divergence, and Laplacian) in periodic geometry, a Fourier–Bessel representation may be more appropriate for cylindrical geometry, spherical harmonics may be more appropriate for spherical geometry, and so on. Of these, only the Fourier transform with sine/cosine basis functions has a *fast* version (the so-called fast Fourier transform, or FFT), and so it is naturally the most useful in this regard.

It is easy to see that the method diagonalizes any linear, homogeneous equation, reducing it to a set of independent ordinary differential equations to be integrated. The challenge is therefore to deal with inhomogeneities and/or nonlinearities, which will couple the modes. The example of the heat equation, which served us well in the last section, is inadequate to illustrate this issue, and so we add a nonlinear term $|\nabla u(\mathbf{x},t)|^2$ on the left, and some inhomogeneous noise $\eta(\mathbf{x},t)$ on the right; the result is the *Kardar–Parisi–Zhang* (KPZ) equation,

$$\frac{\partial u(\mathbf{x},t)}{\partial t} + \tfrac{1}{2}|\nabla u(\mathbf{x},t)|^2 = D\nabla^2 u(\mathbf{x},t) + \eta(\mathbf{x},t), \tag{53}$$

which has received wide attention as a model of interfacial growth (Kardar *et al.*, 1986). If we expand $u(\mathbf{x},t)$ in a set of *orthogonal* basis functions,

$$u(\mathbf{x},t) = \sum_{\alpha} u_\alpha(t)|\psi_\alpha\rangle \tag{54}$$

for $\alpha \in \{1, \ldots, N\}$, we find that

$$\begin{aligned}\frac{du_\alpha(t)}{dt} &+ \tfrac{1}{2}\sum_{\beta<\gamma} u_\beta(t)u_\gamma(t)\langle\phi_\alpha|\nabla\phi_\beta\cdot\nabla\phi_\gamma\rangle \\ &= D\sum_{\beta} u_\beta(t)\langle\phi_\alpha|\nabla^2|\phi_\beta\rangle + \eta_\alpha(t),\end{aligned} \tag{55}$$

where $\eta_\alpha(t) \equiv \langle\phi_\alpha|\eta\rangle$.

To make this concrete, let us take periodic boundary conditions in a cube of side L,

$$|\phi_{\mathbf{j}}\rangle = \exp\left(\frac{2\pi i\mathbf{j}\cdot\mathbf{x}}{L}\right), \tag{56}$$

so that the basis functions are indexed by the wave number $\mathbf{j}$. The Laplacian operator is then diagonalized, and one sum drops out of the nonlinear term to yield

$$\begin{aligned}\frac{du_{\mathbf{j}}(t)}{dt} &- \frac{2\pi^2}{L^2}\sum_{\mathbf{k}} \mathbf{k}\cdot(\mathbf{j}-\mathbf{k})u_{\mathbf{k}}(t)u_{\mathbf{j}-\mathbf{k}}(t) \\ &= -\frac{4\pi^2 D}{L^2}|\mathbf{j}|^2 u_{\mathbf{j}}(t) + \eta_{\mathbf{j}}(t).\end{aligned} \tag{57}$$

Note that the quadratic nonlinearity in the original equation has given rise to a corresponding quadratic nonlinearity in the equation for the mode amplitudes. Suppose that we truncate our spectral representation of $u(\mathbf{x},t)$ at some finite number N of modes in each direction. For a d-dimensional spatial domain, there will thus be a total of N^d modes. It follows that the upper limit of each of the d summations on the left-hand side of Eq. (57) should be N. This yields a closed set of equations for the mode amplitudes. As long as N is chosen to be large enough that the smallest characteristic features of the flow can be represented, this is a valid numerical approximation.

On the other hand, note that the nonlinear term requires on the order of N^{2d} steps to compute, since there are N^d equations, each with d nested N-term sums. Since a fast Fourier transform of N^d data requires only on the order of $N^d \log(N^d) \sim dN^d \log(N)$ steps, it actually becomes less expensive to compute the gradient ∇u in Fourier space, square it in real space, and then transform the result back to Fourier space. This strategy is called a *pseudospectral algorithm.* Symbolically, this procedure may be written

$$\begin{aligned}\frac{du_{\mathbf{j}}(t)}{dt} &- \frac{2\pi^2}{L^2}\mathcal{F}[|\mathcal{F}^{-1}(\mathbf{k}u_{\mathbf{k}})|^2] \\ &= -\frac{4\pi^2 D}{L^2}|\mathbf{j}|^2 u_{\mathbf{j}}(t) + \eta_{\mathbf{j}}(t),\end{aligned} \tag{58}$$

where $\mathcal{F}$ and $\mathcal{F}^{-1}$ denote the Fourier transform and its inverse, respectively.

5.2 Operator Splitting

Multiplication of the dependent variable by a spatially inhomogeneous term can also couple the modes. A classic example of this is provided by the time-dependent Schrödinger equation,

$$i\frac{\partial\Psi(\mathbf{x},t)}{\partial t} = -\tfrac{1}{2}\nabla^2\Psi(\mathbf{x},t) + V(\mathbf{x})\Psi(\mathbf{x},t). \tag{59}$$

We could proceed as above to solve this equation using spectral methods, but there are other considerations: Specifically, we know that Schrödinger evolution should be *unitary*; that is, it should conserve total probability $|\Psi(\mathbf{x},t)|^2$. It would be nice to develop a numerical method that respected this constraint.

Toward this end, we write the Schrödinger equation in the following format:

$$i\frac{\partial\Psi}{\partial t} = \hat{H}\Psi \equiv \hat{T}\Psi + \hat{V}\Psi, \tag{60}$$

where $\hat{T} \equiv -\nabla^2/2$ and $\hat{V} = V(\mathbf{x},t)$ are the kinetic and potential energy operators, respectively. This equation has the formal solution

$$\mathbf{\Psi}(t + \Delta t) = \exp(-i\Delta t\hat{H})\Psi(t) = \exp[-i\Delta t(\hat{T} + \hat{V})]\mathbf{\Psi}(t). \qquad (61)$$

Now we cannot write $\exp[-i\Delta t(\hat{T} + \hat{V})] = \exp[-i\Delta t\hat{T}]\exp[-i\Delta t\hat{V}]$ since the operators $\hat{T}$ and $\hat{V}$ generally do not commute. Motivated by the Baker–Campbell–Hausdorff theorem (see, e.g., Belinfante and Kelman, 1972), however, we can write

$$\exp[-i\Delta t(\hat{T} + \hat{V})] = \exp[-i\Delta t\hat{T}]\exp[-i\Delta t\hat{V}] + O(\Delta t^2), \qquad (62)$$

or

$$\exp[-i\Delta t(\hat{T} + \hat{V})] = \exp\left[-\frac{i}{2}\Delta t\hat{V}\right] \times \exp[-i\Delta t\hat{T}]\exp\left[-\frac{i}{2}\Delta t\hat{V}\right] + O(\Delta t^3), \qquad (63)$$

etc. If we integrate for $O(\Delta t^{-1})$ time steps, the first (second) of these will give rise to an accumulated error of order $O(\Delta t)$ $[O(\Delta t^2)]$. Choosing the first for simplicity, we have

$$\mathbf{\Psi}(t + \Delta t) \approx \exp(-i\Delta t\hat{T})\exp(-i\Delta t\hat{V})\mathbf{\Psi}(t). \qquad (64)$$

Now the first of these operators, $\exp(-i\Delta t\hat{T})$, is diagonalized in Fourier space since

$$\exp(-i\Delta t\hat{T}) = \exp\left(\frac{i\Delta t}{2}\nabla^2\right) = \mathcal{F}^{-1}\exp\left(-\frac{i\Delta t}{2}k^2\right)\mathcal{F}, \qquad (65)$$

where k is the wave vector; the second, $\exp(-i\Delta t\hat{V})$, is diagonalized in real space. We can thus write

$$\mathbf{\Psi}(t + \Delta t) \approx \mathcal{F}^{-1}\left\{\exp\left(-\frac{i\Delta t}{2}k^2\right)\mathcal{F}[\exp(-i\Delta t\hat{V})\mathbf{\Psi}(t)]\right\}. \qquad (66)$$

Given the wave function at time t, the complete algorithm for one time step is therefore to perform a local (in real space) multiplication by $\exp(-i\Delta t\hat{V})$, Fourier transform the result, perform a local (in Fourier space) multiplication by $\exp(-i\Delta tk^2/2)$, and invert the Fourier transform. Like the KPZ equation (53), note that the portion of the dynamics that does not mix modes is treated in Fourier space, while the portion that does mix modes is treated in real space; that is, it is pseudospectral. Also note that this algorithm has the virtue of being *exactly* unitary—or at least to within roundoff error—even for finite Δt.

Note that the presence of the global Fourier transform means that the algorithm is effectively implicit, insofar as the new wave function at any one point depends on the old one everywhere on the grid. In fact, the situation is actually worse than it was for the implicit finite-difference schemes discussed earlier, since those could be handled by a tridiagonal solver in $O(N)$ operations, where N is the number of grid points. The FFT, by contrast, will require $O(N \log N)$ operations. Thus, it would be nice to have a fully *explicit,* operator-splitting methodology for integrating Schrodinger's equation, maintaining exact unitarity. Such a method was discovered only fairly recently (DeRaedt 1987). To understand it, consider a one-dimensional, periodic, finite-difference representation of the Hamiltonian operator that was used above:

$$\hat{H} = -\tfrac{1}{2}\nabla^2 + V(\mathbf{x}) = -\frac{1}{2}\begin{pmatrix} 2 & -1 & 0 & 0 & 0 & \cdots & -1 \\ -1 & 2 & -1 & 0 & 0 & \cdots & 0 \\ 0 & -1 & 2 & -1 & 0 & \cdots & 0 \\ 0 & 0 & -1 & 2 & -1 & \cdots & 0 \\ 0 & 0 & 0 & -1 & 2 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ -1 & 0 & 0 & 0 & 0 & \cdots & 2 \end{pmatrix} + \begin{pmatrix} V_1 & 0 & 0 & 0 & 0 & \cdots & 0 \\ 0 & V_2 & 0 & 0 & 0 & \cdots & 0 \\ 0 & 0 & V_3 & 0 & 0 & \cdots & 0 \\ 0 & 0 & 0 & V_4 & 0 & \cdots & 0 \\ 0 & 0 & 0 & 0 & V_5 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & 0 & 0 & \cdots & V_N \end{pmatrix} = \hat{H}_{\text{even}} + \hat{H}_{\text{odd}}, \tag{67}$$

where we have defined $V_j \equiv V(x_j)$, and the matrix operators

$$\hat{H}_{\text{even}} \equiv \frac{1}{2}\begin{pmatrix} V_1 - 1 & & & & & \cdots & 1 \\ & V_2 - 1 & 1 & & & \cdots & \\ & 1 & V_3 - 1 & & & \cdots & \\ & & & V_4 - 1 & 1 & \cdots & \\ & & & 1 & V_5 - 1 & \cdots & \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & & & & & \cdots & V_N - 1 \end{pmatrix} \tag{68}$$

and

$$\hat{H}_{\text{odd}} \equiv \frac{1}{2}\begin{pmatrix} V_1 - 1 & 1 & & & & \cdots & \\ 1 & V_2 - 1 & & & & \cdots & \\ & & V_3 - 1 & 1 & & \cdots & \\ & & 1 & V_4 - 1 & & \cdots & \\ & & & & V_5 - 1 & \cdots & \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ & & & & & \cdots & V_N - 1 \end{pmatrix}. \tag{69}$$

We have purposely suppressed the zero matrix elements of these operators to emphasize the fact that both $\hat{H}_{\text{even}}$ and $\hat{H}_{\text{odd}}$ are direct sums of 2 × 2 matrices of the form

$$\hat{h}_j \equiv \begin{pmatrix} V_j - 1 & 1 \\ 1 & V_{j+1} - 1 \end{pmatrix}, \tag{70}$$

for j even and odd, respectively.

It is now possible to use operator splitting on the division of the Hamiltonian into $\hat{H}_{\text{even}}$ and $\hat{H}_{\text{odd}}$, rather than its division into $\hat{T}$ and $\hat{V}$. Because $\hat{H}_{\text{even}}$ and $\hat{H}_{\text{odd}}$ are direct sums of 2 × 2 blocks, however, their exponentiation will be likewise; that is, in order to exponentiate this Hamiltonian, all one needs to do is exponentiate a 2 × 2 Hermitian matrix. This is an elementary exercise, and the evolution will consist of the application of a sequence of 2 × 2 block unitary matrices to the wave function. Since these combine only neighboring values of the wave function on the grid, the evolution will be explicit as well as exactly unitary. This method also has the advantage of being straightforwardly parallelized (Richardson, 1991). Finally we note that, more recently, other fully explicit, exactly unitary methods have been developed for the integration of Schrödinger's equation (Boghosian and Taylor, 1998), but they are based on a quantum lattice-gas approach rather than on operator splitting.

5.3 Spectral-Element Methods and Wavelets

The orthogonality of the spectral basis functions in the previous examples has precluded the need to invert a tridiagonal matrix, as was necessary for the Galerkin method in Eq. (47). Moreover, sine and cosine basis functions have the virtue of diagonalizing differential operators, and possessing a "fast" transform—the FFT. At the same time, sine and cosine basis functions have certain disadvantages. All of our foregoing examples employed very simple boundary conditions. Indeed, sine and cosine basis functions are easiest for periodic boundary conditions. Moreover, since sine and cosine functions lack the compact support of basis splines, they are awkward for representing localized features.

A relatively recent numerical technique called the *spectral-element* method seeks to combine the best features of spectral methods and finite elements. Typically, it uses polyhedral elements; since these have a simple geometry, it is straightforward to adopt a spectral representation within each of them. The boundary conditions between elements give rise to a sparse-matrix problem, just as they did for the Galerkin method. By making the elements larger and using more modes to compensate for any loss of resolution, however, the size of this sparse-matrix problem can be reduced; this must be weighed against the benefit of using smaller, more localized elements to represent compact features.

The tradeoff, as stated earlier, would seem to be one between the *orthogonality* of the basis functions, useful for simplifying the solution procedure, and their *compact support,* useful for representing localized features. For example, basis splines are clearly compact but nonorthogonal, whereas sines and cosines are orthogonal but noncompact. From this point of view, one of the more exciting discoveries of the past ten years has been the fact that it is possible to construct sets of basis functions, called *wavelet bases,* that have both orthogonality and compact support. Like basis splines, these consist of different translations of a single canonical function, but they also include different scales as well. That is, a general wavelet expansion is of the form

$$f(x) = \sum_{j,k} b_{jk} W(2^j x - k), \tag{71}$$

where $W(x)$ can be chosen to satisfy a mixture of essential and optional requirements.

To get a general idea of how a wavelet basis is constructed, suppose that we are using the basis of normalized box functions,

$$\phi_j^{(l)}(x) \equiv \begin{cases} 1, & j \le x < j + 1, \\ 0 & \text{otherwise,} \end{cases} \tag{72}$$

where $j \in \{0, 1, 2, \ldots, 2^l - 1\}$, to represent piecewise constant functions on the interval $0 \le x < 2^l$. We can obviate the need for the subscript j by noting that

$$\phi_j^{(l)}(x) = \phi^{(l)}(x - j), \tag{73}$$

where $\phi^{(l)}(x) \equiv \phi_0^{(l)}(x)$; that is, the basis functions for different values of j are just translations of each other.

Next we consider the coarser basis obtained by scaling this one by a factor of 2. We define the scaled function

$$\phi^{(l-1)}(x) = \tfrac{1}{2}\phi^{(l)}\left(\frac{x}{2}\right) \tag{74}$$

and construct a basis with its translations,

$$\phi_j^{(l-1)}(x) = \phi^{(l-1)}(x - 2j). \tag{75}$$

The overall factor of $\frac{1}{2}$ on the right-hand side of Eq. (74) has been included to maintain normalization. Note that this coarser basis has only half as many basis functions as the one we started with. The finer basis is therefore capable of representing everything that the coarser basis can represent and more; specifically, it can represent a factor of 2 finer detail. To make this more explicit, note that each member of the coarse grid can be written as the sum of two members of the finer grid,

$$\phi_j^{(l-1)}(x) = \tfrac{1}{2}[\phi_{2j}^{(l)}(x) + \phi_{2j+1}^{(l)}(x)]. \tag{76}$$

It follows that the difference in resolution between the finer and coarser bases—that is, the space of functions that is spanned by the finer basis but is orthogonal to the coarser basis—is spanned by the set of functions

$$W_j^{(l-1)}(x) = \tfrac{1}{2}[\phi_{2j}^{(l)}(x) - \phi_{2j+1}^{(l)}(x)]. \tag{77}$$

These functions are called the *wavelets* corresponding to the basis of Eq. (72).

In more abstract terms, let us suppose

that the space of functions spanned by the $\phi_j^{(l)}(x)$ is called $\Lambda^{(l)}$, and that spanned by the $W_j^{(l)}(x)$ is called $\Omega^{(l)}$. The argument in the previous paragraph has demonstrated that

$$\Lambda^{(l)} = \Lambda^{(l-1)} \oplus \Omega^{(l-1)}. \tag{78}$$

That is, we have decomposed the original basis into the direct sum of its coarsening and a space of wavelets. We can now repeat this process with the space $\Lambda^{(l-1)}$, etc. The final result will be the decomposition of the original basis into a set of wavelet functions and their translations at each scale (plus possibly a constant function at the very coarsest scale). That is,

$$\Lambda^{(l)} = \Lambda^{(0)} \oplus \Omega^{(1)} \oplus \cdots \oplus \Omega^{(l-1)}. \tag{79}$$

It is clear from the method of construction that this decomposition results in an orthonormal basis.

Note that not all bases are capable of generating wavelets in the manner explained above. A fundamental requirement, satisfied by the hat function used above, is that each basis function at a given level of the hierarchy can be expressed as a linear combination of basis functions at the next finest level. That is, the basis functions ϕ must be such that

$$\phi(x) = \sum_k c_k \phi(2x - k), \tag{80}$$

for some constants c_k. It is not difficult to see that the condition that ϕ is normalized results in the constraint

$$\sum_k c_k = 2. \tag{81}$$

Not all functions will obey this *dilation equation.* Fortunately, as noted by Strang (1989), an amazing variety of familiar families of basis functions do obey it. For example, if $c_j = 2\delta_{j,0}$, then ϕ is the Dirac delta function. Our above example showed that the box function obeys the dilation equation with $c_0 = c_1 = 1$. Likewise, the piecewise linear functions of Eq. (50) on a uniform grid as illustrated in Fig. 7 also solve the dilation equation with $c_0 = c_2 = \frac{1}{2}$ and $c_1 = 1$.

The ability of these functions to represent polynomials in x can also be expressed as conditions on the c coefficients (Strang, 1989). Specifically, if the function

$$P(\xi) \equiv \tfrac{1}{2} \sum_k c_k e^{ik\xi} \tag{82}$$

has a pth-order pole at $\xi = \pi$, then the basis will be able to represent exactly all polynomials in x spanned by the set of monomials $\{1, x, x^2, x^3, \ldots, x^{p-1}\}$. Thus, the hat function used in the example mentioned above had $P(\xi) = \exp(ik\xi/2) \cos(k\xi/2)$, which has a pole of order $p = 1$, so it is capable of representing only piecewise constant functions.

Given a basis that obeys the dilation equation for some coefficients c, then the generalization of the hat-function argument given above shows that the corresponding wavelet basis is given by

$$W(x) = \sum_k (-1)^k c_{1-k} \phi(2x - k). \tag{83}$$

All of this formalism makes it straightforward to construct bases satisfying the dilation equation with the ability to represent polynomials of specified order and to construct the corresponding wavelet basis. Moreover, it can be shown that such wavelet bases, as a result of their hierarchical construction, possess a "fast" transform, like the FFT, so that they are of $O(N \log N)$ computational complexity for N data elements.

It is interesting to note that this procedure does not always result in smooth, well-behaved basis functions. In fact, Daubechies (1988) showed that the choice $c_0 = (1 + \sqrt{3})/4$, $c_1 = (3 + \sqrt{3})/4$, $c_2 = (3 - \sqrt{3})/4$, and $c_3 = (1 - \sqrt{3})/4$ results in a wavelet basis that is orthogonal, is compact on $[-1,2]$, and is capable of exactly representing any piecewise linear function. This function is illustrated in Fig. 8 (though it is differentiable almost nowhere, so that any graphical representation of it is rather dubious).

It is clear that wavelet bases that are able to represent higher powers of x exactly are a straightforward generalization of the above. On the other hand, wavelets do not diagonalize differential operators, as does a Fourier representation. Though a detailed discussion of the theory and usage of wavelets is outside the scope of this article, there are by now a very large number of references on this subject. At the time of this writing, this

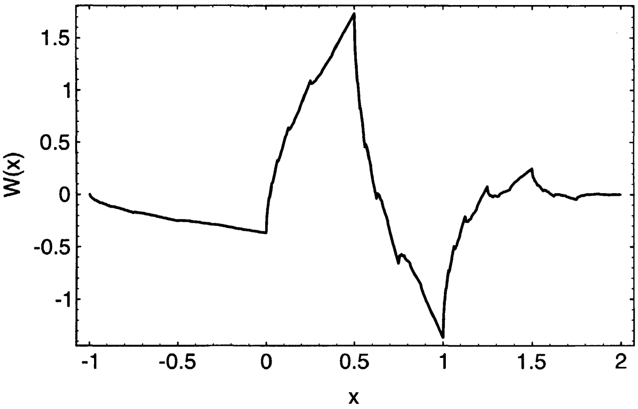

FIG. 8. Daubechies's wavelet function. In spite of this graphical representation, it should be noted that this function is not smooth and is differentiable almost nowhere.

remains a very active area of applied mathematical research.

6. PARTICULATE METHODS

From the above descriptions of finite-difference, finite-element, and spectral methods, the reader may have developed the impression that such methods are adequate for the simulation of any partial differential equation of interest in mathematical physics. In fact, nothing could be further from the truth. Certain partial differential equations are capable of generating structures on arbitrarily small length scales of their dependent variable(s). When we examined finite-difference approximations to the Navier–Stokes equations, for example, we discovered that the need for a grid fine enough to resolve the very smallest vortices was an important and severe restriction; in spite of this, we can feel at least somewhat fortunate that there is some nonzero lower bound on the structures developed by the Navier–Stokes equations at any finite Reynolds number. Imagine how much more difficult it is to simulate the Euler equations of inviscid fluid flow or the Poisson–Vlasov equations of plasma physics, which have no viscous terms to damp out the development of structures below a certain length scale. The structures developed by the evolution of such *Hamiltonian systems* can become arbitrarily filamentary, so that their representation on any fixed spatial grid, or using any fixed set of basis functions, is invalidated in finite time.

In spite of this seeming intractibility, it is possible to make numerical progress on such problems. One approach is to try to develop a spectral method with N modes that is a Hamiltonian system *for all N.* In this way, even the finite-dimensional truncated system is Hamiltonian, and has a symplectic phase-space structure—that is, the time rate of change of any phase-space function F is given by $\{F,H\}$, where H is a Hamiltonian and $\{\cdot,\cdot\}$ is a Poisson bracket that is bilinear and antisymmetric and obeys the Jacobi identity. For example, this was accomplished for Euler's ideal-fluid equations by Miller *et al.* (1992). While such methods are still not capable of representing arbitrarily filamentary modes, they at least respect the various constraints imposed by Hamiltonian evolution—conservation of phase-space volume and the integral invariants of Poincaré—to numerical accuracy (Channell and Scovel, 1990); this is analogous to the way that the operator-splitting method described above respected unitarity.

Another general method for simulating systems of this sort has been to abandon the spatial (or spectral) discreteness that has characterized all of the methods that we have considered thus far, and represent the field by the density of local particles, each of which is free to take its location in the continuum. That is, instead of an *Eulerian representation* of a dependent variable $\Psi(\mathbf{x}_j,t)$ at each point of a spatial grid, we might adopt a *Lagrangian representation* in which we keep track of the spatial coordinates, and perhaps weights, of some finite number of particles at each time step. This method does not require any kind of grid at all, though we note in passing that the finiteness of floating-point precision on any real computer is tantamount to the existence of a very fine grid, in that particle positions are restricted to a discrete set of values. Also, there exist hybrid algorithms, such as the *particle-in-cell* method, in which some quantities are represented on a grid and others are represented by discrete particles.

6.1 Short-Range Interactions

The first and most intuitive application of particulate methods is their use for tracking the positions and velocities of discrete particles, such as molecules, interacting according to a known classical force law. Such *molecular dynamics* (MD) algorithms are distinguished by their application to either short-range or long-range force laws (or both together). An example of the former is the Lennard-Jones potential,

$$V_{\mathrm{LJ}}(r) = V_0[(r_0/r)^{12} - (r_0/r)^6]. \tag{84}$$

This interaction potential drops off so sharply for large r that effects of particles outside of a certain *interaction sphere* can be simply ignored. Alternatively, one may employ a version of this potential for which this cutoff is explicitly enforced by taking

$$V(r) = \begin{cases} V_{\mathrm{LJ}}(r) - V_{\mathrm{LJ}}(r_1) & \text{for } r < r_1, \\ 0 & \text{otherwise,} \end{cases} \tag{85}$$

where the radius of the interaction sphere is $r_1 > r_0$. By contrast, the Coulomb potential

$$V(r) = e^2/r, \tag{86}$$

where e is the electric charge, can almost never be truncated because although the force decays like r^{-2}, the number of particles between distance r and $r + dr$ generally increases like r^2 so that effects of distant particles cannot be ignored.

In a purely Lagrangian representation of a system of particles with short-range interactions, only the coordinates of each particle need to be represented. The data structure might therefore consist of coordinates $\mathbf{x}_j$ for $j \in \{1, \ldots, N\}$, where N is the total number of particles. The force on a particle is computed by taking the vector sum of the forces due to all of the other particles in its interaction sphere. The challenge here is to find a way to compute this in a time that is linear in N, rather than quadratic. This ought to be possible, since for a substance at a given average density and temperature, there are only a fixed characteristic number of particles in an interaction sphere. If we denote this number by ν, then we need to compute on the order of νN forces. While this is linear in N, it is not obvious how to determine which other particles are in the interaction sphere of a given particle in a time that is linear in N. For example, everybody's first try at the problem,

```
DO i = 1, N
 DO j = 1, N
  IF(DISTANCE(i, j) < r1) FORCE(i) =
   FORCE(i) + GET_FORCE(i, j)
 END DO
END DO
```

(where the functionality of the variously called routines is obvious from their names), will decidedly *not* work. Even though the `IF` test is satisfied only on the order of ν times for each i, just the testing to see if the particles are farther than a distance r_1 apart will take on the order of N^2 operations in the above code. Since the very largest MD simulations run today use hundreds of millions of particles, no portion of the algorithm may be of order N^2 complexity.

Fortunately, there are numerous well-researched parallel algorithms for rapidly determining and updating the list of neighbors of a given particle (Allen and Tildesley, 1987). Interestingly, most algorithms for determining neighbors employ an Eulerian grid of some sort. If the grid is regular, each particle may easily determine which grid cell it is in, and the particles may be sorted according to cell number. "Bookkeeping" problems arise due to particles that are near cell boundaries, but they are surmountable. Moreover, once a list of neighbors has been determined for each particle, this *neighbor table* may be updated incrementally, rather than recomputed from scratch at each time step. Using all of these various tricks (and more) on large parallel computers, MD simulations with between 10^8 and 10^9 particles and with a characteristic performance of 10^{-8} s per particle update (the standard figure of merit for MD simulations) have been achieved (Zhou *et al.*, 1997).

6.2 Molecular Dynamics

The most straightforward type of MD simulation tracks the motion of a fixed number N of particles, constrained to move inside a fixed volume V. Periodic boundary conditions are often employed to emulate a large homogeneous sample of matter. Newton's equations for these particles,

$$\dot{\mathbf{r}}_i = \mathbf{p}_i/m_i, \tag{87}$$

$$\dot{\mathbf{p}}_i = \sum_{j\neq i}^{N} \mathbf{F}(i \leftarrow j), \tag{88}$$

where $\mathbf{F}(i \leftarrow j)$ is the force on particle i due to particle j, derivable from a time-independent potential $V(\mathbf{r})$, will conserve the total energy

$$E = \sum_{i}^{N} \frac{p_i^2}{2m_i} + \tfrac{1}{2}\sum_{i\neq j} V(|\mathbf{r}_i - \mathbf{r}_j|). \tag{89}$$

The state of the system thus samples the microcanonical ensemble. The average *kinetic* energy, and hence the temperature, will fluctuate. Typically, some desired property, such as a virial coefficient, a dielectric constant, or the shear viscosity, is time-averaged over the dynamics. For example, if the desired quantity is denoted by χ, the quantity

$$\langle\chi\rangle = \lim_{T\to\infty} \frac{1}{T}\int_0^T dt\chi(t) \tag{90}$$

is accumulated during the run. Its relationship to the true equilibrium value of this quantity thus rests on the assumption of ergodicity.

The first MD simulations were investigations of hard-disk fluids, carried out by Alder and Wainwright (1957) in the late 1950s. In a later article (Alder and Wainwright, 1967), these authors used such simulations to establish the existence of *long-time tails* in particles' velocity autocorrelation functions; that is, the quantity $\langle\mathbf{v}(0)\mathbf{v}(t)\rangle$, averaged over a large ensemble of particles, was found not to decay exponentially in time, as had been the common assumption, but rather to decay according to a power law. This unexpected result, of substantial physical import, was a great triumph of the MD method.

The number of particles that could be simulated at that time was in the tens or hundreds; as noted above, it is now in the hundreds of millions. Though this is undeniably a drastic improvement, it needs to be put into perspective: It is still only 10^{-15} moles of material. In terms of physical time, one time step of an MD simulation is on the order of 10^{-15} s. The very longest runs can carry out 10^7 time steps, for a total of about 10 ns of physical time. This is long enough for the energy to reach equipartition, and to compute many equilibrium properties of interest, transport coefficients, etc. Certain phenomena, however, such as protein folding and the dynamics of molecular clumps in glassy materials, occur on much longer time scales, and MD has been inadequate for their investigation. This is particularly true of *soft condensed-matter* applications, such as the development of micelles from dissolved surfactant, the response of liquid crystals to external fields, and the Brownian fluctuations of colloidal particles. Such *complex fluids* develop *mesoscale* structures—with characteristic lengths and times that are much larger than a mean free path and a mean free time, respectively—that dominate their macroscopic behavior.

Much work has been done over the last 20 years to accelerate the thermalization of molecular dynamics simulations. Two principal methodologies have been adopted for this purpose. One is to alter the particles' positions and/or momenta occasionally in stochastic fashion; the challenge here is to do this in a way that allows the particles to sample the phase space more rapidly than strict adherence to the Newtonian trajectories would allow, but to avoid doing such extensive damage to those trajectories that dynamic properties, such as time correlation functions and transport coefficients, are rendered meaningless. A number of recent methods adopt this strategy; these include, but are not limited to, lattice-gas automata (Frisch *et al.*, 1986, 1987), dissipative particle dynamics (Hoogerbrugge and Koelman, 1992; Espanol, 1995), the Langevin method (see, e.g., Toral, 1995), the lattice Boltzmann equation (Chen, 1998), direct-simulation Monte Carlo (Bird, 1994; Garcia, 1994), hybrid Monte Carlo (Heermann, *et al.*, 1990), and smoothed-particle hydrodynamics (Monaghan, 1992). The first of these is discussed further in Sec. 6.5.

Another method of accelerating the calculation of certain quantities of interest is to use an ensemble other than the microcanonical one (constant E, V, and N) described above. For example, Nosé (1986) and Hoover (1985) have shown how to modify particulate equations of motion so that the particles are no longer constrained to the energy surface, but rather provide a sampling of the full canonical ensemble at specified temperature.

6.3 Long-Range Interactions

Long-range interactions are ubiquitous in physics. Charged particles in a plasma may interact according to the Coulomb potential. Interactions between stars in a galaxy, and indeed between galaxies in the expanding universe, may be modeled by the Newtonian gravitational potential. Somewhat less well known is the fact that particulate methods with long-range interactions may also be used to model incompressible fluid flow. For example, defining the *vorticity* of a fluid as the curl of its hydrodynamic velocity

$$\boldsymbol{\omega} \equiv \nabla \times \mathbf{v}, \qquad (91)$$

and noting that

$$0 = \nabla \cdot \mathbf{v} \qquad (92)$$

for an incompressible fluid, we recognize the similarity of these equations to those of magnetostatics: Velocity plays the role of the magnetic field **B** (whose divergence vanishes), and vorticity plays the role of the current density **J** (equal to the curl of the velocity). It follows that vortex filaments give rise to velocity fields according to the same Biot–Savart law that describes how current filaments give rise to magnetic fields. We can thus represent the fluid motion by vortex filaments in three dimensions (or point vortices in two dimensions), rather than the usual scheme of representing the velocity directly. Furthermore, if we take the curl of both sides of the Navier–Stokes equation for momentum conservation, Eq. (25), we can derive the equation of motion of these vortex filaments (or points). It turns out that each moves in the velocity field of all the other vortices present and also has a random velocity component to model the viscous diffusion of momentum. To move the vortices at each step therefore requires summing the Biot–Savart law for the velocity at each one due to all of the others. Thus, the *vortex method* reduces the problem of incompressible fluid flow to that of long-range "particle" interactions (Gustafson and Sethian, 1991).

The most obvious way to sum up all of the forces is then something like

```
DO i = 1, N
 DO j = 1, N
  FORCE(i) = FORCE(i) +
   GET_FORCE(i, j)
 END DO
END DO
```

Clearly, this has order N^2 complexity, but this seems insurmountable since the forces are long range, and every particle really does interact with every other. In one of the more counterintuitive algorithmic results to be recently discovered in this field, it has been shown (Rokhlin and Greengard, 1987) that—for the special case of the Coulomb force—the required summation can be accomplished to machine precision with order-N computational complexity. This *fast multipole algorithm* makes use of the fact that forces due to distant particles can be approximated by a multipole expansion. It applies this observation in a recursive fashion: We first subdivide the spatial domain into eight parts using three mutually perpendicular planes in three dimensions (four parts using two perpendicular lines in two dimensions) and continue to subdivide the parts in the same way to obtain an *oct-tree* division of the spatial domain in three dimensions (*quad-tree* in two). The two-dimensional case is illustrated in Fig. 9. From its coordinates, it is straightforward for each particle to determine which "leaf" it occupies on such a tree, and the number of branchings is taken such that there is on the average of only a few particles per leaf. The algorithm begins by computing the multipole moments of each leaf. It then takes advantage of the fact that, for the Coulomb potential, multipole moments of "child" and "sibling" domains can be easily combined to get multipole mo-

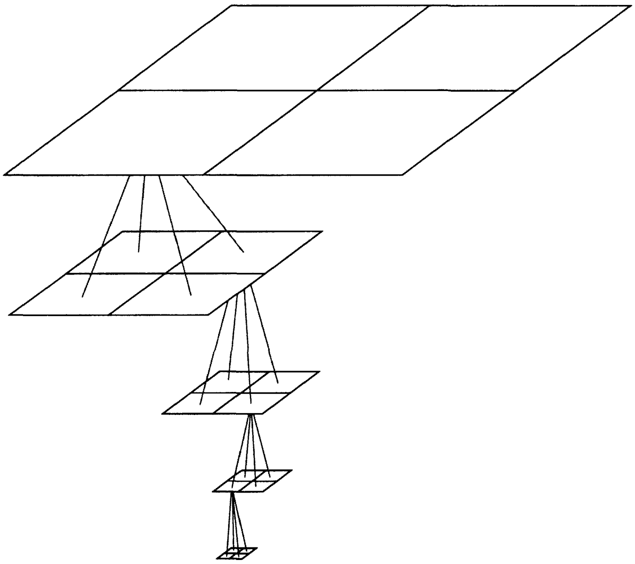

FIG. 9. Quad-tree division of spatial domain.

ments of "parent" domains. Thus, it works its way to the root of the tree, computing the multipole moments of each division at each level. Next, it recursively works its way back to the leaves, using the multipole moments of distant "parent" domains to obtain their contributions to the potential in every "child" domain. When it arrives at the leaves, it has the potential (or the force) at each leaf due to all of the other sites on the finest grid. Finally, it adds the contribution due to the other particles in the same cell. Since there are 4^j domains at level j and $\log_4 N$ levels in the tree, the number of operations performed is on the order of

$$\sum_{j=0}^{\log_4 N} 4^j = \frac{4^{\log_4 N} - 1}{4 - 1} \sim N \tag{93}$$

for a fixed desired accuracy. In practice, this accuracy can be made greater than machine precision, resulting in an algorithm that is, for all intents and purposes, exact.

6.4 Particle-in-Cell Methods

Even with the fast multipole algorithm, the number of Coulombic particles that may be simulated on a computer is far less than the corresponding number for short-range force laws. There is thus great interest in approximate methods with reduced computational complexity. An important example of such a method is the *particle-in-cell* algorithm. This is a hybrid Eulerian/Lagrangian technique, in which one keeps track of particle coordinates, but uses a grid to compute the fields by which these particles move.

As an example, let us consider a particle-in-cell simulation of a pure electron plasma confined by magnetic and electrostatic fields in a Penning trap (Chu, 1993). The plasma is confined in cylindrical geometry, with the magnetic field in the z direction. Each particle undergoes a very rapid gyration in the xy plane due to the magnetic field. Superposed on this is a bounce motion in the z direction due to the confining electrostatic potential. If we average over the cyclotron and bounce periods, we can consider the evolution of the density of gyration/bounce centers as these drift perpendicularly to the magnetic field,

$$\frac{\partial n(\mathbf{x},t)}{\partial t} + \mathbf{v}_{\mathbf{E}\times\mathbf{B}} \cdot \nabla n(\mathbf{x},t) = 0. \tag{94}$$

Here we have defined the $\mathbf{E} \times \mathbf{B}$ drift velocity,

$$\mathbf{v}_{\mathbf{E}\times\mathbf{B}} \equiv c\mathbf{E} \times \mathbf{B}/B^2 = (c/B)\hat{\mathbf{z}} \times \nabla\Phi(\mathbf{x},t), \tag{95}$$

which is a well-known systematic drift of charged particles confined in crossed electric and magnetic fields. In this case, the electric field is due to the plasma itself,

$$\nabla^2\Phi(\mathbf{x},t) = -4\pi(-e)n(\mathbf{x},t). \tag{96}$$

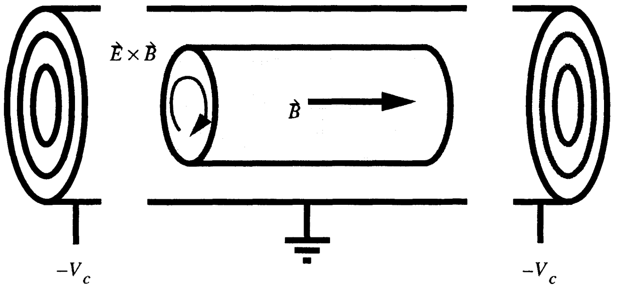

FIG. 10. Penning trap for pure-electron plasma. The plasma is confined radially by an axial magnetic field **B**, and axially by an applied electrostatic potential v_c. It drifts azimuthally with the drift velocity **E** × **B**.

The boundary condition is that the potential must be zero at the grounded outside wall. This is illustrated in Fig. 10.

In a particle-in-cell simulation, we keep track of the position coordinates of each particle. Since we have averaged over the motion in the z direction, our problem is really two dimensional, and so we keep two coordinates (e.g., r and θ) for each particle. At each time step we "smear" these particles onto a grid to get a charge density. This is done by the linear interpolation scheme illustrated in Fig. 11. Note that a polar-coordinate grid is used. The charge is divided among the four grid points at the corners of its cell, and we then divide by the area of that cell to get the local charge density.

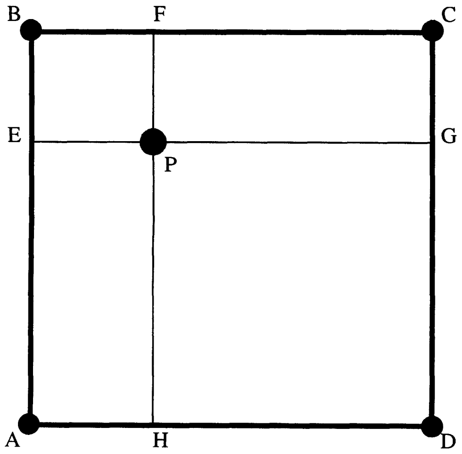

FIG. 11. Linear interpolation of particles to grid. The particle at position P contributes a fraction $a(PFCG)/a(ABCD)$ of its charge to grid point A, $a(PDGH)/a(ABCD)$ to grid point B, $a(PHAE)/a(ABCD)$ to grid point C, and $a(PEBF)/a(ABCD)$ to grid point D; here $a(ABCD)$ denotes the area of the quadrilateral $ABCD$.

Once the charge density is known on the grid, we can solve the Poisson equation, Eq. (96), to get the potential on the grid. This may be done by Fourier transformation in the θ direction (since it is periodic), and by solving a tridiagonal system of linear equations in the r direction. By finite differencing this potential, we can get the electric-field components on the grid. Using the same weighting factors that were used to spread the charge from the particles to the grid points, we can now interpolate to get the field at each particle's position. Each particle can then compute its local **E** × **B** drift velocity and take a step along the characteristics of Eq. (94),

$$\frac{d\mathbf{x}}{dt} = \mathbf{v}_{\mathbf{E}\times\mathbf{B}}. \tag{97}$$

The resulting simulation technique is capable of following the evolution of the plasma as it breaks down into wispy filaments that would be very difficult to capture in a purely Eulerian or spectral representation. Plate 1 illustrates a particle-in-cell simulation with 131 072 particles moving on a spatial grid of dimension 256 × 256.

A wide body of literature is available on this simulation technique. A particularly nice review of plasma-physics applications of the particle-in-cell method can be found in the book by Birdsall and Langdon (1985).

6.5 Lattice-Gas Hydrodynamics

In this subsection, we review a procedure for simulating the *nonequilibrium* behavior of viscous fluids. This technique, called *lattice-gas hydrodynamics,* deserves special mention because it introduces an entirely new paradigm for using the computer to simulate a physical system. Ironically, it is a return to von Neumann's *cellular automata* computational paradigm.

Hydrodynamic lattice gases take the same "minimalist" approach to fluids that the Ising model takes to ferromagnets. The object is not a precise model of the dynamics at the finest scales, but rather to invent a fictitious microdynamics whose *coarse-grained* behavior—in the thermodynamic limit—lies in the same universality class as the phenomenon under study.

At first glance, this approach is not unreasonable. Many different fluids found in nature obey the Navier–Stokes equations of viscous fluid dynamics; for example, oil and air both obey these equations in the proper regime, in spite of the fact that their molecular dynamics are radically different. Clearly there is something universal about the Navier–Stokes equations in the hydrodynamic limit. Indeed, kinetic theory tells us some of the reason for this: The *Chapman–Enskog* expansion in the Knudsen number, by which one derives the form of the hydrodynamic equations from the Boltzmann kinetic equation, yields the Navier–Stokes equations for a wide variety of fluids whose particles interact with short-range forces, as long as those interactions conserve mass and momentum.

A lattice gas is then an attempt to define the simplest system of interacting particles on a lattice, whose collisions conserve mass and momentum, and thus whose coarse-grained behavior can be expected to obey the Navier–Stokes equations. We work on a triangular lattice (Frisch *et al.*, 1986) in two dimensions; since this has a coordination number of 6, we take a dependent variable of 6 bits per site, reflecting the presence or absence of a particle moving along each of the six lattice vectors leaving the site. At each tick of the clock, the particles stream along their respective lattice vectors and collide with the other incoming particles at their new site. The collisions are required to conserve mass and momentum. The only nontrivial collisions for this two-dimensional model are enumerated in Fig. 12.

By taking block space and/or time averages of the velocities of these particles, one can derive a local hydrodynamic velocity. Kinetic theoretical arguments can then be used to demonstrate that this velocity field satisfies the Navier–Stokes equations. Note that this approach is fundamentally different from a finite-difference approximation of the Navier–Stokes equations. The intent here is not to start with the continuum equations and discretize them, but rather to start with a fundamentally discrete system of particles, and make them interact in such a way that the Navier–Stokes equations are *emergent,* just as they are for natural fluids. That is, lattice-gas automata (LGA), like molecular dynamics, are a particulate *simulation* of the physical system under study, rather than the *numerical solution* of hydrodynamic partial differential equations. Because of this approach, LGA share (at least) two important properties of real fluids: First, they have absolutely *exact* conservation laws—down to the last bit in the simulation. Second, approximate methods for computing their transport coefficients (i.e., predicting their viscosity using the Boltzmann molecular

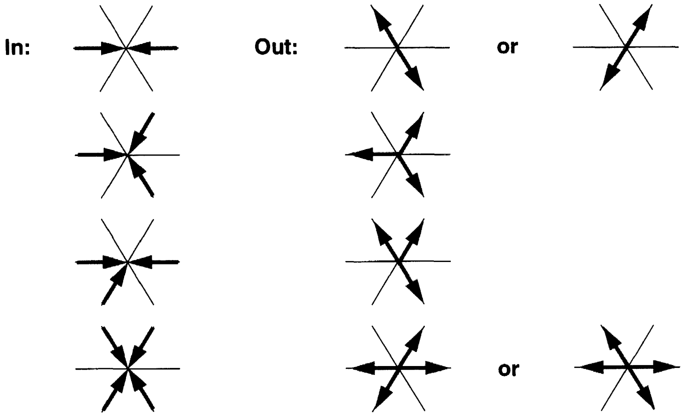

FIG. 12. Nontrivial collisions of a hydrodynamic lattice gas in two dimensions. The collisions shown conserve mass and momentum. In *all* other situations, the particles pass through each other without interacting.

chaos approximation) are often inaccurate. Consequently, practitioners of this method often have to measure such bulk properties in controlled flow situations, sometimes called *numerical experiments,* in order to calibrate runs for more interesting geometries or Reynolds numbers. This is, of course, exactly analogous to what is done by real experimentalists.

The triangular lattice is required for *isotropy* in two dimensions. Indeed, earlier versions of hydrodynamic lattice gases were tried on Cartesian grids in the 1970s (Hardy *et al.,* 1973, 1976) and were demonstrably anisotropic. The method became feasible for computational fluid dynamics only when it was shown by Frisch *et al.* (1986) that going from a Cartesian to a triangular grid did not just improve anisotropy—it eliminated it altogether! The reason for this is tied up with the symmetry properties of the lattice, and it is beyond the scope of this article. Lattices with requisite symmetry exist in three dimensions (Frisch *et al.,* 1987).

It is possible to introduce the Monte Carlo sampling of collision outcomes into this method, in order to hasten the approach to a local thermodynamic equilibrium for systems of interacting particles. By introducing multiple particle species and different types of interactions and by Boltzmann-weighting collision outcomes, immiscible fluid flow (Rothman and Zaleski, 1994), coexisting liquid and gas phases (Appert *et al.,* 1991), and amphiphilic fluids (Boghosian *et al.,* 1996) have all been modeled using this technique.

From a philosophical point of view, it is fascinating that the lattice-gas approach has effectively reduced hydrodynamics to logic. It simulates fluid motion by purely logical operations on bits—the kind of thing that a computer can do exactly, without approximation. Moreover, unlike floating-point representations of data, all of the bits present play essentially the same role in the simulation; this quality is sometimes referred to as "bit democracy," and vaguely indicates that the computer is being used in a more natural and efficient way than it is in a floating-point simulation. Indeed, the success of the lattice-gas paradigm has spurred more general studies of discrete particle mechanics on lattices. In particular, Baez and Gilliam (1994) have used ideas from algebraic geometry to generalize the methods of Lagrangian and symplectic mechanics to systems that are discrete in time, space, and dependent variable—including cellular automata, but also including more general discrete systems. They show how to construct action principles and derive an analog of the Euler–Lagrange equations for such systems. Their methods hold the promise of an entirely new way to discretize physical problems for computer implementation, and it is likely that this will be an active area of research in the coming years.

7. STATISTICAL METHODS

The study of particulate methods naturally leads us to study the statistical methods of computational physics. It is well known that stochastic methods are often useful for the estimation of multidimensional integrals. For example, students in introductory statistics courses are taught to estimate the value of π by placing points (x,y) randomly in the square $-1 \le x < +1$, $-1 \le y < +1$, and determining what fraction of the time they lie within the unit circle $x^2 + y^2 < 1$. As the number of points used goes to infinity, this fraction will approach $\pi/4$. A Fortran 90 program to implement this procedure might be

```
REAL FUNCTION ESTIMATE_PI(n)

 IMPLICIT NONE
 INTEGER :: i, n, count
 REAL :: x, y

 count = 0

 DO i = 1, n
  CALL RANDOM_NUMBER(x)
  x = 2.0*(x - 0.5)
  CALL RANDOM_NUMBER(y)
  y = 2.0*(y - 0.5)
  IF (x**2 + y**2 < 1) count = count
   + 1
 END DO

 estimate_pi = 4.0*FLOAT(count)/
  FLOAT(n)

END FUNCTION ESTIMATE_PI
```

This procedure is estimating the multidimensional integral

$$\int_{-1}^{+1} dx \int_{-\sqrt{1-x^2}}^{+\sqrt{1-x^2}} dy. \tag{98}$$

Suppose that we had checked to see if the points were in the circle of radius $\frac{1}{2}$, rather than the unit circle. Then the fraction of time that points were in the circle would have been $\pi/16$, and we could have multiplied by 16 to get π. This algorithm seems equivalent, but it is actually much worse. This is because the number of points that actually fall into the circle of radius $\frac{1}{2}$ is much smaller (by a factor of 4) than the number that fall into the unit circle, thereby worsening the statistics. In fact, it is an elementary exercise to determine that the fractional error of the result is $[(1 - p)/pn]^{1/2}$, where n is the number of samples and $p \equiv \pi R^2/4$ is the probability of the particle actually falling into the circle of radius $R \leq 1$. There is thus a strong incentive to increase p as much as possible, so the unit circle is preferable to that of radius $\frac{1}{2}$. Indeed, if we could find a way to make $p = 1$, the fractional error would vanish altogether. We could, for example, try to use the inscribed circle of a pentagon, hexagon, etc., rather than a square. Unfortunately, it is much more difficult to sample points efficiently in these polygons than in a square, so that there is a point of diminishing returns. This is, however, a special case of a more general rule: Monte Carlo methods work best when the samples can be taken from the problem's natural distribution function. We shall see this issue reappear in the following subsection.

Note that the standard deviation of the result for n points sampled goes as $n^{-1/2}$, so that something on the order of 10^8 points would be required to obtain π to four decimal places. While this may not be a particularly good way of obtaining the digits of π, it is often the only method available to estimate multidimensional integrals of the sort encountered in statistical physics. Recall that the equilibrium properties of a statistical mechanical system can be computed from the *partition function,*

$$Z = \sum_{s} e^{-\beta H(s)}, \tag{99}$$

where β is the inverse temperature, the sum extends over all possible states s of the system, and $H(s)$ is the energy of the system in state s. The challenge in computing Z is that the sum over states is typically huge. In fact, for systems with a continuum of states, this sum may be replaced by an integral, but in either case it is likely to be multidimensional so that the set of possible states s is enormous. The example of the Ising model, considered in the following subsection, illustrates this point.

7.1 Spin Systems

The *Ising model* is the prototype of a class of statistical physics models known as *spin systems.* It was developed by Lenz (1920) in 1920 as a model of ferromagnetism, and posed as a problem to his student, Ising, who solved the one-dimensional version of the model in 1925 (Ising, 1925). The model considers n "spins" described by $s_i \in \{-1, +1\}$ for $i = 1, \ldots, n$, on a lattice of D dimensions. In its simplest incarnation, the system's Hamiltonian has the form

$$H(s) = \frac{J}{2} \sum_{(i,j)} s_i s_j - B \sum_{i} s_i, \tag{100}$$

where the first sum is taken over all *neighboring pairs* of spins on the lattice. If b is the *coordination number,* the number of neighbors of any point on the lattice, then the first sum has bn terms; since this doubly counts the energy, a factor of $\frac{1}{2}$ is included with the coupling constant J in front of this sum. The second sum models an external field of strength B. The problem is to find the partition function of the system,

$$Z = \sum_{s_1=-1}^{+1} \sum_{s_2=-1}^{+1} \cdots \sum_{s_n=-1}^{+1} e^{-\beta H(s)}, \tag{101}$$

as a function of βJ and βB. While Ising's $D = 1$ solution is elementary, Onsager's $D = 2$ solution for $B = 0$ required almost another 20 years (Onsager, 1944) and is decidedly more complicated. The $D = 2$ solution for $B \neq 0$ is a relatively recent development, first published by Zamalodchikov (1989). The problem for $D = 3$ is outstanding, even for $B = 0$, and our knowledge of the behavior of Z in three dimensions rests almost entirely on numerical simulation.

At the root of the problem is the fact that the sum in Eq. (101) contains 2^n terms, and we would like to have the result in the *thermodynamic limit* as $n \to \infty$. While we may be able to perform this sum numerically for 20 spins (2^{20} terms in the summation) without much problem, it is clear that the problem is completely intractable if the spins number in the hundreds. Moreover, important equilibrium features, such as phase transitions, are sharply defined only in the thermodynamic limit. To see this, we compute the internal energy of the $D = 2$ Ising model by numerically summing Eq. (101) (and its derivative with respect to β) for 2×2, 3×3, and 4×4 lattices, and we plot these alongside Onsager's exact result in Fig. 13.

In analogy to our computation of π, we might suppose that we could *sample* the value of the internal energy by the following procedure:

1. Initialize the totals T_1 and T_2 to zero.
2. Perform the following loop N times:
   a. Randomly choose a state s.
   b. Compute the energy $H(s)$.
   c. Increment T_1 by $e^{-\beta H(s)}$.
   d. Increment T_2 by $H(s)e^{-\beta H(s)}$.
3. Estimate the energy by the ratio T_2/T_1.

This seems straightforward to implement, even for very large lattices, but it has a fatal problem: For all but the highest of temperatures, the vast majority of the total energy is accounted for by a miniscule fraction of the set of all possible states. Thus, if we sample this set *uniformly* in step **2**a of the above algorithm, we will almost never encounter the most important states, and our variance will be unacceptably high.

This is reminiscent of the problem we had when we made the radius of the circle smaller in the algorithm for calculating π in Sec. 7. Here, as there, the solution is to try to sample the states from the problem's natural distribution function. That is, we would ideally like to sample the states s with probability

$$f(s) = e^{-\beta H(s)}/Z. \tag{102}$$

Then we could simply add up the energies sampled, and divide by the total number of samples to obtain the average internal energy. It seems that we cannot do this directly, however, since the probability depends on the partition function Z, and that is, after all, one of the things that we are trying to use the Monte Carlo method to compute in the first place.

7.2 Metropolis Monte Carlo

The apparent impasse described in the last subsection was broken by an ingenious algorithm due to Metropolis *et al.* [1953]. Since then, a number of variants of this algorithm have been developed, but we describe the original one here.

The algorithm allows one to begin with a randomly selected state, but describes a Markov process for selecting all subsequent states. That is, if the system is currently in state s, the probability that this Markov process will induce a transition to a new state s'

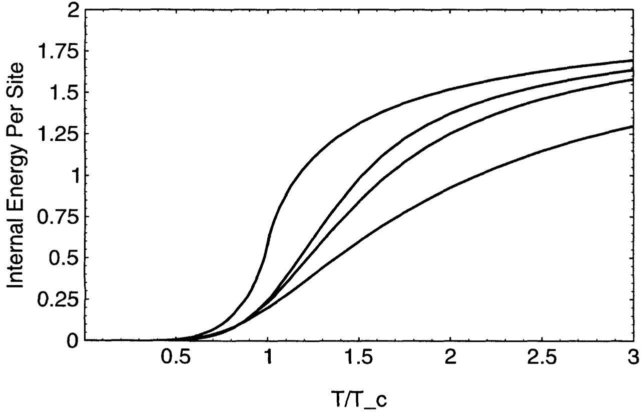

FIG. 13. Internal energy of two-dimensional Ising model. The curves are for 2×2, 3×3, and 4×4 lattices and an infinite lattice, in increasing order. The slope discontinuity at the critical temperature $T/T_c = 1$ is obtained only in the thermodynamic limit.

is called $K(s' \leftarrow s)$ and is specified by the algorithm in such a way that the time asymptotics of the Markov chain will sample the system with some desired probability function $f(s)$. It accomplishes this by demanding that the Markovian dynamics obey the condition of *detailed balance,* which ensures that it will converge to a thermodynamic equilibrium with distribution f. This condition may be written

$$f(s)K(s' \leftarrow s) = f(s')K(s \leftarrow s'). \tag{103}$$

The Metropolis selection process occurs in two steps: In the first, the new *trial state* s' is selected with some probability $T(s' \leftarrow s)$. In the second, the trial state is accepted with probability $A(s' \leftarrow s)$; otherwise, it is rejected and the system returns to the original state s. Thus, we may write

$$K(s' \leftarrow s) = T(s' \leftarrow s)A(s' \leftarrow s), \tag{104}$$

so that the condition of detailed balance becomes

$$f(s)T(s' \leftarrow s)A(s' \leftarrow s) = f(s')T(s \leftarrow s')A(s \leftarrow s'), \tag{105}$$

which may in turn be written

$$\frac{A(s' \leftarrow s)}{A(s \leftarrow s')} = \frac{f(s')T(s \leftarrow s')}{f(s)T(s' \leftarrow s)} \equiv Q(s' \leftarrow s). \tag{106}$$

Note that the identity

$$Q(s' \leftarrow s) = \frac{1}{Q(s \leftarrow s')} \tag{107}$$

is manifest from the definition of Q. We would like to be able to specify the desired distribution f; this is usually a Gibbsian equilibrium distribution for statistical physics applications. We would also like to specify the probability T of choosing a trial state in some convenient fashion. Thus, we would like to regard Q as an independent variable and demand that the acceptance probabilities satisfy the detailed-balance condition. To this end, we demand a functional relationship between the acceptance probability A and the independent variable Q; that is, we demand

$$A(s' \leftarrow s) = F(Q(s' \leftarrow s)) \tag{108}$$

for some function F. It immediately follows that

$$\frac{F(Q(s' \leftarrow s))}{F(1/Q(s' \leftarrow s))} = Q(s' \leftarrow s), \tag{109}$$

or, since this should hold for any Q, we look for functions F that obey

$$F(z) = zF(1/z) \tag{110}$$

for all $z \geq 0$. Fortunately, there is no shortage of functions that obey this condition. The one most often used in simulations of the Metropolis algorithm is

$$F(z) = \min(1,z), \tag{111}$$

though

$$F(z) = z/(1 + z) \tag{112}$$

also works, and there are many other possibilities as well.

We can now give a full statement of the algorithm for the sampling of a Gibbsian distribution, such as are encountered in statistical physics. The distribution is of the form of Eq. (102) for a system with Hamiltonian H and partition function Z. Since we do not know the latter, we cannot sample directly from this distribution. We can, however, sample a trial state from $T(s' \leftarrow s)$ and form the quantity Q described above, since this involves only ratios of the distribution f. In the simplest algorithms of this sort, the selection of a trial state is subject only to the restriction that

$$T(s' \leftarrow s) = T(s \leftarrow s'), \tag{113}$$

in which case

$$Q(s' \leftarrow s) = f(s')/f(s) = e^{-\beta[H(s')-H(s)]}. \tag{114}$$

The acceptance probability is then

$$A(s' \leftarrow s) = F(Q(s' \leftarrow s)) = \min(1,e^{-\beta[H(s')-H(s)]}). \tag{115}$$

The Markov process is then simple to describe: If one is in state s and proposes to move to a new state s', one first computes the change in energy $\Delta H(s' \leftarrow s) = H(s') - H(s)$ associated with this move. If it is negative—so that the move is to a state with less energy—one accepts the move unconditionally. If, on the other hand, $\Delta H(s' \leftarrow s)$ is positive—so that the move is to a state with greater energy—one accepts this move only with a probability $\exp[-\beta \Delta H(s' \leftarrow s)]$. Alternatively stated, one generates a uniformly distributed random number $r \in [0,1]$ and accepts the move to state s' only if $r < \exp[-\beta \Delta H(s' \leftarrow s)]$ [since this will always be true if $\Delta H(s' \leftarrow s) < 0$]. Note that for high temperatures this criterion is likely always to be accepted, so the sampling of states is really uniformly distributed; for low temperatures, on the other hand, the algorithm actively prevents one from visiting states with energies that are too high. In practice, since the randomly selected starting state is not likely to be particularly probable, one must "thermalize" this algorithm for some number of Markov steps before beginning to measure expectation values.

Using the Metropolis algorithm one can, for example, determine the equilibrium properties of a gas of classical molecules with arbitrary interaction potential. Recall that an analytic treatment of this problem results in an Ursell–Mayer cluster expansion (see, for example, Reichl, 1980). A serial algorithm for this problem is easy to describe: Begin with a random configuration of molecules, and try to move them at random, one at a time. For each proposed move, calculate the change of energy that would result and accept or reject that move according to the Metropolis criterion. After a while, the molecules will reach thermal equilibrium, and one can begin to take samples of any thermodynamic quantity of interest.

In recent years, a wide variety of improvements on this basic algorithm have been proposed. The most basic of these is the *biased sampling* of trial configurations, favoring those that are most consistent with the natural distribution function of the system under study—to the extent that it is known. This generally gives up the equality of $T(s' \leftarrow s)$ and $T(s \leftarrow s')$, but this can be done if their ratio is included in the Q factor that is used to determine acceptance, as indicated in Eq. (106).

The logical conclusion of the biased sampling procedure would be to bias the generation of new configurations toward the natural distribution function so successfully that every trial configuration is accepted with unit probability. Remarkably, this is sometimes possible. Swendsen and Wang (1987) showed how it could be done with the Ising and Potts models by sampling only those new configurations that differ from the original by the flipping of *clusters* of like spins. In this way they were able to reduce dramatically the problem of *critical slowing down* that plagues these methods for systems near a critical point. At criticality the correlation length tends to diverge, and so particles can be correlated with other particles that are arbitrarily far away. In this situation, the random flipping of individual spins is a "bull in a china shop" approach: Far more often than not, it badly damages the sensitive network of natural correlations and results in the trial configuration being rejected. Since the particles can be correlated on all scales, the solution is to flip them in clusters at corresponding scales, and this is precisely what Swendsen and Wang did. The sampling of the clusters can be accomplished by laying down "bonds" between each site with a probability that depends on the energy of the bond and the temperature; sites connected by an unbroken network of bonds are then said to be in the same cluster. For the Ising model, for example, the probability of such a bond is zero if the spins are not aligned, and $1 - e^{-2\beta J}$ if they are. Once the clusters are determined, they are flipped with probability $\frac{1}{2}$ (in the unmagnetized version of the model). All of this constitutes the sampling of a new configuration, which is then unconditionally accepted.

Subsequent work by Kandel and Domany (1989) generalizes the Swendsen–Wang procedure by introducing a hierarchical cluster algorithm capable of dealing with a wide variety of Hamiltonians. More recently, Machta *et al.* (1995) has developed an *invaded cluster* algorithm that is capable of sampling a critical system without prior knowledge of the critical temperature, and with no apparent critical slowing down.

7.3 Lattice Gauge Theory

There is a close similarity between statistical physics and quantum physics, since the Feynman path-integral formulation of the latter subject tells us that the complex amplitude for a particle at point $\mathbf{x}_1$ at time t_1 to propagate to point $\mathbf{x}_2$ at time t_2 is

$$Z[(\mathbf{x}_2,t_2) \leftarrow (\mathbf{x}_1,t_1)] = \int d[\mathbf{x}(t)] \exp\left[i \int_{t_1}^{t2} dtL(\mathbf{x},\dot{\mathbf{x}})\right], \tag{116}$$

where the outer *path integral* is over all paths connecting the two points in space-time, and L is the Lagrangian. Since a classical field $\psi(\mathbf{x},t)$ is just a function of the space-time coordinates, the analog of the above for a field is just

$$\mathscr{Z}[\psi_2(\mathbf{x},t) \leftarrow \psi_1(\mathbf{x},t)] = \int d[\psi(\mathbf{x},t)] \exp\left[i \int dt \int d^3x \mathscr{L}(\psi,\nabla\psi,\partial_t\psi)\right], \tag{117}$$

where $\mathscr{L}(\psi,\nabla\psi,\partial_t\psi)$ is the Lagrangian density of the field, so that $L = \int d^3\mathscr{L}$. One can then take expectation values of any (time-ordered) quantity by weighting it with the complex measure

$$\frac{1}{\mathscr{Z}[\psi_2(\mathbf{x},t) \leftarrow \psi_1(\mathbf{x},t)]} \exp\left[i \int dt \int d^3x \mathscr{L}(\psi,\nabla\psi,\partial_t\psi)\right], \tag{118}$$

in exact analogy to Eq. (102). In fact, by analytically continuing the time coordinate to the complex plane, $t = ix_4$, we can write the above in the form

$$\frac{1}{\mathscr{Z}} \exp\left[-\int d^4x \mathscr{L}(\psi,\boldsymbol{\partial}\psi)\right], \tag{119}$$

where $\mathbf{x}$ is now understood to be a space-time coordinate, and $\boldsymbol{\partial}$ is the four-gradient. The appearance of the manifestly covariant space-time volume element d^4x makes this formulation natural for relativistic field theories.

By discretizing the Lagrangian density onto a lattice, we can extract vacuum expectation values of any quantity of interest using the Metropolis procedure. Just as we did when introducing the finite-element method, we restrict the independent variable to a lattice $\mathbf{x_j} = \mathbf{j}\Delta x$, where Δx is the lattice spacing. The four-gradient is then approximated by

$$\partial_\alpha\psi(\mathbf{x_j}) \approx \frac{1}{\Delta x}[\psi(\mathbf{x}_{\mathbf{j}+\hat{e}_\alpha}) - \psi(\mathbf{x_j})]. \tag{120}$$

Gauge field theories, such as *quantum electrodynamics* (QED) or *quantum chromodynamics* (QCD), are associated with an underlying Lie group G; these are U(1) for QED and SU(3) for QCD. A set of group generators, denoted by λ^a, obey closed commutation relations,

$$[\lambda^a,\lambda^b] = if^{abc}\lambda^c, \tag{121}$$

where the f^{abc} are the structure constants of G (for this choice of generators). For example, if G is $SU(2)$, we could take the λ's to be (half) the Pauli matrices, in which case the structure constants are just the components of the Levi–Civita tensor $f^{abc} = \epsilon^{abc}$. An arbitrary element of the Lie algebra of G may then be expanded in terms of these generators; thus, the *gauge potentials,* which take their values in the Lie algebra, may be written

$$\mathbf{A}(\mathbf{x}) = \sum_a \mathbf{A}^a(\mathbf{x})\lambda^a. \tag{122}$$

Let us discretize the gauge field by storing $\mathbf{A}(\mathbf{x})$ at each lattice site. Exponentiation of the elements of the Lie algebra gives elements of G, so that

$$U(\mathbf{j},\alpha) \equiv \exp\left[\frac{ig\Delta x}{2} \sum_a \lambda_a \hat{\mathbf{e}}_\alpha \cdot \mathbf{A}^a(\mathbf{x_j})\right] \tag{123}$$

is an element of G that can be *associated with the link* connecting lattice site $\mathbf{x_j}$ with its neighboring site $\mathbf{x_j} + \hat{\mathbf{e}}_\alpha$. Here g is the coupling constant of the theory. The Lie group elements associated with the links have the virtue that their product around any closed path on the space-time lattice is gauge invariant. In terms of these quantities, Wilson (1971) showed that the discretized action ($S \equiv \int d^4\mathscr{L}$) of quantum chromodynamics could be written

$$S = -\frac{1}{g^2} \sum_{\text{plaquettes}} \text{Trace}(U_p), \tag{124}$$

where U_p is the product of the four elements of G around the edges of a closed unit square, or *plaquette,*

$$U_p = U(\mathbf{j},\alpha)U(\mathbf{j} + \hat{\mathbf{e}}_\alpha,\beta)U(\mathbf{j} + \hat{\mathbf{e}}_\alpha + \hat{\mathbf{e}}_\beta, -\alpha)U \times (\mathbf{j} + \hat{\mathbf{e}}_\beta, -\beta), \tag{125}$$

and where the sum is taken over all such plaquettes on the space-time lattice. Note that the U matrices are associated with *directed* links, so that

$$U(\mathbf{j} + \hat{\mathbf{e}}_\beta, -\beta) = U^\dagger(\mathbf{j},\beta). \tag{126}$$

One then computes expectation values of operators O depending on the $\mathbf{U}$ matrices (any gauge-invariant operator can be thus expressed) by

$$\langle O(\mathbf{U})\rangle = \frac{1}{Z}\int d[\mathbf{U}]e^{-S}. \tag{127}$$

This is exactly the kind of quantity that we were computing in Sec. 7.2, in the context of statistical physics, and can thus be estimated using the Metropolis procedure. Changing the gauge potential at any lattice point affects only those plaquettes that actually pass through the point, so that the change in the lattice action is a straightforward local calculation.

Because the coupling constant g of QCD is large, it is not useful as an expansion parameter, as it is in QED. Thus, many of the known consequences of QCD have been determined by numerical simulations of the sort described above. In particular, the form of the interquark potential has been estimated in this way, as have baryon masses, and the method has been used to investigate the elusive "glueball." A large literature exists on algorithms for lattice gauge theory, and on their supercomputer implementation; see Dasgupta *et al.* (1996) for details on the Fortran 90 implementation.

8. THE FUTURE OF COMPUTATIONAL PHYSICS

8.1 The State of the Art

In the previous sections, we have traced the evolution of the relationship between computation and physics. By implementing many of the methods described on the largest supercomputers available today, extremely large computations have been performed. Some of the largest computations thus performed have been compiled into a list of "World Scientific Records" by Stauffer (1996), and we mention some highlights here:

- At the time of this writing, the largest $D = 2$ Ising simulations on record employ a $1\,000\,000 \times 1\,000\,000$ grid (10^{12} sites) (Linke *et al.*, 1995), and the largest with $D = 3$ Ising simulations employ a $3072 \times 3072 \times 3072$ grid (2.9×10^{10} sites) (Munkel *et al.*, 1993). The fastest such simulations can perform Metropolis updates on 11 billion sites per second (Ito, 1996).
- *Exact* solutions of the $D = 3$ Ising model, using computer-assisted symbolic manipulation methods for carrying out the algebra, have been accomplished for a $5 \times 5 \times 6$ lattice (150 spins) (Guttmann and Enting, 1994). (Note that a brute-force approach to this problem would involve the summation of 2^{150} terms—an impossible task.)
- As mentioned earlier, molecular-dynamics simulations with between 10^8 and 10^9 particles and with a characteristic performance of 10^{-8} s per particle update have been achieved (Zhou *et al.*, 1997) on large parallel supercomputers.
- Quantum chromodynamics simulations have achieved 7 billion updates per second (Sexton *et al.*, 1995).
- Floating-point fluid-dynamics calculations in three dimensions have been performed on $512 \times 512 \times 512$ grids (Oran and Boris, 1992).

8.2 Quantum Computation

As the above-mentioned doubling of computer performance every 1.5 years continues unabated at the time of this writing, one can expect the above performance records to continue to improve substantially. When it became clear that this could not continue forever (see Fig. 1), computer manufacturers exploited parallelism so that the trend would continue. Most of the effort in the supercomputer industry today centers on making parallel clusters of computers on fast networks easy to use; one method of doing this is to develop efficient and elegant parallel programming paradigms, embodied in high-level languages, such as Fortran 90.

In spite of this success at warding off the problem for the time being, Fig. 1 still gives one the feeling that supercomputer manufacturers and users are heading for a "brick wall" in the not-too-distant future, and raises the question of whether or not any powerful new strategies for physical computation will come to the rescue, as did parallelism in the 1980s. In a development that has many a computer scientist scrambling to (re)learn quantum physics, one of the most interesting, exciting, and potentially explosive new computational paradigms currently under consideration centers on the computational properties of quantum-mechanical systems, and is called *quantum computation.*

Recall that all of classical computation theory, as prototyped by the Turing machine model, is carried out by logical operations on sequences of bits—quantities that take their values in the set {0,1}. By contrast, the fundamental element of information in a quantum computer is the *qubit* (pronounced "Q-Bit") or *quantum bit.* Like its classical counterpart, the measurement of a single qubit can yield one of two results, $|0\rangle$ or $|1\rangle$. Unlike its classical counterpart, however, a qubit can be in a complex superposition of these two states,

$$c_0|0\rangle + c_1|1\rangle, \tag{128}$$

where the coefficients obey the normalization condition $|c_0|^2 + |c_1|^2 = 1$. To borrow from the parlance of quantum mechanics, when the qubit is measured, it "collapses" to a classical bit of value 0 with probability $|c_0|^2$, and of value 1 with probability $|c_1|^2$. As long as we do not measure the qubit, however, its complex amplitude may combine and interfere with those of other qubits.

Just as a classical computer manipulates classical bits and combines them according to various logical operations, called *gates,* a quantum computer manipulates qubits and combines them according to unitary operations, called *quantum gates.* We note that even a single qubit with a unary quantum gate is capable of behavior that is totally unfamiliar from the classical theory of computation. For example, suppose that the unary quantum gate is the application of the unitary operator

$$\frac{1}{\sqrt{2}}\begin{pmatrix} +1 & +1 \\ -1 & +1 \end{pmatrix} \tag{129}$$

in the representation of Eq. (128). If we begin with a qubit that is assuredly (perhaps because of a measurement) in state $|0\rangle$, one pass through this quantum gate will yield

$$\frac{1}{\sqrt{2}}|0\rangle - \frac{1}{\sqrt{2}}|1\rangle. \tag{130}$$

If we were to perform a measurement at this point, the result would be 0 or 1, each with probability $\frac{1}{2}$. Thus, a random-bit generator is trivially realized on a quantum computer, unlike the classical case where we had to take a great deal of care to deterministically generate sufficiently uncorrelated pseudorandom numbers.

The fact that a measurement of the qubit yields a random bit does *not* mean that the quantum gate has destroyed the information that was in the originally prepared qubit. Indeed, quantum gates can never destroy information precisely because they are unitary; in this respect they are analogous to the *reversible gates* of classical computation, described earlier in this article. Of course, the measurement process is nonunitary and would indeed destroy the information, but suppose that instead of measuring the outgoing bit, we were to pass it back through the very same quantum gate one more time. The result would be $-|1\rangle$; that is, the result, if measured, would yield 1 with unit probability. Thus, two passes through the above unary quantum gate yield the classical "NOT operation," which is perfectly reversible. This has led one author (Hayes, 1995) to refer to the above quantum gate as "the square root of NOT."

Inspired by oddities of this sort, physicists and computer scientists began to examine what computations might be like on such computers back in the 1980s (Feynman, 1982, 1986; Deutsch, 1985, 1989). A central, if somewhat ill-posed, hope was that quantum computers would somehow be capable of calculations completely inaccessible to classical computers. At first, it is rather difficult to see what is meant by this. Consider, however, the above-described computation of an actual *random* (as opposed to pseudorandom) bit; this is clearly something outside the purview of a classical computer. An even more striking example is provided by DiVincenzo's (Barenco *et al.*, 1995) observation that 2-qubit quantum gates are sufficient to build a universal quantum computer; recall that 3-bit gates were necessary to do this with classical computation.

The net result of these observations is that quantum computation is a new paradigm of computation—completely distinct from the Turing-machine paradigm. Until the investigation of quantum computation, it was implicitly believed that the axiomatization of computation by the Turing machine paradigm was a unique mathematical construction. While Turing's ideas are often described with the cartoon of a "head" sliding along a "paper tape," this was considered to be nothing more than an intuitive picture to aid the understanding of an abstract mathematical concept. From a philosophical point of view, the observation that this is *not* true, and that the power of a computational paradigm does depend at least in part on its underlying physical realization, is just as profound as the 19th century observation that Euclidean geometry is not a unique mathematical construction, and the early 20th century discovery that the most natural geometry of the real world is in fact non-Euclidean.

While these issues are undeniably interesting, they seemed to be of exclusively academic interest until Shor proved that the integer factoring problem, long suspected to be of exponential complexity on a classical computer, could be solved in polynomial time on a quantum computer (Shor, 1994). Though the details of Shor's demonstration lie outside the scope of this article, one might intuitively imagine that a problem can be subdivided into exponentially many subproblems, and these may be superposed and "parallel processed" because of the linearity of quantum evolution. Shor showed that by selectively "interfering" the results in a certain way, it is possible to extract a desired final result in a time that is exponentially faster than the corresponding classical computation.

It is impossible to overstate the impact that such a result might have. As noted earlier, simulations of N quantum particles are necessarily of a classical complexity that is exponential in N. In analogy with Shor's result, it has been shown that such simulations are possible in polynomial time on a quantum computer, and an explicit quantum computational algorithm has even been developed for this purpose (Lloyd, 1996; Boghosian and Taylor, 1997). Indeed, the use of one quantum system to simulate another has a certain intuitive appeal, as it forcefully underscores the point that *all computation is physical,* and bodes for a future in which computation is regarded as the use of one physical system to emulate another.

Nowhere, however, is the result of Shor's observation more acutely felt than in the field of encryption. Though encryption algorithms are not commonly thought of as part of computational physics, and are therefore outside the scope of this article, suffice it to say that most all business and intelligence applications of encryption are predicated on the exponential difficulty of factoring large numbers. It is mostly for this reason that there has been an explosion of work in this area in the few years since Shor's article appeared.

Given that a quantum computer is demonstrably able to do these things, one may wonder why one is not being built today. In fact, a number of groups are actively trying to do exactly this, but it is difficult. The difficulty lies in the great care that must be taken to preserve the unitary evolution of the qubits involved. If the environment of the computer performs any "measurement" whatsoever on the qubits before they have completed their unitary evolution, they will collapse in a nonunitary fashion, and results that depend on their interference will no longer follow. In other words, the qubits must be kept coherent for the duration of the computation. This consideration sets upper bounds on the length of a computation that may be performed on a quantum computer, and hence the number of cycles in any algorithm that may be carried out. This bound is analogous to that of sensitivity to errors in trajectories such as we encountered in our earlier discussion of classical, reversible "billiard-ball" computers; since that problem had a solution, we might expect that this one does as well. Indeed, within the past year a number of interesting results have emerged on *quantum error correction* (Shor, 1996), and it has been shown that the reconstruction of a *damaged* qubit is possible in principle. It is hoped that this will provide some relief from the coherence requirements. In the meantime, researchers are trying to use a number of different physical systems to realize quantum computation (see, e.g., Turchette *et al.*, 1995; Mattle *et al.*, 1996; Cory *et al.*, 1997; Wineland *et al.*, 1997; and references therein).

9. CONCLUSION

We have surveyed the history and speculated about the future of the relationship between physics and computation. Though it is impossible to achieve completeness in any general survey of this sort, our intent has been to focus on examples that illustrate the principal issues involved, with emphasis on recent developments. We have surveyed physical computation, computational complexity, algorithms, languages, applications of computation to physics, and applications of physics to computation. Like any other important branch of physics, we have found that computational physics is interesting on many different levels; like any of the great revolutions of physics, we see that some of its most significant challenges and opportunities lie in questioning foundations and tenets long imagined to be inviolable.

ACKNOWLEDGMENTS

The author would like to thank Peter V. Coveney, Norman H. Margolus, Claudio Rebbi, and Francis Alexander for their careful critical reading of the draft version of this article and for the valuable comments they provided.

GLOSSARY

Abacus: Mechanical computing aid developed in Middle East at least 2500 years ago in which numerical data are represented by beads sliding on wires.

Analytical Engine: The first programmable general-purpose mechanical digital computer, designed by Charles Babbage in England in the mid-19th century.

Banded Matrices: Sparse matrices whose elements vanish except on certain diagonals, and which arise naturally from finite-difference problems.

Bit: Variable taking its value from a set of two elements, usually denoted {0,1} or `{false,true}`. The smallest unit of digital information.

Byte: Eight bits.

Cellular Automaton: Dynamical system that is discrete in space, in time, and in its dependent variable.

Church–Turing Hypothesis: Hypothesis, named after Alan Turing and Alonzo Church, that any universal computer can simulate and be simulated by a Turing machine.

Courant Condition: Condition for numerical stability when integrating partial differential equations, usually imposed as an upper bound on the time step.

Digital: The representation of numbers as $\Sigma_i d_i B^i$, where $d_i \in \{0, \ldots, B-1\}$. Here B is called the *base* of the representation.

Dissipative Particle Dynamics (DPD): A particulate method for accelerating molecular-dynamics simulations, using idealized collisions that conserve momentum exactly, but letting the energy fluctuate within the canonical ensemble at some fixed temperature. DPD is similar to the Nosé–Hoover method, but conserves momentum.

Finite-Difference: Method of integrating partial differential equations in which classical fields are discretized on a grid and partial derivatives are represented by differences of neighboring values.

Finite-Element: Method of integrating partial differential equations in which classical fields are represented as sums of localized spline functions.

Floating-Point Numbers: The computer representation of a real number by some number of bits of mantissa and exponent and by a sign bit. The format for this representation has been standardized by the IEEE.

Galerkin Approximation: Approximation at the heart of many finite-element methods that demands that the error incurred must lie outside of the space of basis functions used to represent the dependent variable.

Game of Life: Two-dimensional cellular automaton with 1 bit per site and simple nearest-neighbor rules, invented by John Horton Conway in the early 1970s, that is provably capable of universal computation.

Gödel's Incompleteness Theorem: Theorem stating that any axiomatic system capable of representing truths of number theory is necessarily *incomplete,* in that it contains truths that cannot be proven from its axioms.

Halting Problem: "Computer science version" of the Gödel incompleteness theorem, stating that there is no *a priori* way of knowing whether or not a given computer program is a legitimate algorithm, in that it is guaranteed to produce results and halt.

Ising Model: Prototypical statistical spin system defined on a grid at each site of which there is 1 bit of data, corresponding to a spin pointing either up or down. The system Hamiltonian is defined to be quadratic in the products of neighboring spin states.

Lattice Boltzmann Method: Similar to **Lattice-Gas Automata,** but keeps track of discrete-velocity, single-particle distribution function only, and lacks kinetic fluctuations. The distribution is represented by a floating-point number for each of the velocities present in the model.

Lattice-Gas Automata: Particulate hydrodynamic method in which particles are represented by individual bits moving about on a lattice, and suffering collisions that maintain exact mass and momentum conservation. Can be used as an alternative to molecular dynamics for the study of universal properties that depend on the presence—but not the details—of an underlying kinetic model.

Lattice Gauge Theory: Quantum gauge field theory on a lattice. Provides a Monte Carlo algorithm for sampling the expectation values of such theories.

Mark I: Electronic computer developed by Howard Aiken of Harvard University during World War II.

Metropolis Method: Markov chain method for the sampling of a large statistical ensemble without prior knowledge of its partition function.

Molecular Dynamics: The simulation of the dynamics of molecules to discern the bulk properties of materials.

Monte Carlo: Computational method that uses random numbers to estimate statistically a desired quantity.

Napier's Bones: Seventeenth-century computational aid that used logarithmically spaced divisions to multiply. Predecessor of the slide rule.

Nosé–Hoover Method: A particulate method for accelerating molecular-dynamics simulations that lets particles explore the canonical, rather than microcanonical, ensemble.

Operator Splitting: Method of integrating partial differential equations by splitting the time-development operator into several pieces that can be treated separately.

Parallel Computation: The coordinated use of many processors to share the work of, and thereby accelerate, a calculation.

Particle-in-Cell Method: Hybrid between grid and particle method, whereby individual particles move about according to self-consistent fields that are computed on a spatial grid.

Qubits: Elemental data of quantum computation that take their values in the Hilbert space spanned by the various classical states that the system can have. A single qubit is thus a complex superposition of $|\mathtt{true}\rangle$ and $|\mathtt{false}\rangle$.

Quantum Computation: Computational paradigm that is an alternative to the Turing machine model and that involves the unitary manipulation of *qubits.*

Slide Rule: Computational aid that uses logarithmically spaced divisions to multiply and divide. In widespread use until the 1970s.

Sparse Matrices: An $N \times N$ matrix with $O(N)$ nonvanishing elements.

Spin Systems: Statistical models, usually consisting of a lattice of "spins," each interacting with their neighbors according to some specified Hamiltonian. Closely related to cellular automata.

Symplectic Structure: Structure of the equations of classical mechanics that ensures the preservation of the invariant integrals of Poincaré, and an action principle based on a Lagrangian function. Invertible symplectic structures also give rise to a Poisson-bracket structure of the equations of motion. In recent years, numerical integration techniques have been developed to preserve the symplectic structure of the equations of motion, with the philosophy that this is probably more important than conserving other quantities such as the energy.

Theory of Computation: The theory of what computers can and cannot do, from both mathematical and physical considerations.

Turing Machine: Mathematical axiomatization of the computational process, developed by Alan Turing in the 1930s, and picturesquely described by a "machine" sliding along a "paper tape" imprinted with various symbols, and taking actions based on the values of those symbols.

Universal Computation: The capability to simulate any Turing machine.

INTRODUCTION

The membranes and vesicles considered here are ultrathin and highly flexible sheets composed of lipids and other amphiphilic molecules (which have both a water-soluble, hydrophilic part and a water-insoluble, hydrophobic part). In biological systems, these membranes represent complex interfaces that partition space into different compartments and, thus, are responsible for the amazing architecture of these systems. One example of this architecture is shown in Fig. 1.

Biomembranes have been studied for a long time in biology, pharmacology, and medicine. On the micron scale, these membranes exhibit a unique combination of properties:

1. They form closed surfaces without edges;
2. they are highly flexible and, thus, can easily adapt their shape to external perturbations; and
3. in spite of this flexibility, they are rather robust and keep their structural integrity even for strong deformations.

This *combination of stability and flexibility* is a consequence of their molecular struc-

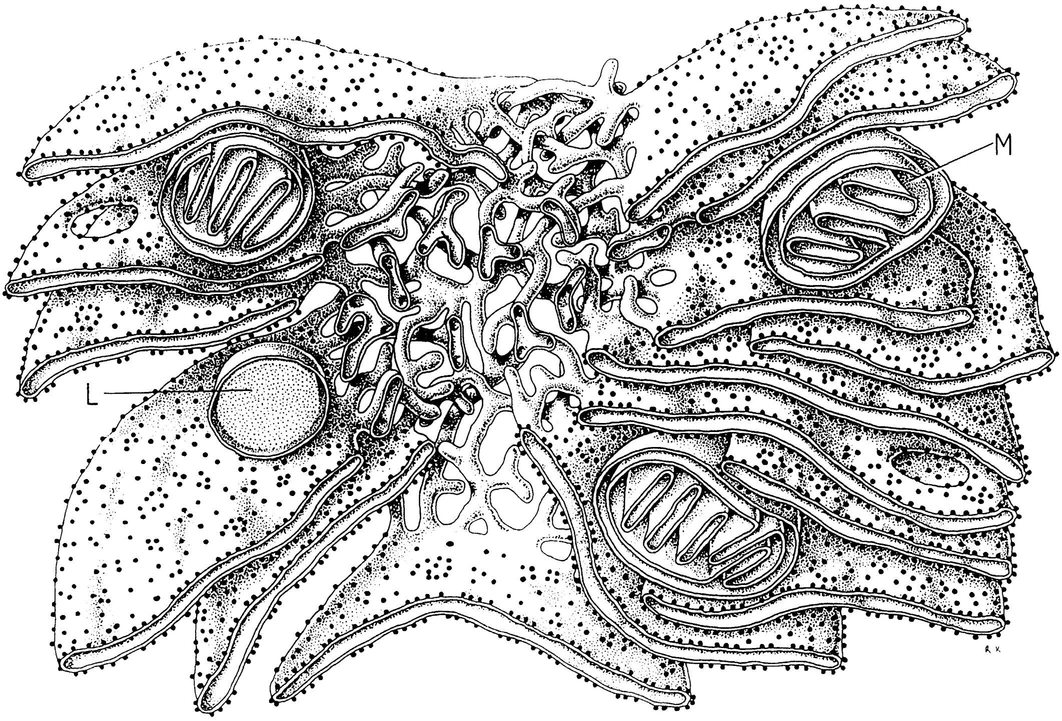

FIG. 1. Some internal membranes of a liver cell. The labyrinth of membrane sheets and tubes defines the endoplasmic reticulum; within the lamellar region, one sees the membranes of three mitochondria (M) and of one lysosome (L). (Krstic, 1976.)

ture. When viewed on the nanometer scale, each biomembrane consists of a specific mixture of many different amphiphilic molecules that reflect its diverse biological functions. However, in spite of this chemical complexity, all biomembranes are organized according to the same universal construction principle: their basic building block is provided by a *bilayer of lipid molecules.* The latter molecules are essentially *insoluble* in the aqueous solution, which ensures membrane stability. In addition, these lipid bilayers are maintained in a *fluid* state, which is the main mechanism underlying their enormous flexibility.

This article focuses on fluid bilayers that contain only one or a few lipid components. Even the simplest model membranes of this kind already exhibit several levels of *self-organization* that are reminiscent of biomembranes: The lipid molecules arrange themselves into bilayers; the bilayers spontaneously form closed bags or vesicles without edges; the vesicles adhere to one another and form various multilayer structures.

In addition, lipid bilayers in their fluid state can easily adapt to external forces by reorganization of their supramolecular structure. Indeed, one intriguing aspect of these membranes is their ability to undergo morphological changes: Depending on temperature and osmotic conditions, free membranes and vesicles exhibit a large variety of different shapes and shape transformations; similar shape changes can be induced by the formation of intramembrane domains; interacting membranes undergo transitions between bound and unbound states. A new level of self-organization is obtained when such bilayers are "decorated" with anchored polymers. These polymers form "mushrooms," "pancakes," or "brushes," which tend to curve the bilayers and to change their interactions.

Just like biomembranes, lipid bilayers are flexible but stable structures, which makes it possible to isolate them and to manipulate them in various ways: One can suck them into micropipettes, attach them to other surfaces, and grasp them with optical tweezers generated by focused laser beams. These bilayers can even tolerate local perturbations that lead to the formation of small holes: The bilayers restore their structural integrity since the holes close again spontaneously as long as the membranes do not experience a large lateral tension.

1. FROM CELLS TO VESICLES

1.1 Plasma Membrane and Internal Membranes

All living matter is built up from cells. Each cell is enclosed by its outer plasma membrane that controls the interaction between the cell and its environment. This applies both to the relatively small cells of bacteria or prokaryotes, which have no cell nucleus, and to the much larger cells of eukaryotes, which have such a nucleus. The latter class of organisms includes all animals and plants as well as single-celled microorganisms such as amoeba or yeast. In addition to the outer plasma membrane, all eukaryotic cells contain internal membranes that represent the boundaries of the internal organelles such as the nucleus, mitochondria, chloroplasts, etc. The membranes shown in Fig. 1, for example, represent the internal membranes that bound the endoplasmic reticulum and some mitochondria of a liver cell (Darnell *et al.,* 1990; Alberts *et al.,* 1994).

The total membrane area of an eukaryotic cell is relatively large. The membranes of a single liver cell, for example, have a total surface area of about 1.1×10^5 μm^2 while its volume is about 5×10^3 μm^3. About 98% of this large area belongs to the internal membranes and only 2% to the outer plasma membrane of the cell.

1.2 Evolution of Biomembranes

Membranes are quite old and thus have evolved over a long period of time. Indeed, membranes defined the boundaries of the first cells on earth and thus played a crucial role in the origin of life. The oldest microfossils that are viewed today as remnants of cells have an age of about 3.5×10^9 years. As a result of this long evolution, we now have an enormous variety of different cells and organelles, which live in very different environments. The interactions between the cells or organelles and their environments are mediated by their membranes. The basic function of these membranes is to act as highly selective barriers for the exchange of molecules between the different spatial regions and compartments. In this way, they sustain concentration gradients between their two sides, which are used, for example, in order to produce energetic molecules or to propagate localized excitations along the membranes. Likewise, these membranes act as transducers for chemical, optical, or mechanical signals and as supporting surfaces for anchored polymers and polymer networks.

1.3 Universal Construction Principle

In order to fulfill its specific biological functions, each biomembrane is composed of a specific mixture of hundreds of different molecules. However, in spite of this complex chemical composition, all biomembranes exhibit the same universal construction principle: a *bilayer of lipid molecules,* which provides a two-dimensional solvent for the hydrophobic anchors of membrane proteins. Therefore, the simplest model systems for biomembranes are lipid bilayers without any proteins. When dissolved in water, these bilayers form closed bags or vesicles that resemble the closed compartments as formed by biomembranes.

1.4 Fluidity of Biomembranes

Under physiological conditions, biomembranes are in a fluid state; i.e., the membrane molecules can diffuse rapidly along these membranes. On the molecular scale, this fluidity is necessary for the proper functioning of membrane proteins. On the supramolecular scale, it ensures that the biomembrane is highly flexible and can undergo shape changes such as the formation of small spherelike buds. Therefore, both prokaryotic and eukaryotic cells adjust the lipid composition of their membranes in such a way that they remain in a fluid state irrespective of the ambient temperature and of other external conditions. Prokaryotic cells achieve this by increasing the number of unsaturated double bonds within the hydrocarbon chains of the lipid molecules. These unsaturated bonds act as defects within the bilayer that prevent the freezing of these membranes. Eukaryotic cells, on the other hand, increase the concentration of cholesterol within their membranes in order to maintain the fluidity.

2. MOLECULAR STRUCTURE OF LIPID BILAYERS

2.1 Lipid Molecules in Water

Lipids are amphiphilic molecules with a hydrophilic head group and usually two lipophilic (= hydrophobic) hydrocarbon chains. The head group of phospholipids and glycolipids contains a phosphate group and some sugar groups, respectively.

Those lipid molecules that are contained in biomembranes are essentially insoluble in water. More precisely, single lipid molecules can be dissolved in water only up to a critical monomer concentration X_*. This concentration is very small and decreases with increasing length of the hydrocarbon chains. For phospholipids with two identical chains containing $2N_c$ carbon atoms, one has $X_* \sim \exp(-1.7N_c)$ at room temperature, as can be measured for relatively small values of $N_c \lesssim 10$ (Cevc and Marsh, 1987). For the lecithin DPPC (dipalmitoyl phosphatidyl choline) with $N_c = 16$, this leads to the estimate $X_* \sim 10^{-12}$, i.e., less than one monomer per 10 μm^3 or per 10^{-8} mL of water.

2.2 Self-Assembly of Lipids

As soon as the lipid concentration in the aqueous solution exceeds the critical monomer concentration X_*, lipid molecules assemble into supramolecular structures. These structures are built up from *lipid bilayers* in which the polar head groups of the lipid molecules form the two lipid/water interfaces whereas the hydrophobic chains are buried within the bilayer and have essentially no contact with the aqueous solution. This process is an example of the so-called hydrophobic effect, which has a large entropic contribution arising from the configurational entropy of the hydrogen bond networks within the water (Tanford, 1991). Because of this effect, the lipid bilayers also arrange themselves in such a way that they have no edges and thus form closed vesicles or liposomes.

In practice, there are several preparation methods in order to produce lipid vesicles starting with a lipid/water solution (see, e.g., Lasic, 1993). Small vesicles with a relatively narrow size distribution can be prepared from larger bilayer structures by sonification with ultrasound or by millipore extrusion. These vesicles are usually too small to be visible in the optical microscope. Relatively large vesicles with a linear size of the order of 10 μm are obtained if ordered stacks of membranes are swollen in a controlled way. In general, one then obtains a mixture of both unilamellar vesicles, consisting of a single bilayer, and multilamellar liposomes, consisting of several, closely packed bilayers.

In principle, the bilayers exchange lipid molecules with the aqueous solution surrounding them. However, since the monomer concentration X_* is so small, the exchange of molecules between the bilayers and the solution is extremely slow. As long as one considers phenomena that are fast compared to this rather slow exchange process, the chemical equilibrium that would arise from this exchange of molecules is blocked, and the number of lipid molecules within each bilayer is practically constant.

2.3 Lateral Diffusion and "Flip-flops"

Lipid bilayers are essentially two-dimensional systems: Their thickness is 4–5 nm, whereas their lateral extension often exceeds 10 μm. A two-dimensional system can exhibit distinct thermodynamic phases. Lipid monolayers at the water–air interface, for example, exhibit a large number of different phases, which have been studied by optical microscopy and x-ray and neutron scattering. Likewise, lipid bilayers always exhibit a fluid phase at high temperatures and one or several gel or solidlike phases at low temperatures. This article focuses on the *fluid states* of bilayers since these are the relevant states of biomembranes.

Within a fluid phase, the molecules can freely diffuse along the bilayer. The corresponding diffusion coefficients are typically of the order of 10^{-7}–10^{-8} cm^2/s. This implies that each lipid molecule covers of the order of 1 μm in 1 s.

While lateral diffusion within the fluid bilayer is rather rapid, "flip-flops," i.e., the transverse diffusion between the two monolayers, are much slower. In bilayers consisting of a single phospholipid, it takes usually several hours and more to exchange half of the phospholipid molecules between the two monolayers. In multicomponent bilayers, on the other hand, smaller molecules such as cholesterol can flip-flop more easily, and the corresponding time scale may be of the order of minutes.

2.4 Transport across Bilayers

Even though lipid bilayers are very thin, they provide selective barriers for the diffusive transport of molecules. Water and small uncharged molecules such as CO_2 or N_2 can permeate the bilayers: They first dissolve into their hydrophobic interior, cross it by simple diffusion, and finally dissolve into the aqueous solution on the other side of the membranes. The water permeability can be directly measured if one studies mixtures of H_2O with isotopically labeled water such as DHO or THO. On the other hand, lipid bilayers are essentially impermeable to ions and to larger uncharged molecules such as glucose. The transport of these latter molecules through biomembranes is facilitated by special membrane proteins such as ion channels and carriers. Some carriers represent ion pumps that provide an active, i.e., energy-consuming, transport mechanism against the concentration gradients (Darnell *et al.*, 1990; Alberts *et al.*, 1994).

3. ELASTIC PROPERTIES OF FLUID MEMBRANES

Fluid membranes have rather special elastic properties: Any shear deformation relaxes by flow within the membrane; i.e., the (zero-frequency) shear modulus of such a membrane vanishes. Thus, a fluid membrane exhibits only two types of elastic deformations: stretching and bending (Canham, 1970; Helfrich, 1973; Evans, 1974).

3.1 Stretching Deformations

The stretching of lipid bilayers is limited to rather small deformations, since they start to rupture as soon as their area is changed by about 1%. If a membrane segment with area $\mathcal{A}_0$ experiences the lateral tension Σ, one has the area increase $\Delta\mathcal{A}$ with $\Sigma = K_{\mathcal{A}}\Delta\mathcal{A}/\mathcal{A}_0$. The area compressibility modulus $K_{\mathcal{A}}$ is of the order of $K_{\mathcal{A}} \simeq 200$ mJ/m^2, as has been measured in micropipette aspiration experiments; see Fig. 2. By this method, one can also determine the tension of rupture, $\Sigma_{\max}$, which is of the order of a few mJ/m^2 (Evans and Needham, 1987).

3.2 Bending Deformations

Consider a planar membrane segment and let us focus on a cut perpendicular to such a membrane. If this membrane is bent, the surface of the cut is tilted; i.e., it is subject to a torque. This torque is proportional to the curvature of the membrane and to the length of the cut; the proportionality constant represents the *bending rigidity* κ, which has the dimension of an energy. For phospholipid bilayers, the bending rigidity is of the order of $\kappa \simeq 10^{-19}$ J $\simeq 20T$ as deduced from the thermally excited flickering of vesicles, see Sec. 6.1 (here and hereafter, the temperature T has energy units; i.e., T is a short-hand notation for Boltzmann constant $k_B \times$ temperature in kelvins).

As mentioned, the admixture of cholesterol to lipid bilayers increases their fluidity. At the same time, it also increases the bending rigidity of these membranes. For phospholipid bilayers, for example, the bending rigidity was measured to increase by a factor 3–4 if the bilayer contained 30% cholesterol. These combined effects of cholesterol are rather remarkable and must be the result of a long optimization process during evolution.

4. RELATED BUT DISTINCT SYSTEMS

4.1 Soap Films

The behavior of fluid membranes as discussed below is often counterintuitive. This is understandable since there is no macroscopic analog for such systems. The only fluid surfaces in our macroscopic world are soap films and soap bubbles. A soap film consists of a thin layer of water that is bounded by two monolayers of surfactant molecules. The latter molecules are also amphiphilic but they are soluble in water, at least to a certain extent: Their critical monomer concentration X_* typically varies between 10^5 and 10^7 molecules per 1 μm^3 or per 10^{-9} mL of water.

Each surfactant monolayer represents an air–water interface that is characterized by a relatively large interfacial tension. The latter tension represents the free energy per interfacial area and ensures that soap bubbles at-

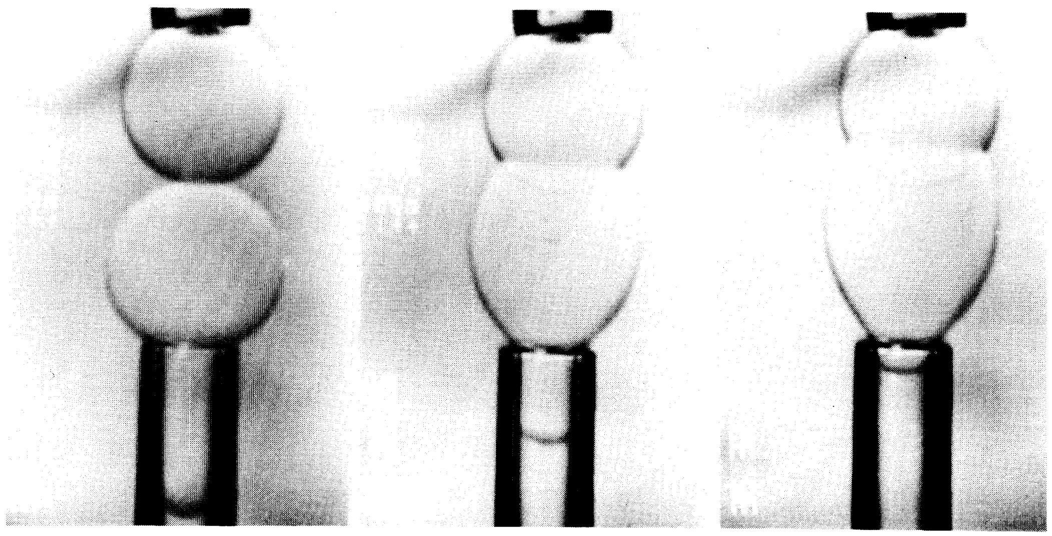

FIG. 2. Lipid vesicles may be sucked into small glass pipettes and can then be manipulated mechanically. The vesicle radii are about 10 μm. The top vesicle is almost spherical since it is exposed to a relatively large suction pressure. (Courtesy of E. Evans.)

tain a spherical shape. In addition, this interfacial tension is also responsible for the intrinsic instability of soap films: If one punches small holes into them, the tension acts to enlarge these holes and, thus, to rupture the soap films.

4.2 Surfactant Layers

Fluid monolayers of surfactant also form in multicomponent systems containing water and oil. Such mixtures exhibit many different phases in which these monolayers separate oil from water domains. Likewise, binary mixtures of water and surfactant may lead to liquid phases in which the surfactant molecules form bilayers separating two water domains. Since the critical monomer concentration X_* of the surfactant molecules is relatively large, these mixtures relax relatively fast toward states of thermal and chemical equilibrium, which are characterized by constant temperature and constant chemical potentials of the different components. These thermodynamic phases have been studied for a long time in physical chemistry and chemical engineering (for recent reviews, see Kahlweit and Lipowsky, 1996).

Surfactant layers are even more flexible than lipid bilayers, but they are also less stable and more sensitive to external perturbations. For example, it is usually not possible to transfer a single surfactant layer into a surfactant-free solution since this layer will dissolve rather rapidly. Likewise, it is hardly possible to manipulate surfactant layers by micropipettes or optical tweezers without destroying their structure. Therefore, in contrast to lipid bilayers, the behavior of *single* surfactant layers is not accessible to experimental studies.

4.3 Solidlike or Polymerized Membranes

Another class of membranes that has been recently studied in the theoretical physics community but will not be discussed in what follows consists of solidlike or polymerized membranes (for reviews, see Nelson *et al.*, 1989; Lipowsky, 1991). These latter membranes, which are characterized by a fixed connectivity of their building blocks, are more familiar since there are many examples for such membranes in our macroscopic world (such as an ordinary piece of paper, a thin film of rubber, or a fishnet). Solidlike membranes have a nonzero shear modulus, which leads to a coupling between bending and stretching deformations. Indeed, all bending deformations that change the Gaussian curvature of a solidlike membrane are necessarily coupled to strong stretching deformations of this membrane. Therefore, if the membrane (such as a piece of paper) is essentially unstretchable, it is impossible to deform it smoothly, i.e., without creating lots of folds or defects, from a planar into a spherical state. In contrast, such a shape transformation can be obtained easily for a fluid membrane; see Fig. 3.

5. THE MORPHOLOGY OF VESICLES

As mentioned, one can prepare relatively large vesicles with a linear size of the order of 10 μm that are bounded by a single bilayer. These vesicles can be directly observed in the optical microscope. One then finds that these vesicles exhibit a large variety of different shapes and various shape transformations as illustrated in Fig. 3.

A vesicle that is osmotically swollen experiences a lateral tension and, thus, attains a spherical shape just like a fluid droplet or a soap bubble. However, since water can permeate the membrane, the vesicle can adapt its volume and relax the tension. In this way, the membranes can attain an essentially tensionless state, the shape of which is governed by bending energies; compare Sec. 3 above. These shapes can be determined from systematic theories based on the relation between bending and curvature as described in the following section.

5.1 Shape of Homogeneous Membranes

First, consider a homogeneous fluid membrane with uniform elastic properties. As explained, the only elastic deformations that are relevant for fluid membranes are bending deformations governed by curvature.

5.1.1 Curvature and Bending Energy In general, each point of the membrane surface is characterized by its mean curvature

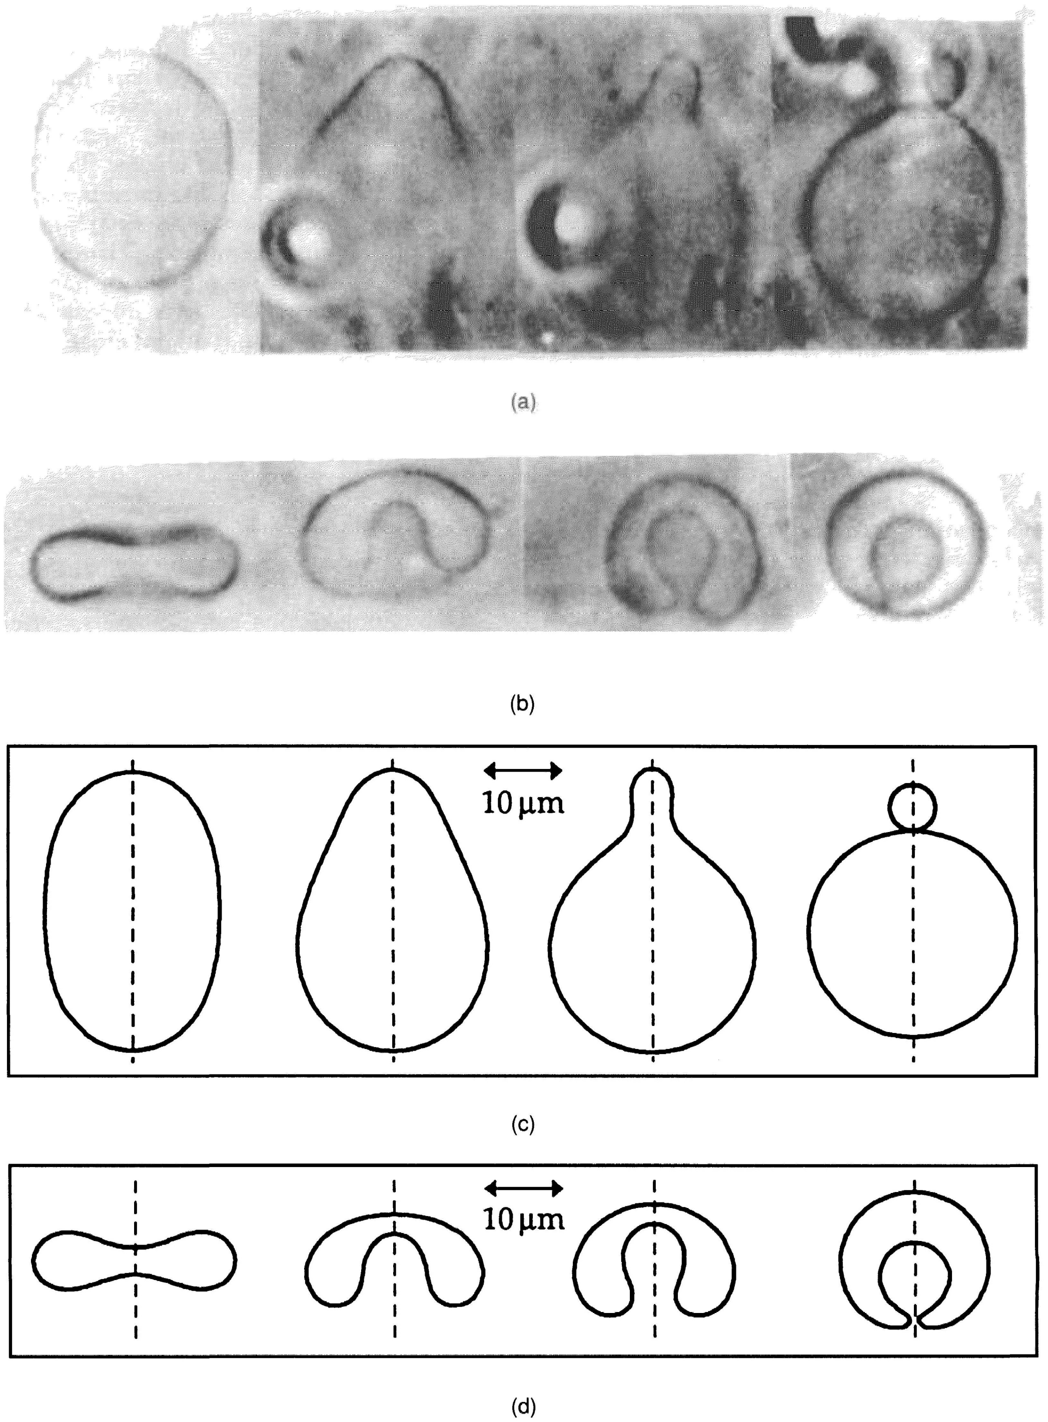

FIG. 3. Shape transformation of a single vesicle as observed via phase-contrast microscopy and calculated from curvature models. The transformations were induced by an increase in temperature that leads to an increase of the surface area of the vesicle. (a),(c) Budding, i.e., expulsion of a small vesicle from a larger one via the transformation from a prolate to a pear; (b),(d) inverse budding (or “endocystosis”) via the transformation from a discocyte to a stomatocyte. The shapes are axisymmetric with respect to the broken line. In both cases, the bud is connected to the large vesicle by a small neck.

$$M \equiv (C_1 + C_2)/2 \qquad (1)$$

and by its Gaussian curvature C_1C_2, where C_1 and C_2 are the two principal curvatures, which are equal to the inverse curvature radii.

If the two sides of the membrane are identical, the total bending energy has the form

$$\mathcal{H} = \oint d\mathcal{A}\,\tfrac{1}{2}\kappa(C_1 + C_2)^2 + \oint d\mathcal{A}\,\kappa_G C_1 C_2 \qquad (2)$$

up to second order in the principal curvatures C_1 and C_2. The surface integrals extend over the whole membrane surface, and $d\mathcal{A}$ is the intrinsic area element. The two parameters κ and κ_G have the dimensions of energy and represent the bending rigidity and the modulus of the Gaussian curvature, respectively. For closed membranes without edges, the integral over the Gaussian curvature does *not* depend on the shape of the surface but only on its topology, as follows from the Gauss–Bonnet theorem.

The mean curvature term $\sim\oint d\mathcal{A}(C_1 + C_2)^2$ is a dimensionless and thus scale-invariant quantity. In fact, it is even invariant under arbitrary conformal transformations of three-dimensional space (Willmore, 1982).

5.1.2 Asymmetric Membranes In general, the two monolayers of the bilayer membrane may differ in their chemical composition, and the two sides of the bilayer may face different surroundings. This asymmetry can be described by a spontaneous mean curvature M_{sp} (Helfrich, 1973). Furthermore, the difference in density between the two monolayers adapts locally to the curvature: If the bilayer is bent, one of the monolayers is compressed and the other one is stretched (Evans, 1974).

The coupling between the density difference and the mean curvature leads to a constraint on the total mean curvature

$$\mathcal{M} \equiv \oint d\mathcal{A} M = \oint d\mathcal{A}\tfrac{1}{2}(C_1 + C_2), \qquad (3)$$

which is proportional, for the *closed* bilayer, to the area difference of the two monolayers. This area difference can be changed by membrane proteins, which actively produce flip-flops of lipids between the two monolayers (Farge and Devaux, 1992). On the other hand, if flip-flops play no role, the total mean curvature would like to attain the preferred value, which corresponds to an unconstrained packing of the lipid molecules for which they all occupy the same (optimal) area (Miao *et al.*, 1994).

5.1.3 Constraints on Area and Volume In practice, vesicles exhibit a great variety of nonspherical shapes. This polymorphism arises, to a large extent, from two global constraints that are present for real vesicles:

1. The area of the bilayer membrane is constant (at constant temperature) since the exchange of molecules between the membrane and the solution can be neglected; and
2. the volume $\mathcal{V}$ of the vesicle does not adjust freely but is determined by the osmotic pressure P_{os} arising from those solutes that cannot permeate the bilayer; compare Sec. 2.4.

If X_{out} is the solute concentration outside of the vesicle and $\mathcal{N}_{in}$ is the number of solute molecules within the vesicle, one has $P_{os}\mathcal{V} \approx TX_{out}\mathcal{V} - T\mathcal{N}_{in}$ for small solute concentrations.

5.1.4 Shape Transformations and Limit Shapes As one changes a control parameter such as the osmotic pressure or the temperature, the shape of minimal bending energy usually evolves in a smooth way. However, for certain values of the control parameter, the shape undergoes a transformation that can be continuous or discontinuous. The shape transformations shown in Fig. 3 represent continuous transformations between a discocyte and a stomatocyte shape [Figs. 3(b) and 3(d)] and between a prolate and a pear shape at which the up–down symmetry of the shape is broken [Figs. 3(a) and 3(c)].

In addition, the shape may evolve into limit shapes in which different segments of the membrane surface start to come into contact. One type of limit shape consists of two segments connected by an infinitesimal neck that costs no bending energy; see the last shapes in Fig. 3.

5.1.5 Vesicles with Handles Recently, toroidal vesicles with one or several handles have also been studied both theoretically and experimentally. For vesicles with two or more handles, the shape of minimal bending energy is degenerate even if one includes the various constraints on the vesicle shape (Jülicher *et al.*, 1993). In this degenerate region, theory predicts a diffusion process in shape space along a conformal mode with constant area, volume, and total mean curvature as shown in Fig. 4. Such a process has been recently observed by phase-contrast microscopy (Michalet and Bensimon, 1995).

5.2 Shape of Inhomogeneous Membranes

In general, a bilayer is composed of different types of molecules. In such a multicomponent system, the composition can become inhomogeneous, which affects the elastic properties and thus the shape of the membrane. Several cooperative phenomena that are driven by this coupling between composition and shape have to be distinguished. One rather general effect is provided by the budding of intramembrane domains.

5.2.1 Composition and Shape Small vesicles that are composed of two different lipids often exhibit a strong asymmetry in the composition of the two monolayers. This compositional asymmetry reduces the mismatch or "frustration" between the spontaneous curvatures of the two monolayers. Likewise, conelike molecules within the membrane tend to diffuse toward membrane regions with an appropriate curvature. Thus, curvature may induce phase segregation.

The phase diagram of a multicomponent bilayer usually exhibits one-phase regimes and two-phase coexistence regimes depending on the temperature and the membrane composition. When such a bilayer is prepared in the two-phase regime, it will undergo phase separation, which leads to the formation of lateral domains or patches within the membrane. These intramembrane domains often form ordered patterns as originally observed by freeze fracture and electron microscopy (Sackmann, 1990). The theoretical work on these domain patterns is reviewed in Lipowsky (1995b).

5.2.2 Domain-Induced Budding and Fission Now, let us focus on a single domain within the membrane. In general, this domain may have a spontaneous curvature that differs from the spontaneous curvature of the surrounding matrix. In addition, the edge of the intramembrane domain has an energy that is proportional to its length. Therefore, the domain has a tendency to attain a circular shape in order to minimize its edge energy.

However, a *flat* circular domain does not represent the state of lowest edge energy since the length of the edge can be further reduced if the domain forms a bud: The domain edge now forms the neck of the bud, and this neck narrows down during the budding process; see Fig. 5. Because of the edge energy, the domain must bud as soon as its linear size exceeds a certain critical size even if it has no spontaneous curvature. Simple theoretical estimates also show that the bud is likely to break off from the membrane matrix. There is some evidence for such budding and fission processes from experiments on vesicles that contain mixtures of phospholipids and cholesterol.

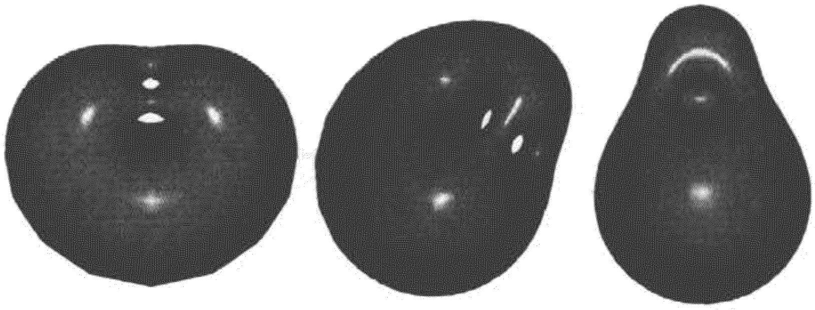

FIG. 4. Conformal diffusion of a vesicle with two handles: all three shapes have the same bending energy and the same area, volume, and total mean curvature.

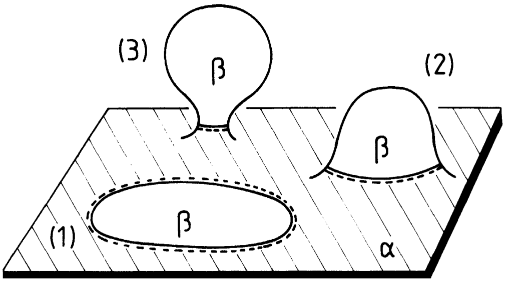

FIG. 5. Budding of the membrane domain β embedded in the membrane matrix α. The domain edge is indicated by the full-broken line. The length of this edge decreases during the budding process from (1) to (3).

5.2.3 Bud Size A vesicle that consists of two domains α and β could be obtained, for example, as a result of complete phase separation within the membrane. For such a vesicle, the shape of minimal bending energy exhibits a bud for a large range of parameters. This budded state attains a limit shape in which the bud β consists of a closed sphere that is connected to the mother vesicle α by an infinitesimal neck. The domain boundary with line tension σ is contained in this neck. The mean curvature M^β of this bud and the mean curvature M^α of the mother vesicle adjacent to this neck satisfy the general condition

$$\kappa^\alpha M^\alpha + \kappa^\beta M^\beta = \sigma/2 + \kappa^\alpha M^\alpha_{\text{sp}} + \kappa^\beta M^\beta_{\text{sp}}, \qquad (4)$$

where the bending rigidities κ^α and κ^β and the spontaneous curvatures M^α_{sp} and M^β_{sp} of the α and β domains may be different (Jülicher and Lipowsky, 1996).

The size of the bud is given by $1/M^\beta$. If the spontaneous curvatures are negligible, the bud size becomes $1/M^\beta \approx 2\kappa^\beta/\sigma$ in the limit of a relatively small β domain. In this limit, the size of the bud is determined by the elastic properties of the domain alone, and domain-induced budding then represents a *local* mechanism.

5.2.4 Domain-Induced Budding of Biomembranes In biological cells, budding of intramembrane domains represents the first step in the production of vesicles for the intracellular transport between different cell compartments. These domains can grow by diffusion-limited aggregation of molecules within the membrane or by the adsorption of molecules from the surrounding medium.

The budding of these domains could be governed by their spontaneous curvature. The aggregated molecules may have membrane-spanning anchors that induce such a curvature in the bilayer. Likewise, the adsorption of coat proteins onto one side of the bilayer leads to an asymmetric membrane. In any case, the reduction of the edge energy of these domains during the budding process will always act to facilitate this process.

5.3 Adhesion of Vesicles

A vesicle that is attracted toward a surface gains adhesion energy but increases its bending energy. For large vesicles, the adhesion energy must dominate since it is proportional to the contact area whereas the bending energy is scale-invariant and thus independent of the vesicle size.

5.3.1 Contact Potential A vesicle near a wall or substrate experiences various molecular forces; see Sec. 7. The typical range of these forces is usually small compared to the size of the vesicle. In order to study the overall shape of the bound vesicle, the microscopic interaction can be replaced by a contact potential. This potential is described by a single parameter W, which is equal to the adhesion energy per unit area. The value of the potential strength W is determined by the competition between direct molecular forces and fluctuation-induced forces; see Sec. 7.

5.3.2 Adhesion Threshold Since the bound vesicle is curved more strongly than the free vesicle, the contact potential $|W|$ has to exceed a certain threshold

$$|W_a| = w_a \kappa / \mathcal{A} \qquad (5)$$

before the vesicle starts to adhere to the wall. The dimensionless coefficient w_a depends on the reduced volume $\mathcal{V}/\mathcal{A}^{3/2}$ and is of order 1 (Seifert and Lipowsky, 1995).

For an ensemble of vesicles with different sizes, the relation (5) implies that large vesicles with surface area $\mathcal{A} > w_a\kappa/|W|$ stick to the wall, whereas vesicles with smaller surface area do not. This difference in the size distribution of bound and free vesicles is accessible to reflectivity measurements.

6. SHAPE FLUCTUATIONS OF MEMBRANES

The membranes of vesicles undergo thermally excited shape fluctuations, which can be directly observed in the light microscope. For adhering vesicles, one can use reflection interference microscopy as shown in Fig. 6 (Rädler *et al.*, 1995). In this way, one can probe fluctuations with wavelengths between about 0.4 μm and the vesicle size. There are, however, many more length scales involved in these fluctuations, which have wavelengths down to molecular dimensions.

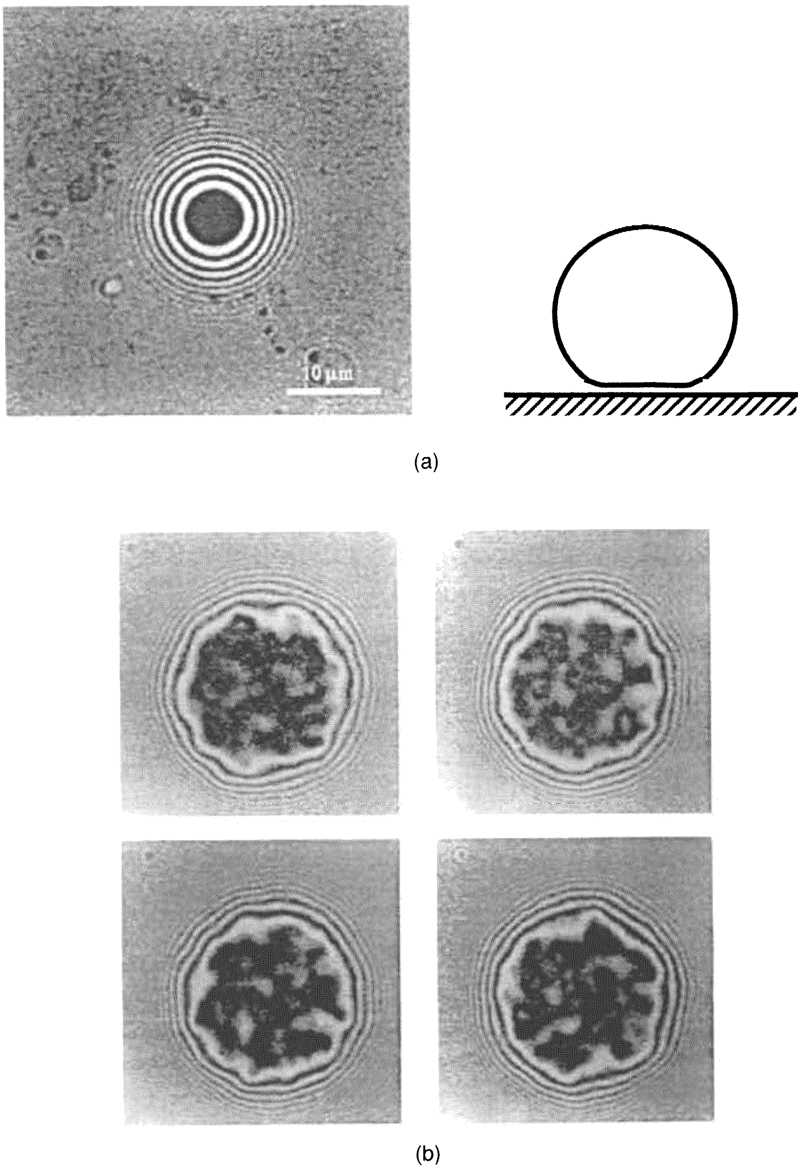

FIG. 6. Membrane of a bound vesicle as observed by reflection interference contrast microscopy. (a) Relatively large lateral tension, which suppresses all shape fluctuations, and (b) pronounced shape fluctuations for relatively small tension. (Courtesy of J. Rädler and E. Sackmann.)

6.1 Bending Modes or Undulations

On scales that are large compared to the membrane thickness, the typical shape fluctuations of fluid membranes are bending modes or undulations in which the surface area of the membrane remains unchanged.

6.1.1 Roughness Arising from Bending Modes An almost planar membrane segment that has bending rigidity κ and experiences the lateral tension Σ undergoes bending undulations that can be expanded in Fourier modes. The amplitude of these excitations depends on the temperature T. For a segment of linear size $L_{\|}$, these undulations lead to the membrane roughness $L_{\perp}$ with

$$\begin{aligned} L_{\perp}^2 &\approx (T/2\pi\Sigma)\ln(L_{\|}/\xi_{\Sigma}) \qquad \text{for } L_{\|} \gg \xi_{\Sigma}, \\ &\approx (T/16\kappa)L_{\|}^2 \qquad \text{for } L_{\|} \ll \xi_{\Sigma}, \end{aligned} \tag{6}$$

provided the crossover length $\xi_{\Sigma} \equiv (4\kappa/\Sigma)^{1/2}$ is large compared to the molecular scales (Brochard and Lennon, 1975). Thus, one has a rigidity-dominated regime for $L_{\|} \ll \xi_{\Sigma}$ and a tension-dominated regime for $L_{\|} \gg \xi_{\Sigma}$.

6.1.2 Measurement of the Bending Rigidity Since the roughness $L_{\perp} \sim (T/\kappa)^{1/2}L_{\|}$ within the rigidity-dominated regime, measurements of this roughness can be used to determine the bending rigidity κ. In practice, this is done by optical microscopy of nearly spherical vesicles for which the undulations are expanded in spherical harmonics. In this way, one finds the typical values $\kappa \simeq (10 - 20)T$ for phospholipid bilayers (for a recent list, see Seifert and Lipowsky, 1995). It is, however, difficult to obtain high-precision values for κ. This is understandable since the bending rigidity of lipid bilayers is affected by small changes in their molecular structure arising, e.g., from conelike defects or from the molecular roughness of the lipid–water interfaces.

6.2 Thermal Fluctuations on Molecular Scales

The concept of a bending mode is no longer meaningful as soon as its wavelength becomes of the order of the membrane thickness. On these small scales, the molecular structure of the lipid–water interface should be taken into account. This interface is roughened by thermal fluctuations, as has been observed in computer simulations (Pastor, 1994) and has been deduced from scattering experiments (Koñig *et al.*, 1992; Wiener and White, 1992; McIntosh and Simon, 1993). These thermal fluctuations correspond to relative displacements or deformations of the lipid head groups: Since they will, in general, change the surface area of the lipid–water interface, they are governed by an effective tension Σ_{eff}. The roughness arising from these fluctuations is set by the length scale $(T/2\pi\Sigma_{\text{eff}})^{1/2}$, which is expected to be of the order of a few ångströms.

6.3 Persistence Length on Large Scales

On sufficiently large scales, a fluid surface that does not experience any lateral tension starts to crumple, i.e., to behave as a random surface without any average orientation. This happens as soon as its size exceeds the so-called persistence length (de Gennes and Taupin, 1982; Gompper and Kroll, 1995). For phospholipid bilayers with bending rigidities $\kappa \gtrsim 10T$, the persistence length is, however, very large compared to the largest accessible sizes of these bilayers. Therefore, under normal circumstances, lipid bilayers (and biomembranes) do not behave as random surfaces with no average orientation.

7. GENERIC INTERACTIONS OF TWO MEMBRANES

The behavior of interacting membranes is governed by the interplay of direct interactions arising from the forces between the molecules and shape fluctuations such as bending undulations that act to renormalize these interactions.

7.1 Direct Interactions between Rigid Membranes

The direct interaction $V(l)$ between two rigid membranes at separation l can be measured by the surface force apparatus consisting of two mica surfaces onto which the membranes are immobilized (Marra and Israelachvili, 1985). The simplest example is provided by lipid bilayers that

1. are electrically neutral and
2. interact across a water layer that contains no macromolecules or colloids.

In this case, the interaction potential $V(l)$ is composed of a repulsive hydration and an attractive van der Waals interaction and has the schematic form shown in Fig. 7(a).

Lipid bilayers may become charged by adsorption of ions from the solution or by dissociation of their head groups. They then exhibit electric double layers, which usually lead to *repulsive* interactions between the surfaces as predicted by the classical Poisson–Boltzmann theory. The combination of van der Waals and electrostatic interactions often leads to a potential barrier as shown in Fig. 7(b).

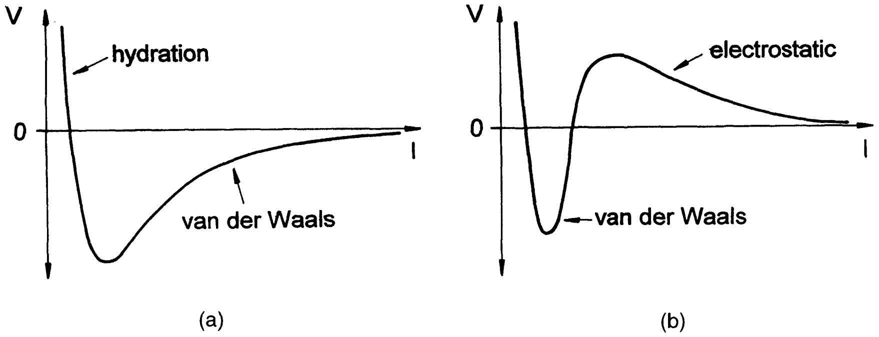
7.2 Renormalization by Bending Undulations

Two interacting membranes that are in thermal equilibrium with the surrounding liquid undergo bending undulations. Since the configurational entropy of the undulations increases with the membrane separation, these fluctuations lead to a repulsive force that drives the membranes apart and, thus, reduces the attractive part of their interaction. It will be tacitly assumed here that the interaction potential $V(l)$ is effectively short-ranged and decays faster than $\sim 1/l^2$ for large l. Van der Waals forces eventually decay as $\sim 1/l^4$ and thus belong to this strong-fluctuation regime.

7.2.1 Repulsive Interactions If the interaction $V(l)$ between the membranes is effectively repulsive, the membranes can be kept together by an osmotic pressure P arising, e.g., from macromolecules in the surrounding solution that cannot permeate the membranes. In this case, the membranes are bound for finite $P > 0$ but unbind in the limit of zero P. The mean separation $\langle l \rangle$ behaves as $\langle l \rangle \sim 1/P^{\psi}$ for small P with the unbinding exponent $\psi = \frac{1}{3}$. As the membranes unbind, the probability $\mathcal{P}_2$ for pair contacts or two-membrane collisions decays to zero as $\mathcal{P}_2 \sim 1/\langle l \rangle^{\zeta_2}$ with the contact exponent $\zeta_2 = 3$. This is completely analogous to the behavior of one-dimensional strings, which are governed by a finite line tension.

The behavior of the mean separation $\langle l \rangle$ can be obtained from the entropic or fluctuation-induced interaction $V_{\text{fl}}(l) \sim 1/l^2$, as deduced by Helfrich (1978) using a heuristic scaling picture even though this picture implies the incorrect behavior $\mathcal{P}_2 \sim 1/\langle l \rangle^2$ for the contact probability.

7.2.2 Attractive Interactions and Continuous Unbinding For a direct interaction as shown in Fig. 7(a) that is dominated by attractive van der Waals forces, the membranes undergo a *continuous* unbinding transition from a bound state at low temperatures to an unbound state at high temperatures, as was first predicted theoretically (Lipowsky and Leibler, 1986). If the interaction potential $V(l)$ is parametrized by the effective potential depth $|U|$ and the effective potential range l_v, the unbinding temperature is given by



(a) (b)

FIG. 7. Direct interaction V between two planar membranes as a function of the membrane separation l: (a) hydration and van der Waals interaction between electrically neutral membranes; (b) hydration, van der Waals, and electrostatic interaction between electrically charged membranes leading to a potential barrier.

$$T_u \simeq \sqrt{\kappa |U|} l_v^2. \qquad (7)$$

As one approaches $T = T_u$ from below, the mean separation $\langle l \rangle$ of the membranes diverges as $\langle l \rangle \sim 1/|T - T_u|$, and the strength $|W|$ of the renormalized potential vanishes as $|W| \sim -|T - T_u|^2$. The same critical behavior is found for two interacting strings in two dimensions where the unbinding process represents a wetting transition.

The adhesion of large vesicles is also diminished by thermally excited fluctuations; compare Fig. 6. From the relation (5) and the behavior $|W| \sim -|T - T_u|^2$ of the adhesive strength, one obtains the unbinding temperature $T_u^{\text{ves}} \approx T_u - c\kappa l_v/\sqrt{\mathcal{A}}$ for large vesicles with surface area $\mathcal{A} \gg \kappa/|U|$.

7.2.3 Potential Barriers and Discontinuous Unbinding The direct interaction $V(l)$ may exhibit a potential barrier as shown in Fig. 7(b). In this case, the unbinding transition can be continuous or discontinuous depending on the relative strength of the potential barrier. If the potential barrier is relatively weak, the undulations "tunnel" through the barrier and the unbinding transition is continuous. This is again analogous to one-dimensional strings in two dimensions, which tunnel, however, through *any* potential barrier that decays faster than $1/l^2$ for large l. In contrast, two-dimensional membranes cannot tunnel through sufficiently strong barriers. In the latter situation, they are trapped by the barrier, and the unbinding transition is discontinuous.

7.3 Tension-Induced Adhesion

A lateral tension Σ acts to suppress the bending undulations and thus to decrease the fluctuation-induced repulsion. In fact, this interaction now becomes short-ranged and decays exponentially as $V_{\text{fl}}(l) \sim \exp(-l/l_\Sigma)$ for separations $l \gg l_\Sigma \equiv (T/2\pi\Sigma)^{1/2}$. Thus, for sufficiently large separations, this fluctuation-induced repulsion cannot compete with the attraction arising from van der Waals forces, and the membranes form a bound state in the presence of lateral tension. In the limit of vanishing tension, the membranes unbind provided the temperature exceeds the unbinding temperature T_u.

It has been argued by Helfrich (1989) that some lipid bilayers show a more complex behavior in the low-tension regime and that these layers develop a superstructure that acts as an additional reservoir for membrane area. This issue remains to be clarified.

7.4 Repulsive Interactions at Small Separations

It has been well established by many experiments that lipid bilayers in aqueous solution experience a strong repulsion at small separations of the order of 1 nm (Rand and Parsegian, 1989). The corresponding force per unit area or disjoining pressure, P, is observed to decay exponentially as $P \sim \exp(-l/l_{\text{eff}})$, where the effective decay length l_{eff} is of the order of a few ångströms; see Fig. 8. It was originally thought that this short-ranged repulsion represents a hydration effect and reflects the perturbed water structure in front of the polar head group (Marcelja and Radic, 1976). On the other hand, a similar repulsive force can also arise from the molecular roughness of the lipid–water interfaces (Israelachvili and Wennerström, 1990). In general, both mechanisms should contribute, and their relative importance will depend on the temperature and on the lipid–solvent composition (Lipowsky and Grotehans, 1994).

8. BUNCHES AND STACKS OF MEMBRANES

Lipid bilayers in solution often form bunches in which several membranes are, on average, parallel to each other. Two different geometries must be distinguished:

1. free bunches in solution, as shown in Fig. 9(a), and
2. bunches that adhere to a rigid surface or wall; see Fig. 9(b).

The latter geometry is obtained, e.g., by spreading a concentrated lipid solution on a glass slide.

The structure of such a bunch can be characterized by its density profile, which depends on the mean separations of the membranes within the bunch. If the shape fluctuations of these membranes are strong, they drive the membranes apart and lead to loosely bound or highly swollen states (Lipowsky, 1995a).

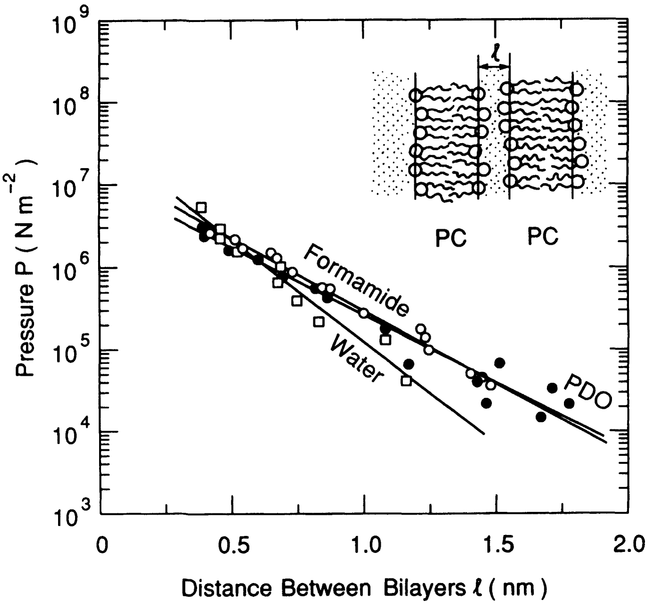


FIG. 8. Disjoining pressure P of phosphatidyl choline (PC) bilayers as a function of the mean separation $\langle l \rangle$ of lecithin or PC bilayers for the three solvents water, formamide, and 1,3-propanediol (PDO) (McIntosh *et al.*, 1989).

8.1 Free Membranes in Solution

For a free bunch of N identical membranes as shown in Fig. 9(a), all membranes have the same bending rigidity κ, and each adjacent pair of membranes interacts with the direct interaction $V(l)$. If the bunch is kept together by short-ranged attractive interactions arising, e.g., from van der Waals forces, it undergoes a *unique* unbinding transition as observed

1. in experiments for up to 20 sugarlipid membranes (Mutz and Helfrich, 1989) (see Fig. 10), and
2. in Monte Carlo simulations for up to four membranes (Netz and Lipowsky, 1993).

The unbinding temperature T_u^f of the free bunch is *independent* of N and thus identical to the unbinding temperature of two membranes.

Analytical work on bundles of strings (Hiergeist *et al.*, 1994) leads to the prediction that the mean separation $\langle l \rangle_n$ of the adjacent

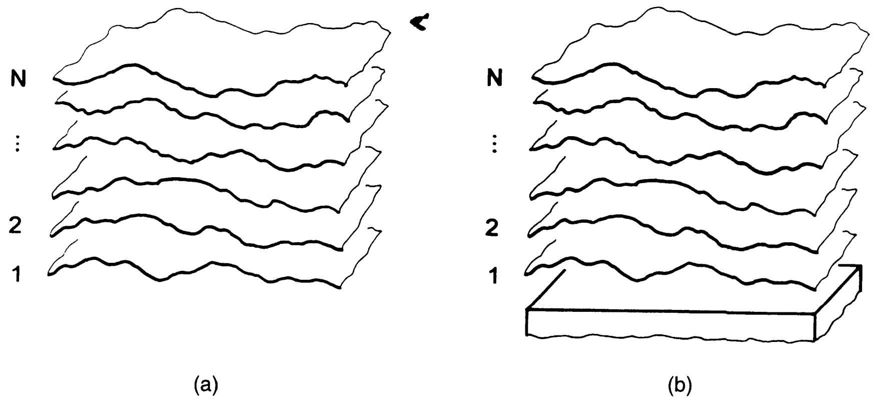

FIG. 9. Bunches of N fluctuating membranes: (a) Free bunch in solution; (b) bunch adhering to a rigid surface or wall.

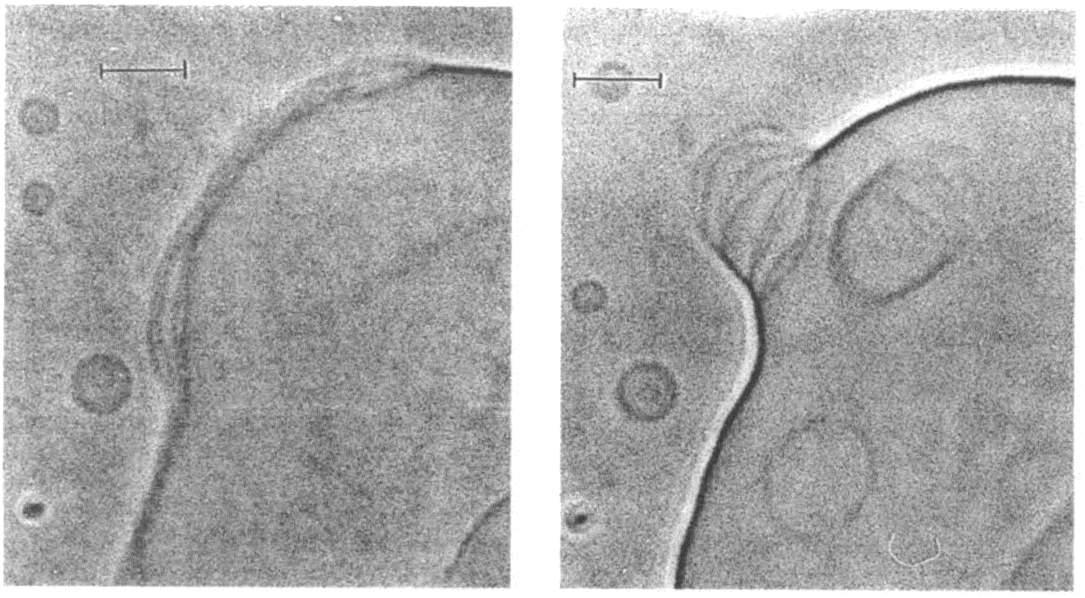

FIG. 10. Unbinding or adhesion transition as experimentally observed for a bunch of eight lipid bilayers in aqueous solution. (Left) For $T \simeq 22.4$ °C, the membranes undulate very strongly and then appear as thick fuzzy lines. (Right) For $T \simeq 22.1$ °C, the membranes form a bound state that corresponds to the sharp dark line. The water between the membranes has been squeezed into the large water pocket. The bars represent 10 μm. (Courtesy of W. Helfrich.)

membranes labeled by n and $n + 1$ is given by

$$\langle l\rangle_n \sim 1/n(N - n)|T - T_u^f|^{\psi} \qquad \text{with } \psi = 1. \tag{8}$$

Thus, all length scales should diverge with the universal unbinding exponent $\psi = 1$ but should exhibit an amplitude that depends strongly on N and on the position n within the bunch. This implies that the temperature interval in which the behavior is dominated by fluctuations shrinks as $\sim 1/N$ for large N. Therefore, for large N the continuous unbinding transition will appear to be discontinuous.

8.2 Membranes at a Rigid Surface

In the case of N membranes attracted toward a rigid surface or wall, as shown in Fig. 9(b), the unbinding behavior depends on the relative strength of the surface–membrane and the membrane–membrane attraction. There are essentially two possibilities:

1. If the attraction toward the substrate is sufficiently weak, one has a sequence of two transitions: the whole N-bunch unbinds from the substrate at the unbinding temperature $T = T_u^b < T_u^f$ and then undergoes the transition toward completely unbound membranes at $T = T_u^f$.
2. If the attraction toward the rigid surface is relatively strong, one has a sequence of N unbinding transitions and thus a sequence of unbinding temperatures T_u^n with $T_u^f < T_u^n \leq T_u^1$. At each of these transitions, a single membrane peels off from the bunch. Such peeling processes should always occur during the formation of vesicles from oriented samples. Thus, in this case, the presence of the rigid surface is still felt by the outermost membrane even in the presence of many intervening membranes.

8.3 Limit of Lyotropic Liquid Crystal

In the limit of large N, the membrane stack becomes a lyotropic liquid crystal, which can be studied by x-ray and neutron scattering.

8.3.1 Power-Law Peaks of the Scattering Intensity The renormalization of the direct interaction $V(l)$ by bending modes with small wavelengths leads to the effective potential $V_{\text{eff}}(l)$, which determines the mean separation $\langle l \rangle$ via $\partial V_{\text{eff}}(l)/\partial l = 0$. Expanding this effective potential up to second order in the displacements, one obtains a harmonic model, which leads to the prediction that the scattering intensity $S(q)$ exhibits the power-law behavior

$$S(q) \sim (q_z - q_m)^{-(2-X_m)} \quad \text{with } X_m \equiv Tq_m^2/8\pi\sqrt{\kappa v_{\text{eff}}} \qquad (9)$$

in reciprocal space along the q_z direction close to $q_z = q_m = 2\pi m/\langle l \rangle$ with $m = 1, 2, \ldots$ and $v_{\text{eff}} \equiv \partial^2 V_{\text{eff}}(l)/\partial l^2$ at $l = \langle l \rangle$. These power-law peaks are known as Landau–Peierls singularities and have been studied by x-ray scattering on lamellar phases of oil–water–surfactant mixtures (Meunier *et al.*, 1987).

8.3.2 Melting of Lamellar States Lamellar phases of oil–water–surfactant mixtures often melt into isotropic phases. If the melting is initiated by bending undulations, one may assume that the lamellar phase becomes unstable as soon as the roughness $\xi_\perp$ of the membrane separation satisfies $\xi_\perp > c_* \langle l \rangle$ (de Gennes and Taupin, 1982) (note that the roughness of a single "tracer" membrane within the liquid crystal increases logarithmically with the size of the membrane). This relation corresponds to the so-called Lindemann criterion for the melting of solids. Within the harmonic model, this implies that the lamellar phase becomes unstable as soon as the bending rigidity becomes too small and satisfies $\kappa < T^2/(2\pi c_*)^2 v_{\text{eff}} \langle l \rangle^4$.

9. POLYMER-DECORATED MEMBRANES

In addition to the lipid bilayer, biomembranes contain a complex mixture of macromolecules. These molecules, which are anchored in the membranes, are usually connected to a network of relatively stiff, rodlike filaments that belong to the so-called cytoskeleton within the cell. Likewise, the outer plasma membrane is often covered by a "coat" of polysaccharides, i.e., of branched polymers, which are also anchored within the membranes. These systems can be modeled, to a certain extent, by the decoration of lipid bilayers with polymers.

9.1 Anchored Polymers

Any polymer with one or several hydrophobic segments that fit into the hydrophobic interior of the lipid bilayer can be anchored to this bilayer. The simplest geometry is obtained for a polymer with a single anchor attached to one of its ends. Artificial systems of this kind are water-soluble polymers covalently bound to a single lipid molecule (Lasic, 1994) or block copolymers with a short hydrophobic block. Another possibility is to use polymers with hydrophobic side groups (Simon *et al.*, 1995). In this case, the polymers can be attached by several anchors. Such a system is shown in Fig. 11. In contrast to polymers grafted to solid surfaces, these anchored polymers can diffuse laterally along the fluid membrane.

If the nonanchored segments of the polymer are effectively repelled from or attracted to the membrane surface, the anchored polymer is in a desorbed or in an adsorbed state, respectively. In the desorbed state, a polymer that is attached to the membrane by a single anchor has the form of a "mushroom," the size of which is comparable to the dissolved polymer. Weak adsorption leads to squashed mushrooms; strong adsorption, to polymer "pancakes" that are tightly bound onto the membrane surface.

9.2 Dilute and Semidilute Regimes

First, consider effectively repulsive interactions between the anchored polymer and the membrane surface. If the concentration of anchors within the membrane is sufficiently small, the anchored polymers form well-separated mushrooms. This dilute regime applies up to the overlap concentration at which the membrane surface becomes completely covered by anchored polymers. If one increases the coverage beyond this overlap value, the polymers start to squeeze and to stretch each other and one enters the brush regime. This brush regime extends up to a maximal coverage at which the loss of entropy arising from the stretched state of the polymers exceeds their anchoring energy.

A similar distinction applies to anchored

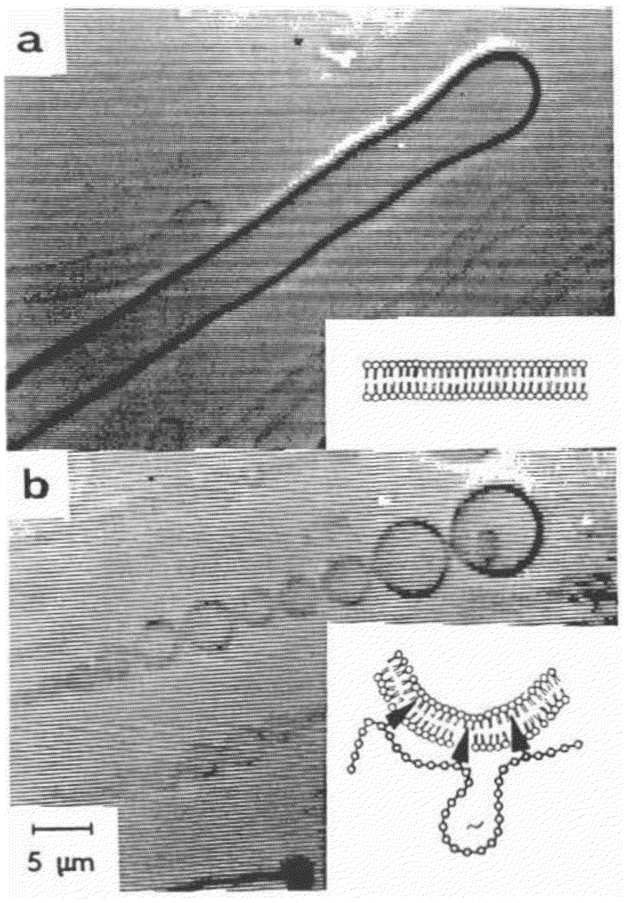

FIG. 11. Shape transformation of (a) a tubular vesicle into (b) a string of spheres as induced by the addition of polymers with hydrophobic side groups. This transformation is presumably governed by the interaction of these side groups with the lipid bilayer. (Courtesy of H. Ringsdorf.)

polymers that are adsorbed onto the membrane. In the dilute regime, one has well-separated pancakes. Beyond the overlap concentration, these pancakes start to interpenetrate each other and to form a semidilute adsorption layer.

9.3 Polymer-Induced Curvature

A bound polymer or mushroom suffers a loss of entropy compared to the free state. This entropy loss depends on the shape of the membrane; see Fig. 12. Therefore, the mushroom exerts entropic forces on the membrane that bend the membrane away from the polymer (Lipowsky, 1995b).

In the unbound state, a linear flexible polymer consisting of N monomers of linear size a forms a coil of linear dimension $R_{po} \simeq aN^{\nu}$ with $\nu \simeq 3/5$ for good solvents. In the bound mushroom state, the polymer induces the "spontaneous" mean curvature

$$M_{\mathrm{sp}} \sim T/\kappa R_{po} \sim T/\kappa a N^{\nu} \qquad (10)$$

of the decorated membrane. In a similar way, curvature is induced by a polymer brush that is attached to the membrane in a nonsymmetric way. If the polymer is adsorbed onto the membrane, on the other hand, it induces the opposite sign of the curvature: The membrane now bends toward the membrane in order to maximize the number of contacts.

9.4 Polymer-Induced Adhesion

The adhesion of cell membranes is mediated by rodlike polymers that have a linear extension of 10–30 nm. In the absence of these sticky rods, the cell membranes experience an effectively repulsive interaction arising from the electric charges on their surfaces. The adhesive strength mediated by

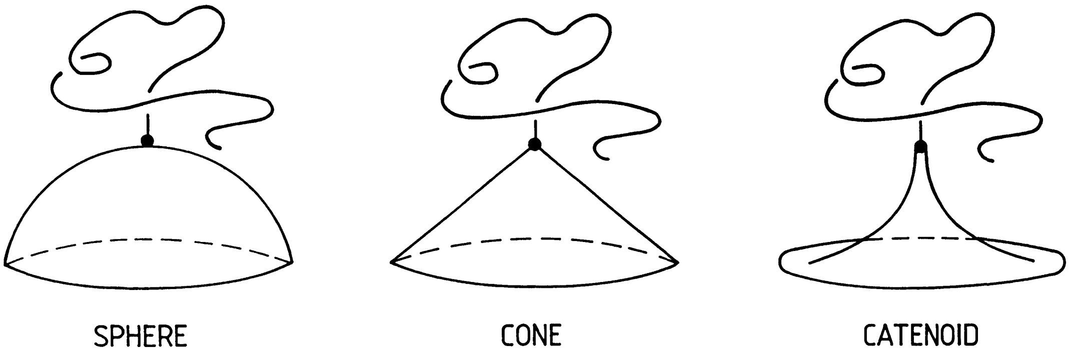

FIG. 12. A polymer attached to the membrane by a single anchor forms a mushroom that bends the membrane by entropic forces. For the three shapes of the membrane segment shown here, the cone leads to the highest entropy for the anchored polymer.

the sticky rods depends on the concentration X of their anchors within the membrane.

Since this strength must exceed a certain threshold value in order to overcome the repulsion arising from the membrane undulations, the anchor concentration must also exceed a critical value X_c. If the rod anchors attract one another, the bilayers may undergo phase separation into polymer-rich domains with $X > X_c$ and polymer-depleted domains with $X < X_c$. In the latter case, the membranes will only adhere via the polymer-rich domains.

10. APPLIED ELECTROMAGNETIC FIELDS

For the phenomena discussed in the previous sections, the molecular structure of the lipid bilayer is not perturbed in an essential way. In contrast, the application of pulsed electric fields or of optical tweezers built up from a laser beam strongly perturbs the bilayer structure, which leads to new cooperative effects.

10.1 Alternating Electric Fields

The lipid membrane has a dielectric constant (or permittivity) $\epsilon_M \simeq 2$, which is small compared to the dielectric constant $\epsilon_W \simeq 80$ of water. Likewise, the electrical conductivity γ_W of water is large compared to the conductivity γ_M of the lipids. This implies that the electric field is *amplified* within the membrane. This is the basic mechanism that is responsible for the electroporation and electrofusion of lipid bilayers and biomembranes (Neumann *et al.*, 1989; Chassy *et al.*, 1992).

If the alternating electric field $\mathbf{E}_W \exp[i\omega t]$ is applied in the water and the two lipid–water interfaces are treated as dividing surfaces with no intrinsic width, the transmembrane potential $\Delta\Phi_M$ across a planar membrane is given by

$$\begin{aligned} \Delta\Phi_M &= E_M a_\perp \\ \text{with } E_M &= \left[\frac{(\omega\epsilon_W)^2 + \gamma_W^2}{(\omega\epsilon_M)^2 + \gamma_M^2}\right]^{1/2} E_W, \end{aligned} \tag{11}$$

where $a_\perp$ represents the thickness of the membrane (this relation follows from Maxwell's equations and the continuity equation for the charge carriers). For water without salt, the square root prefactor is about 5×10^3.

10.2 Electroporation

If the lipid membrane is exposed to a transmembrane potential $\Delta\Phi_M$ that exceeds $\simeq 0.2$ V for an extended period of time, the membrane ruptures in an irreversible way. On the other hand, if one applies a potential $\Delta\Phi_M$ of the order of 1 V for a relatively short time period Δt within the range 10^{-7} s $\leq \Delta t \leq 10^{-4}$ s, one obtains a reversible electrical breakdown of the lipid bilayer: The permeability of the bilayer is strongly increased right after the pulse has been applied but then relaxes back to its original value. This behavior is observed both for artificial lipid bilayers and for biomembranes. In both cases, the high-permeability state arises from the formation of pores within the lipid membrane. These pores have been directly observed by freeze-fracture electron microscopy.

10.3 Electrofusion

Two membranes that are in close contact can be fused by applying a short electrical pulse. It is widely believed that this process of electrofusion is induced by the simultaneous electroporation of both membranes within the contact area. It has also been found, however, that fusion can even occur when the membranes are treated with electrical pulses before being brought into close contact. Electrofusion is a universal fusion mechanism that has been applied to many different types of biomembranes. An example in shown in Fig. 13.

The initial fusion step presumably consists in the juxtaposition of two pores in the two adjacent membranes. The next step should be the formation of a neck or "wormhole" that bridges the gap between the two membranes. Several intermediate structures that could be involved in this topological transformation have been proposed.

10.4 Optical Tweezers

Optical tweezers, arising from a laser beam that is focused through a microscope objective, provide localized light traps and can be used to manipulate various objects in the micron range. Recently, such tweezers have been directly applied to lipid bilayers and were found to induce novel shape transformations. When applied to cylindrical vesicles consisting of a single bilayer, the tweezers induce a pearling instability, which spreads from the trap and eventually produces a chain of pearls that again resembles the Plateau–Rayleigh instability of capillary tubes. When applied to bunches of several bilayers, the light trap acts to unbind the membranes locally and to induce a characteristic shape of the loosely bound structure (Bar-Ziv *et al.*, 1995).

It is presently believed that the focused laser beam destroys the bilayer structure locally and acts to pull lipid molecules into the light trap. This process should generate a lateral tension for the rest of the membrane, which is not exposed to the beam. A theoretical model has been developed that is based on this interpretation and has been used to calculate the selected wavelength of the pearling instability (Goldstein et al., 1996).

11. OUTLOOK ON APPLICATIONS

The tendency of lipids to form closed compartments such as vesicles is used in pharmacology, food industry, and cosmetics in order to enclose and transport drugs, enzymes, vitamins, moisturizers, and other in-

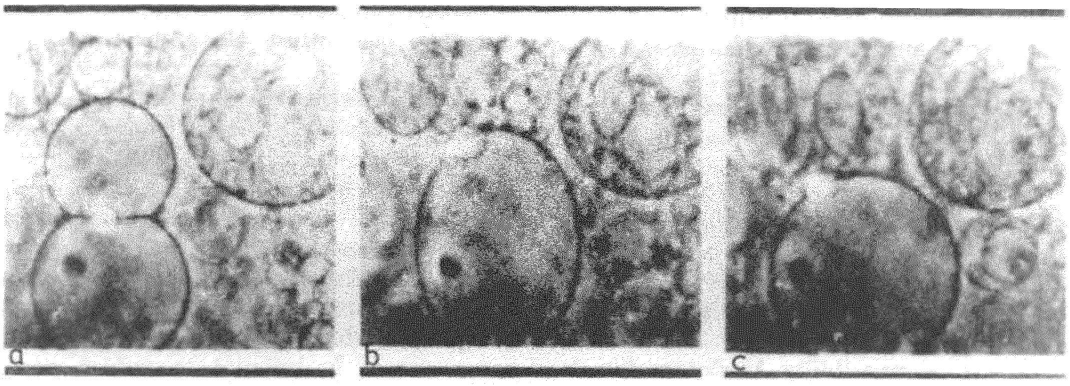

FIG. 13. Electrofusion of two lipid vesicles as observed by phase contrast microscopy: (a) The two vesicles, with diameters of about 45 and 37 μm, are brought into close contact by an alternating electric field; (b) fused vesicle about 1 s after the application of a short electrical pulse; (c) the fused vesicle, which has a diameter of about 51 μm, becomes roughly spherical when the alternating field is switched off. (Courtesy of U. Zimmermann.)

gredients. The delivery of drugs via vesicles can be improved by the decoration with polymers that are attached to the lipid head groups and that prevent the uptake of these vesicles by lymphocytes in the blood. Furthermore, vesicles composed of lipid mixtures might be used in order to transport drugs directly through the skin and, thus, to replace the use of hypodermic needles.

Other interesting areas are attempts to attach lipid layers to solid substrates in order to build up new types of biosensors, or to cover artificial bones by such layers in order to improve their biocompatibility.

The mechanisms of electroporation and electrofusion have been applied to many areas of biotechnology. For example, electroporation is now widely used in order to transfer genes into all kinds of cells.

In summary, flexible membranes already play an important role in various soft-matter technologies. It seems rather likely that an improved understanding of the physics of these systems will lead to new technological applications: The future is in the flexible!

GLOSSARY

Aggregation Colloids: Supramolecular structures that arise from the self-assembly of single molecules or monomers in solution.

Amphiphilic Molecules: Molecules that have a lyophilic part, which dissolves in the solvent, and a lyophobic part, which is insoluble in the solvent. One important example is molecules dissolved in water that have a polar hydrophilic part and a nonpolar hydrophobic part.

Anchored Polymer: Polymer chain attached to the bilayer membrane by one or several hydrophobic segments that fit into the hydrophobic interior of the bilayer. If the nonanchored segments of the polymer are effectively repelled or attracted to the membrane surface, the anchored polymer attains the form of a "mushroom" or "pancake," respectively.

Area Compressibility Modulus: Elastic modulus of membranes that governs their resistance against stretching.

Bending Rigidity: Elastic modulus of membranes that governs their resistance against bending.

Bilayer: Membrane consisting of two monolayers that are arranged in such a way that the polar head groups of the lipid molecules form the two lipid–water interfaces, whereas the hydrophobic chains are buried within the bilayer and have essentially no contact with the aqueous solution. The thickness of these bilayers is 4–5 nm.

Budding: Shape transformation in which the membrane produces a small bud that is essentially spherical and connected to the original membrane via a small neck.

Conformal Diffusion: For vesicles with two or more handles, the shape of the vesicle can undergo a diffusion process along degenerate states that are related by conformal transformations.

Critical Monomer Concentration: This concentration represents

1. the upper limit for the concentration of amphiphilic monomers in solution and
2. the critical concentration at which the amphiphilic molecules start to aggregate into supramolecular structures.

It is also called *critical micelle concentration* since many surfactant molecules assemble into micelles.

Curvature: Any point on a two-dimensional surface that is embedded in three-dimensional space can be characterized by two principal curvatures, C_1 and C_2, which are equal to the inverse curvature radii. The mean curvature is given by $M \equiv (C_1 + C_2)/2$.

Decorated Membrane: Lipid bilayer with anchored polymers. For fluid bilayers, these polymers can diffuse along the membrane surface.

Direct Interaction: Interaction between two rigid membranes arising from the forces between the molecules. This interaction can be measured by the surface-force apparatus in which the membranes are immobilized onto two mica surfaces.

Electrofusion: Two adjacent membranes that are separated by a small water layer can be fused by the application of an electrical pulse, which is believed to induce pores through both membranes.

Electroporation: Pores that go through a bilayer can be induced by the application of a short electrical pulse with a voltage of the order of 1 V.

Flip-flops: The slow exchange of molecules between the two monolayers of a bilayer membrane.

Fluid Membranes: Membranes for which shear deformations relax by flow within the membrane. The molecules within such membranes undergo rapid lateral diffusion.

Hydrophobic Effect: The tendency of amphiphilic molecules in water to form supramolecular structures in which the hydrophilic groups of these molecules form the outside interface toward the aqueous solution, whereas the hydrophobic groups are buried inside and have essentially no contact with the water; the corresponding free-energy change has a large entropic contribution arising from the configurational entropy of the hydrogen bond networks in the water.

Internal Membranes: Biomembranes within the cell that cover many intracellular organelles such as the cell nucleus, the endoplasmic reticulum, mitochondria, etc.

Lipids: Amphiphilic molecules for which the hydrophobic part consists of two hydrocarbon chains and the hydrophilic part consists of a polar head group.

Lyotropic Liquid Crystal: Liquid crystals that can be swollen by the addition of solvent. In the present context, these liquid crystals consist of stacks of bilayer membranes.

Monolayer: Monomolecular layer of amphiphilic molecules that can be found, e.g., at the interface between two immiscible liquids such as water and oil.

Optical Tweezers: Light trap with a linear size of about 0.5 μm, which is generated by a focused laser beam and which can be used to grasp and to move a single lipid membrane or a whole bunch of membranes.

Plasma Membrane: Biomembrane that represents the boundary between a biological cell and its environment; it consists of a lipid bilayer with many anchored proteins.

Polymer-Induced Curvature: Polymers that are anchored onto the membrane exert entropic forces that induce a "spontaneous" curvature of the decorated membrane.

Shape Fluctuations: Membranes flicker and thus undergo thermally excited undulations that are directly visible in the optical microscope.

Shape Transformations: The shape of vesicles can be transformed in a controlled way by changing the temperature or the osmotic conditions. Such shape transformations can occur in a continuous or discontinuous fashion.

Surfactants: Amphiphilic molecules for which the hydrophobic part usually consists of one hydrocarbon chain.

Tension of Rupture: Lateral tension, of the order of a few mJ/m^2, at which the lipid membrane ruptures.

Unbinding Transition: Phase transition of interacting membranes between a bound adhesive state at low temperatures and an unbound nonadhesive state at high temperatures.

Vesicle: Closed bilayer without edges, which can attain a large variety of different shapes. An onionlike structure consisting of several closed bilayers is usually called a liposome.

INTRODUCTION

The atomic vibrations of solids play a fundamental role in many of their properties. These vibrations determine thermal energy contents and heat transport, and they also influence many other properties of solids, like optical absorption or electrical conduction. In their pioneering work Debye (1912) and Born and von Kármán (1912) have shown that in crystals the vibrational states can be well described as collective excitations, in which atoms oscillate with certain phase relations relative to their neighboring atoms. The motions are described as waves with wavelength λ and frequency of vibration ν. These waves travel through the crystal with velocity v and can pick up or give up energy like a harmonic oscillator. In the quantum picture, the quanta of these vibrations are called phonons.

The vibrational states of highly perfect crystals have been studied by now in detail, and the concept of elastic waves has been well confirmed. However, as more highly disordered solids, like amorphous solids and mixed crystals, have been investigated more thoroughly, it has been recognized that their vibrational states are more complex. In this article, some of the experimental observations of these vibrational states are reviewed, and the models proposed for their description are described.

1. EXPERIMENTAL METHODS

The measurements to be discussed below are thermal conductivity, specific heat, and propagation of ultrasound. These techniques are shown schematically in Fig. 1. Thermal conductivity Λ is defined as the proportionality factor between heat current density and temperature gradient; for the simple geometry shown in Fig. 1(a),

$$\Lambda = (d/A)P/\Delta T, \tag{1}$$

where P, the constant thermal power generated in an electric heater, enters the sample of cross section A at the top and leaves it at the bottom. The temperature difference ΔT is measured with two thermometers that are spaced along the sample by the distance d. To ensure that P only flows through the sample, it is mounted in an evacuated space. Since at elevated temperatures, typically above ~100 K, a non-negligible fraction of the heat also travels through vacuum as infrared radiation, a different technique is preferable at these temperatures (Cahill, 1990), as sketched in Fig. 1(b): A thin metal strip evaporated onto the sample is heated by an alternating current. It creates a temperature wave that diffuses into the sample. The amplitude of this temperature wave varies inversely as the thermal conductivity of the sample. Since the electrical resistance of the metal strip varies with its temperature, it

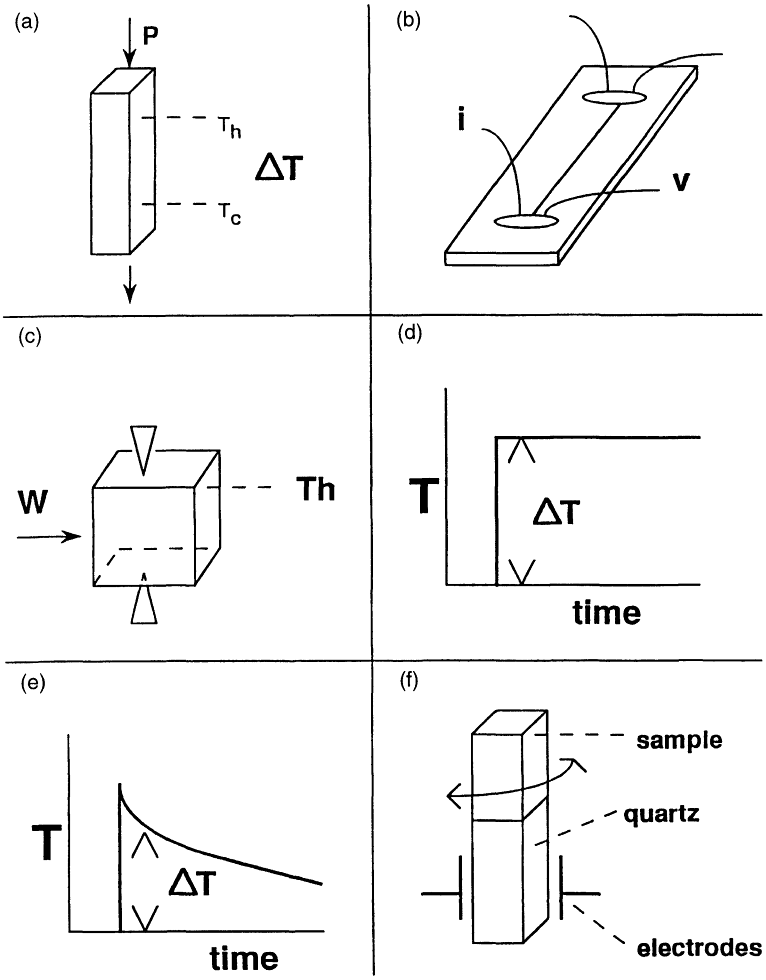

FIG. 1. Sketches of the experimental methods used. (a) Thermal conductivity. A steady heat flow sets up a temperature gradient along the sample. (b) Thermal conductivity measured with an alternating electric current flowing through a thin metal film deposited on a flat sample. The film is also used as thermometer. (Cahill, 1990.) (c) Specific heat. The sample (drawn as a cube) is supported in an evacuated chamber between pins, to ensure thermal isolation. When heat W is added (Joule heating of a heater attached to the sample), the temperature rise is monitored with a thermometer (Th). (d): After the heat W has been added in (c), the temperature T rises rapidly (ΔT) in a crystalline solid. In an amorphous solid, (e) thermal equilibrium is reached only gradually: "time-dependent specific heat," see text. (f): Torsional oscillator driven by an electric quadrupole field applied perpendicularly to the long axis of the quartz rod that acts as transducer.

can also be used to measure the latter. From this temperature amplitude, the thermal conductivity of the sample can be obtained. It can be shown that because of the geometry, the radiative heat losses are negligible.

For specific-heat measurements, the sample (mass m) is mounted such that it is essentially thermally isolated from its surroundings, Fig. 1(c). A very small electric heater is used to add the energy W to the sample, raising its temperature by ΔT; see Fig. 1(d). The specific heat C_p is then calculated through

$$C_p = (1/m)W/\Delta T. \tag{2}$$

(The subscript "p" indicates that the measurement is carried out at constant pressure, and not at constant volume; below 300 K, the difference is usually negligible.) If thermal equilibration is reached slowly, the temperature measured by the thermometer will at first rise steeply, and then will decrease with time, as the heat is slowly absorbed by the weakly coupled excitations; see Fig. 1(e). From such a measurement, the thermal relaxation of these excitations can be determined. If this time-dependent $\Delta T(t)$ is inserted into Eq. (2), one obtains a quantity $C_p(t)$, which is often called a time-dependent specific heat. This terminology is somewhat misleading, because the thermodynamic definition of C_p requires ΔT to be constant, i.e., the sample to be in thermal equilibrium. Nonetheless, in the following we will use this generally accepted term.

For the ultrasonic measurement, a variety of techniques can be used to measure either longitudinal or transverse sound attenuation. In Fig. 1(f), a setup is sketched in which the sample is attached to a quartz transducer that is excited by a time-varying electric field applied perpendicular to its axis to perform a torsional (twisting) motion around its axis (Cahill and VanCleve, 1989). Transducer and sample have been cut to the proper length so that a standing torsional wave is excited, with half a wavelength in the transducer and half a wavelength in the sample. For a typical driving frequency of 50 kHz, the quartz transducer must be ~3 cm long; the length of the sample depends on its transverse speed of sound. With this arrangement ultrasonic losses in the epoxy that is used to bond the sample to the transducer are minimized, since the glue line is in a plane of maximum torsional amplitude, and hence of minimum strain.

The quantity measured is the attenuation of the amplitude A of this compound oscillator:

$$A = A_0 \exp(-Q_{\mathrm{co}}^{-1}\pi\nu t), \qquad (3)$$

where A_0 is the amplitude of the wave at the time $t = 0$, ν is its frequency, and Q_{co}^{-1} is called the internal friction of the compound oscillator. The internal friction Q^{-1} of the sample itself is then calculated from

$$Q^{-1} = \frac{I_s + 1.06 I_t}{I_s} Q_{\mathrm{co}}^{-1}, \qquad (4)$$

where I_s and I_t are the rotational inertias of sample and transducer, respectively.

2. ORDERED CRYSTALS

In order to illustrate the properties of a solid in which the elastic excitations are waves, Figs. 2 and 3 show specific heat and thermal conductivity of several highly perfect crystals containing a minimum amount of chemical and physical imperfections. Over most of the temperature range, the specific heat C_p varies as the third power of the temperature T. The dashed lines are the predictions of the Debye theory based on the assumption that the entire thermal energy is contained in plane waves, all moving with

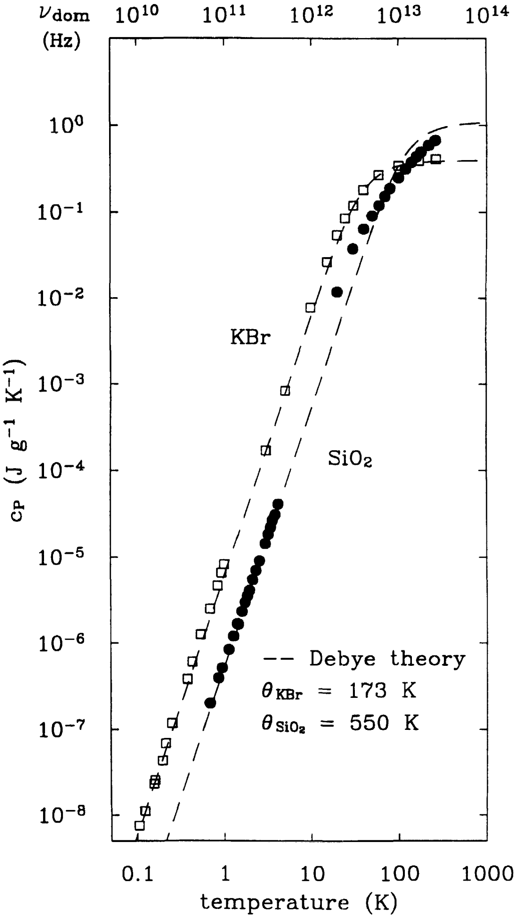

FIG. 2. Specific heat of two perfect single crystals. Measurements compared with the Debye theory (dashed lines). As the temperature increases, increasingly larger frequencies of vibration are thermally excited, shown as ν_{dom} on the upper horizontal scale (see text). Thus, by varying the temperature, one can vary the frequency of the waves studied.

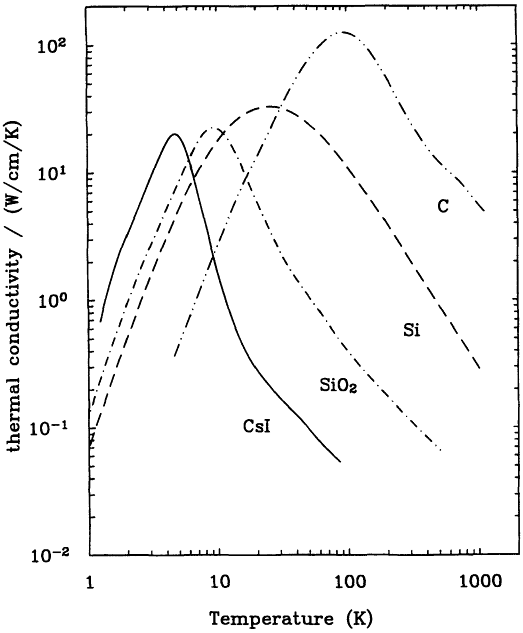

FIG. 3. Thermal conductivity of four perfect single crystals. C is diamond. By changing the measuring temperature, one can learn about the scattering of different phonon frequencies (see caption of Fig. 2).

the speed of sound, which is an average of the transverse and the longitudinal speeds of sound.

The Debye theory for elastic waves parallels that of Planck's theory for electromagnetic waves, in particular at low temperatures, where the energy contents of both vary as T^4, or the specific heat varies as T^3 (the only qualitative difference is that elastic waves can also be longitudinal; a quantitative difference is that the elastic waves have velocities about 10^5 times smaller than the electromagnetic ones). As the temperature increases, waves of increasingly larger frequency are excited. In Planck's theory this shift is called Wien's displacement law. It connects the frequency ν_{Wien} that, in a given frequency interval, carries most of the energy, with the temperature T. ν_{Wien} varies linearly with T:

$$\nu_{\mathrm{Wien}} = 5(k_B/h)T \approx (10^{11}\ \mathrm{Hz/K})T = \nu_{\mathrm{dom}}, \tag{5}$$

where $k_B = 1.38 \times 10^{-23}$ W s K^{-1} is Boltzmann's constant, and $h = 6.62 \times 10^{-34}$ W s^2 is Planck's constant. For elastic waves, this frequency is called the dominant frequency ν_{dom}. It is shown on the top axis in Fig. 2.

An important difference between Planck's and Debye's theories occurs only at high temperatures, at which the latter predicts a deviation of C_p from the T^3 behavior. In Fig. 2, this deviation occurs at ~10 K. The simple explanation is that at high temperatures the specific heat of solids must approach the classical Dulong–Petit value, which is derived from the fact that each atom in a solid can be viewed as a harmonic oscillator vibrating in the three spatial directions with the total energy

$$w = 3k_BT, \tag{6}$$

leading to a specific heat

$$C_p = 3Nk_B\rho = 3R\rho, \tag{7}$$

where $N = 6.02 \times 10^{23}$ mole^{-1} is Avogadro's number, ρ the mass density, and $R = 8.31$ W s mole^{-1} K^{-1} the universal gas constant. The high-temperature asymptotic value of the Debye theory is the Dulong–Petit value. Another way to understand the deviation of C_p from the T^3 behavior is that the total number density of normal modes (the traveling waves) cannot be larger than $3n$, where n is the number density of the atoms in the solid. This means that in the Debye theory an upper limit ν_D exists for the vibrational frequencies. It is called the Debye cutoff frequency ν_D and is given by

$$\nu_D = (6/8\pi)^{1/3}n^{1/3}v, \tag{8}$$

where v is the average speed of sound and $n^{1/3}$ the inverse of the interatomic spacing. One also talks about the Debye temperature, defined as $\Theta_D = \nu_D h/k_B$.

The elastic waves in solids carry energy, and this leads to conduction of heat (in metals, the electrons will also carry energy, but we restrict the discussion to electric insulators—also called dielectrics). The thermal conductivity of four highly perfect crystals is shown in Fig. 3. It differs significantly from that of the crystal's electromagnetic counterpart, vacuum. In empty space, the electromagnetic waves travel uninhibited, which leads to an infinite thermal conductivity. In the perfect crystal, scattering processes apparently exist at all temperatures, i.e., for waves of all frequencies (see the dominant frequency scale on the top axis in Fig. 2). At temperatures above the conductivity maximum, the anharmonic forces between the atoms lead to an increasingly larger scattering probability for the elastic waves (one talks about phonon–phonon scattering; Peierls, 1929). Below the maximum, this process vanishes in importance as a new process dominates: that of phonon scattering at the sample boundaries (Casimir, 1938). Using an analogy to the heat transport in a gas, we can express the thermal conductivity of the dielectric crystals as

$$\Lambda = \tfrac{1}{3}C_p\rho v l = \tfrac{1}{3}Cvl \qquad (9)$$

where $C = C_p\rho$ is the specific heat of the lattice vibrations or phonons per volume, v their average velocity, and l their mean free path between collisions (most easily visualized in the phonon picture). At low temperatures, when l is determined by collisions with the sample boundaries, $l \sim d$, where d is the sample diameter [see Fig. 1(a)]. Hence one expects $\Lambda \propto C \propto T^3$, as is indeed observed experimentally; see Fig. 3.

3. AMORPHOUS SOLIDS

3.1 Experiments

Having seen how the elastic waves in highly perfect dielectric crystals determine specific heat and thermal conductivity (we address the internal friction later), we now consider amorphous solids, interchangeably also called glasses. These solids can be viewed as having been quenched from the melt, although this is not the only way to produce them. Structurally, they are defined as solids lacking long-range order. Figure 4 shows the profound effect this disorder has on the thermal conductivity of SiO_2 (Zeller and Pohl, 1971). The thermal conductivity decreases monotonically with decreasing temperature, and even at the lowest temperature the Casimir boundary limit has not yet been reached. Most remarkable is the fact that all amorphous solids studied to date have very similar thermal conductivities, regardless of their chemical composition, their bonding, or their atomic arrangements. This is demonstrated in Fig. 5 on seven different amorphous solids with widely different bonding, some disordered on the atomic scale, some with some degree of order, like the polymeric solids. All amorphous solids measured lie in the range spanned by the seven solids shown. They all share the same temperature dependence: The thermal conductivity Λ varies at the lowest temperatures, up to a few kelvins, according to a power law:

$$\Lambda \propto T^\delta, \qquad (10)$$

with δ close to 2.0. The thermal conductivity levels off at intermediate temperatures, sometimes with some kind of dip or plateau, and near room temperature it becomes nearly independent of temperature.

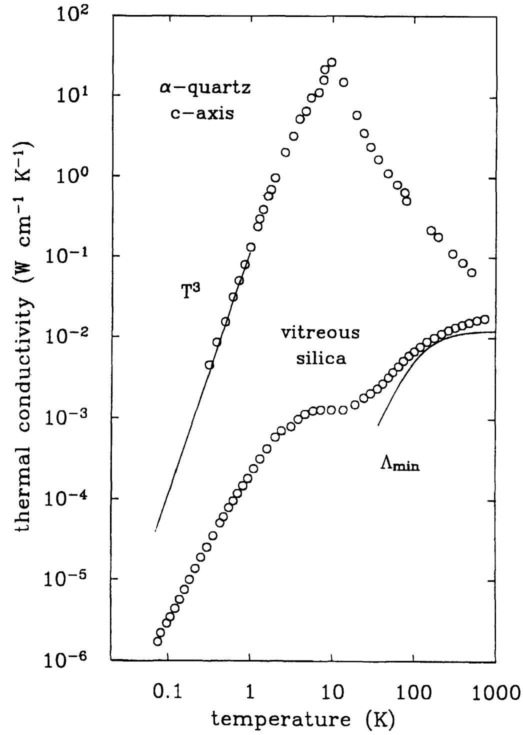

FIG. 4. Thermal conductivity of SiO_2 in the crystalline phase (α quartz) and in the amorphous phase (vitreous silica, a-SiO_2). The solid line indicates the Casimir prediction (boundary scattering). The curve called Λ_{min} is based on the model first proposed for crystals by Einstein (1911). It fits the amorphous data very well above ~50 K, considering that it contains no adjustable parameters.

The profound effect of the amorphous

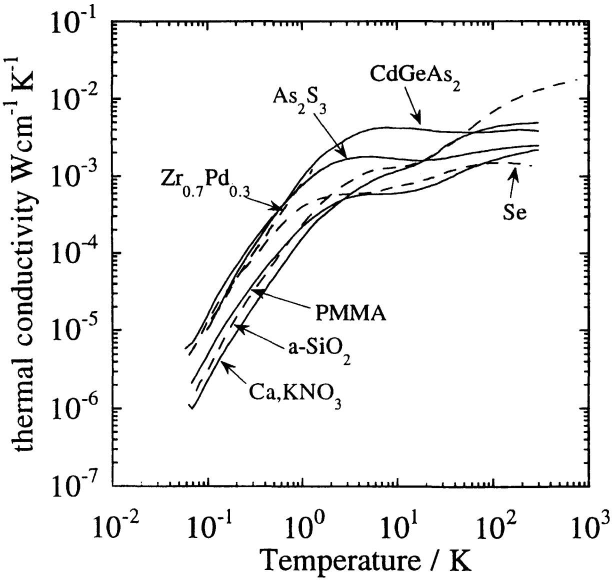

FIG. 5. Universal thermal conductivity of amorphous solids. At temperatures below 1 K the thermal conductivity of all amorphous solids becomes proportional to the square of the temperature. In addition, the magnitude of the thermal conductivity of all amorphous solids lies within a factor of 10 of that of *a*-SiO$_2$ at all temperatures. Zr$_{0.7}$Pd$_{0.3}$ is superconducting in the temperature range shown here and therefore behaves like a dielectric solid in this experiment.

structure on the lattice vibrations is emphasized in Fig. 6. Using Eq. (9), the phonon mean free path has been plotted for three amorphous solids, and for crystalline SiO$_2$ (α quartz). Beginning with quartz, the phonon mean free path l is found to be constant at low temperatures, and close to the sample diameter, as expected for boundary scattering. Above 10 K, l drops precipitously, as a result of phonon–phonon scattering. However, even at 300 K, l ~ 5 nm, which is much larger than the wavelength of the waves that carry most of the heat in quartz at this temperature (see the dashed line in Fig. 6). In the amorphous solids, l is much smaller at all temperatures. Above ~50 K, l becomes comparable to the dominant phonon wavelength. This is a particularly important observation, because a wave that does not even travel the distance of its wavelength before being scattered cannot be considered a wave any more. This is the first indication that the concept of elastic waves needs to be revised in disordered solids.

The specific heat of the amorphous solids shows equally strange, and also universal, behavior, as shown for three solids in Fig. 7. A comparison with the Debye prediction (the dashed lines) based on their known speeds of sound demonstrates the poor fits, which seem worst at the lowest temperatures. A fairly good fit to the experimental specific heat can be obtained with a polynomial,

$$C_p = AT + BT^3, \qquad (11)$$

where A is of very similar magnitude for all amorphous solids (to within about one order of magnitude), and B is close to, though never smaller than, and sometimes more than a factor of 2 larger than, the Debye value based on the speed of sound.

Ultrasonic attenuation in amorphous solids is shown in Fig. 8, measured through internal friction with the technique described in Fig. 1(f). All amorphous solids have a nearly temperature-independent internal friction in the temperature range 1–10 K, followed by a decrease at even lower temperature (Topp and Cahill, 1996). As in the case of the thermal conductivity, the magnitude of the temperature-independent internal friction Q_0^{-1} lies in a narrow range: $10^{-4} \lesssim Q_0^{-1} \lesssim 10^{-3}$.

The internal friction measured on a single crystal of silicon is very much smaller (see Fig. 8), and is determined by losses in the mounting and by accidental impurities (the latter causing the narrow peaks). The internal friction of a perfect crystal is expected to be orders of magnitude smaller yet.

The experiments described in this section have demonstrated strikingly different behavior from that of crystals, both at low (less than a few kelvins) and at high temperatures (~300 K), corresponding to low and high frequencies of the excitations, respectively.

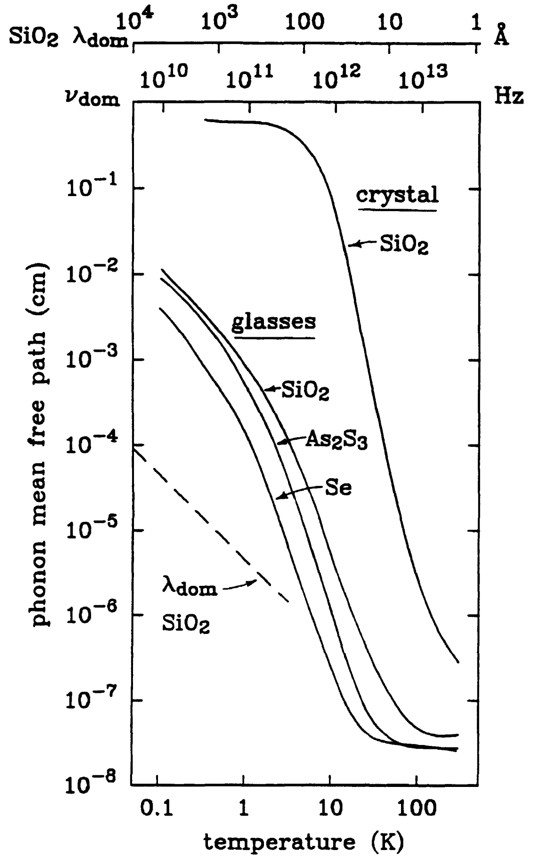

FIG. 6. Phonon mean free path l calculated with the help of Eq. (9). The specific heat used for the calculation is the Debye specific heat based on speeds of low-frequency sound. At the top is shown a scale of the dominant phonon frequency ν_{dom} (see text) and dominant phonon wavelength (for a-SiO_2, using the Debye speed of sound $v = 4.1 \times 10^5$ cm s^{-1}). The dashed line marked "λ_{dom}, SiO_2" shows how much shorter this quantity is below ~10 K than the mean free paths measured in the glasses (Zeller and Pohl, 1971).

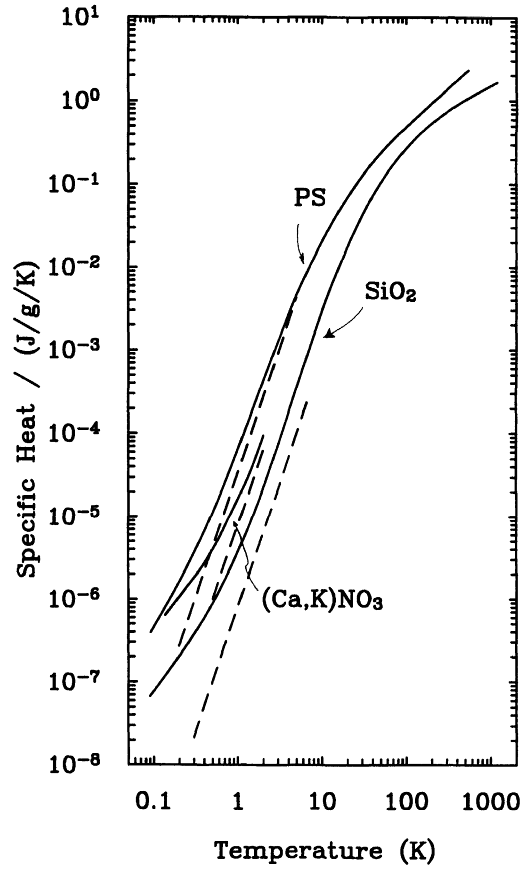

FIG. 7. Specific heat C_p of three amorphous dielectric solids: polystyrene (PS), a-SiO_2, and $Ca_{0.40}K_{0.60}NO_3$ [(Ca,K)NO_3]. Below 1 K, they all approach a linear temperature dependence, the magnitude of which is very similar, independent of chemical composition (and impurities) or sample preparation. The dashed lines are Debye-model calculations based on the measured speeds of sound: top, PS; bottom, SiO_2.

In the next section we review theoretical models proposed to explain these phenomena.

3.2 Theoretical Models

3.2.1 Low-Temperature Properties; Tunneling Model This model is based on the observation that some impurity atoms or molecules in otherwise perfect crystals are known to have more than one equilibrium position or orientation in their lattice sites, between which they move not only by thermally activated jumps over the potential barriers separating the wells but also by a quantum-mechanical process described as tunneling through the barriers (Narayanamurti and Pohl, 1970). As an example we mention KCl containing LiCl in small concentration ($\ll 1\%$); the small Li+ ion has eight equilibrium positions in its K^+ vacancy, which are displaced from the cavity center in the direction toward its eight Cl^- neighbors. The energies required for tunneling to occur between these positions are much smaller than those required for the

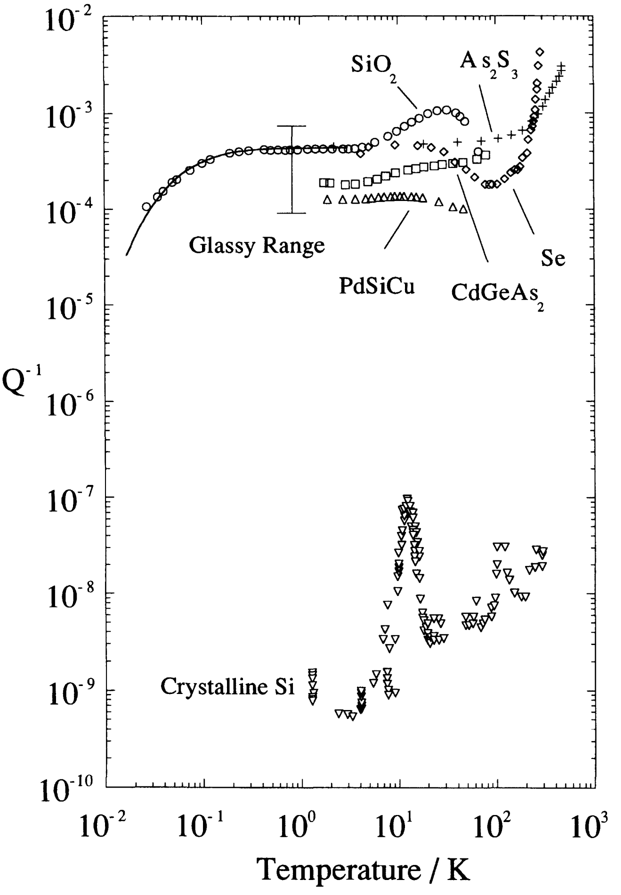

FIG. 8. Internal friction of amorphous and crystalline solids. At temperatures below ~10 K, the internal friction of amorphous solids becomes temperature independent with a magnitude between 10^{-4} and 10^{-3}, marked with the bar labeled "glassy range." This can be contrasted with the behavior found in crystalline solids where the internal friction can be some five orders of magnitude smaller and is then determined by mounting losses and accidental impurities. Data for amorphous solids are taken from Topp and Cahill (1996) while data for crystalline Si are from McGuigan *et al.* (1978). Solid line through the *a*-SiO$_2$ data is a fit based on the tunneling model. The dropoff of Q^{-1} in amorphous solids at the lowest temperatures is frequency dependent, also in agreement with the model. The large Q^{-1} is also observed in normally conducting amorphous metals (e.g., in PdSiCu).

thermally activated jumps between different equilibrium configurations; in KCl:Li, these so-called tunnel splitting energies are of the order of (1 K)k_B, but much smaller splittings have been observed in other doped solids. The thermal population of the excited tunneling states leads to specific-heat anomalies (so-called Schottky anomalies), which peak close to the temperature at which the dominant phonon energy $h\nu_{\mathrm{dom}}$ is equal to the tunnel splitting energy. An example of this is shown later (Fig. 15). Resonant scattering by these states has been observed through a depression of the thermal conductivity in the same temperature range.

In order to explain the low-temperature specific-heat anomaly varying linearly with temperature in all amorphous solids, the assumption was made (Anderson *et al.*, 1972; Phillips, 1972) that atomic or molecular tunneling is common to this state of matter. Because of its random structure, however, neighboring potential minima are separated by barrier heights of different magnitude [Figs. 9(a) and 9(b)]. Furthermore, asymmetries were postulated for the neighboring potential minima [Figs. 9(c) and 9(d)]. Under reasonable assumptions about the distribution of barrier heights and asymmetries, a constant density of states of the tunneling states could be derived with which both the linear specific heat anomaly and the thermal conductivity varying as T^2 below 1 K could be obtained, in agreement with the experiment. This model also predicted the existence of a temperature-independent plateau in the internal friction below a few kelvins, followed by a dropoff at the lowest temperatures, as subsequently indeed discovered in elastic measurements, shown in Fig. 8. The solid curve is the theoretical fit to the experimental data for *a*-SiO$_2$.

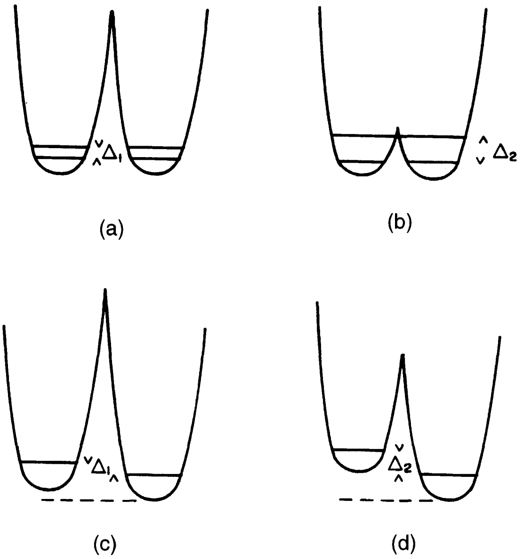

FIG. 9. Tunneling model (Anderson *et al.*, 1972; Phillips, 1972): The splitting of the tunneling states, Δ_i, depends on the barrier height [(a), (b)] and also on the asymmetry of neighboring potential minima [(c), (d)]. At any given temperature, states with one particular splitting Δ_i will be thermally excited.

This model made the additional prediction that the thermal relaxation in an amorphous solid should occur only gradually, a phenomenon that would lead to a time-dependent specific heat as described in Sec. 1. Its origin can be visualized with the help of Fig. 9: At a certain temperature T the states with a certain energy splitting, say Δ_2, will dominate the specific heat, where $k_BT \approx \Delta_2$. Nearly symmetric potential wells (Fig. 9b), leading to states for which Δ_2 is determined mostly by the tunneling probability, will relax much faster than states for which Δ_2 is determined largely by asymmetry (Fig. 9d), and for which the barrier height is high, hence the tunneling probability is small. The specific-heat measurements on a-SiO$_2$ shown in Fig. 10 largely confirmed this prediction. Large thermal-relaxation effects occur on measuring-time scales less than ~1 s, but even on the time scales of hours the thermal relaxation is still measurable.

Figure 10 also illustrates that on time scales exceeding those on which specific-heat measurements are usually carried out, 1–10^2 s, the increase of the specific heat with measuring time becomes rather small [note in Fig. 10 the increase expected between 10^4 s and 10^9 y (!), based on the tunneling model]. Thus, measurements of the kind shown previously (see Fig. 7) may to a good approximation be considered as having been performed in thermal equilibrium, although strictly speaking, the low-temperature data in Fig. 7 will grow forever—as illustrated in Fig. 10.

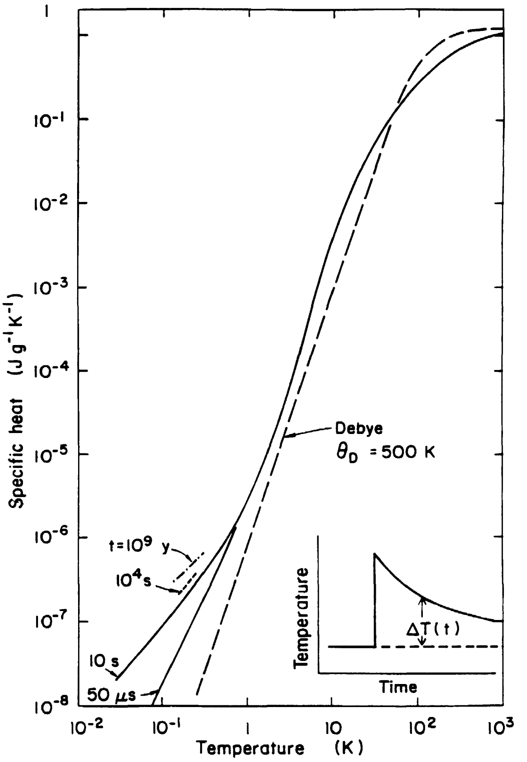

FIG. 10. Specific heat C_p of vitreous silica compared with the Debye theory based on elastic measurements (reviewed in Pohl, 1987). The inset shows an effect observed only below 1 K [see Fig. 1(e)]. After a heat pulse has been added to the sample, which is assumed to be perfectly thermally isolated from its surroundings, the temperature rise ΔT decays logarithmically with time, as an increasing number of the slowly relaxing low-energy excitations take up energy from the rest of the sample. As a consequence, the specific heat appears to increase with time. After 50 μs, the heat is distributed only over the most rapidly relaxing excitations, and thus C_p appears small. After 10 s (the usual time scale of specific heat measurements), C_p has become essentially independent of time, as shown with measurements after 10^4 s and an extrapolation to a time comparable to the age of the solar system.

One other point needs to be mentioned:

The tunneling model postulates the existence of the tunneling states in addition to the collective elastic excitations, the Debye waves. The existence of the latter in amorphous solids has indeed been proven for waves of frequencies as large as 10^{11} s^{-1}. The tunneling model considers the heat to be carried by the elastic waves; the latter are scattered by the tunneling states, which are spatially localized.

The tunneling model predicts that for sufficiently short measuring times, most of the tunneling states will not reach thermal equilibrium; the tunneling states will be "decoupled," and the specific heat should approach its Debye limit (the dashed curve in Fig. 10). This, however, has not been observed. According to the existing measurements, the short-time specific heat always exceeds the Debye prediction. If this excess were caused by strongly coupled defects other than the ones considered in the tunneling model, they should show up in thermal conductivity through their phonon scattering, which, however, does not seem to be the case. This is not understood.

One final point: The tunneling model makes no assumption as to why the tunneling density of states is nearly the same, within an order of magnitude, for all amorphous solids. This point, which appears to be an experimental fact, continues to be the major puzzle in our understanding of the tunneling model.

3.2.2 High-Temperature Properties; Einstein's Model Revisited It has been shown earlier (Fig. 6) that the assumption of elastic waves carrying the heat in amorphous solids at temperatures above, say, 50 K, corresponding to frequencies exceeding several THz, leads to unphysically short mean free paths. Thus, another model for the heat transport is needed in that temperature or frequency range. It has been shown experimentally that a model first considered for crystals by Einstein (1907), and also found by him to be inappropriate for these solids (Einstein, 1911), works very well for amorphous solids, yet for so-far unknown reasons. This is discussed next.

Einstein considered the lattice vibrations of solids to be individual atomic vibrations. Each atom vibrates with a characteristic frequency (the Einstein frequency) about its equilibrium position, with no well-defined phase relation to the motion of its neighbors, in contrast to wavelike motions. By applying the quantum concept to these mechanical oscillators, he successfully explained, at least qualitatively, the decrease of the specific heat from its high-temperature Dulong–Petit value, as the temperature decreased. However, when he applied the random-phase model of oscillations to the thermal conductivity of crystalline dielectrics, the model failed completely: Einstein showed that harmonic oscillators oscillating with equal frequencies but random phases should exchange their energies with the neighboring atoms on the time scale of one-half of a period of vibration. Setting this period equal to that of the Einstein oscillator, he calculated with no free parameters a thermal conductivity, as shown in Fig. 4, where it is labeled as $\Lambda_{\min}$ (this name is explained later). The computed curve disagrees completely both in magnitude and temperature dependence with the experimental thermal conductivity of crystalline SiO_2 (α quartz). This disagreement paved the way for the model of elastic waves proposed in 1912. What Einstein did not notice, however, was the good agreement of his theory with the thermal conductivity of amorphous SiO_2 (vitreous silica), also shown in Fig. 4 (Cahill and Pohl, 1989a). This close agreement suggested that above $\sim$50 K not elastic waves but randomly vibrating atoms were the proper description of the thermal vibrations in this amorphous solid. Note that this model closely resembles the one proposed to describe the heat transport in liquids viewed as a densely packed gas; each atom moves with its thermal velocity through the cavity it occupies, passing on its energy upon colliding with one of its neighbors (Bridgman, 1931). As a test for the model, which had worked so well for one amorphous solid, the Einstein picture was applied to a wide range of amorphous solids; note that in Fig. 5, the high-temperature thermal conductivity of amorphous solids ranges over about one order of magnitude. Using the measured elastic constants, an approximate average Einstein frequency was determined for each solid, and from that and the known average atomic mass and diameter, a thermal conductivity was calculated with no free parameters (Cahill *et al.*, 1992). Figure 11 shows the comparison of the cal-

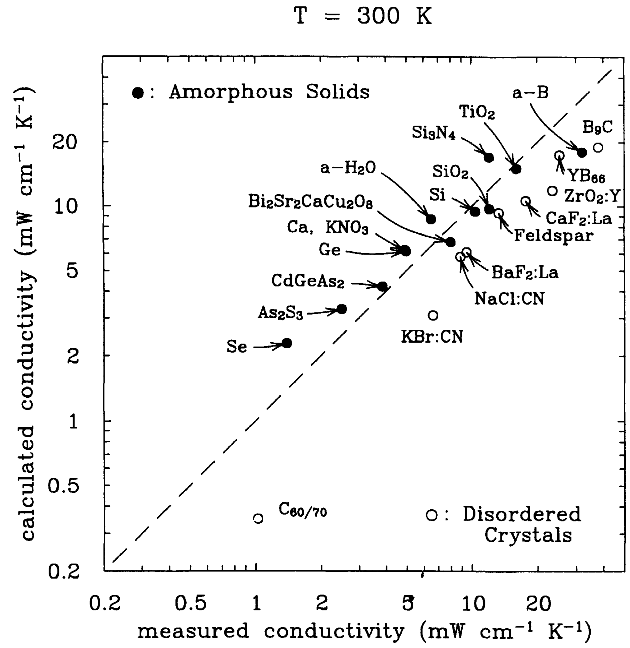

FIG. 11. Composite plot of the calculated minimum thermal conductivity at 300 K vs the measured values; all points lie close to the dashed line, which is drawn to indicate perfect agreement between experiment and Einstein's model (Cahill *et al.*, 1992). Amorphous solids are shown as filled circles and disordered crystals as open circles. The disordered crystals are single crystals, with the exception of $C_{60/70}$, which was compacted from microcrystalline powder (Olson *et al.*, 1993). While for perfect and also for lightly disordered crystals data to the right of the dashed line are common, no disordered (fully dense) solids have yet been found with thermal conductivities significantly smaller than the Einstein prediction (i.e., with data points to the left of the dashed line). This justifies calling this prediction the minimum thermal conductivity; see Fig. 4.

culated thermal conductivity of 11 amorphous solids with that measured at 300 K (ignore the open circles for the moment). The dashed line is drawn to indicate what would be perfect agreement between theory and experiment. Given the simplicity of the model, the agreement observed is quite satisfactory. It suggests that this model is indeed appropriate, although an understanding of the time for energy exchange is still lacking.

4. HIGHLY DISORDERED CRYSTALS

Intermediate between perfect crystals and amorphous solids are the disordered crystals. In general, their lattice vibrations depend critically on the type of disorder, although in most cases a combination of propagating elastic waves and of somehow localized excitations provides an adequate description. In this section, it is shown that the lattice vibrations observed in amorphous solids can also occur in certain highly disordered crystals. Thus, the universality stressed above for amorphous solids also extends to disordered crystals. Following common usage, we call these vibrations "glasslike." Since the disorder in crystals can be controlled, in contrast to that of amorphous solids, one may hope that a study of the glasslike lattice vibrations will provide a better handle for their understanding.

The evolution of glasslike lattice vibrations with increasing disorder is illustrated on the mixed crystal $Ba_{1-x}La_xF_{2+x}$ for increasing x. Its crystal structure is the cubic fluorite structure, Fig. 12, like that of BaF_2, as confirmed by x-ray diffraction. The third F ion introduced through the addition of the LaF_3, labeled F_i, occupies a vacant interstitial site in the center of a cube formed by eight fluorine ions. For $x = 8 \times 10^{-3}$, the thermal conductivity is nearly as expected for a perfect crystal; see Fig. 13 (Cahill *et al.*, 1992). As x increases, the thermal conductivity decreases, and approaches the low-temperature T^2 temperature dependence with the magnitude characteristic for amorphous solids. At high temperatures, it approaches a temperature-independent value with a magnitude close to that predicted by the Einstein model (see the curve labeled $\Lambda_{\min}$). Note that as x approaches 1.0 (pure LaF_3), the conductivity rises again and shows the temperature dependence characteristic for crystals. Measurements of the low-temperature specific heat and internal friction have also confirmed the glasslike lattice vibrations inferred

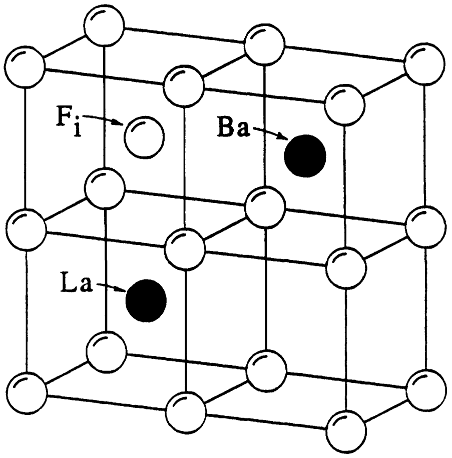

FIG. 12. Structure of an isolated defect in $Ba_{1-x}La_xF_{2+x}$. The La^{+++} ion substitutes on a Ba^{++} site. The charge-balancing fluorine interstitial, marked F_i, is shown in a nearest-neighbor position.

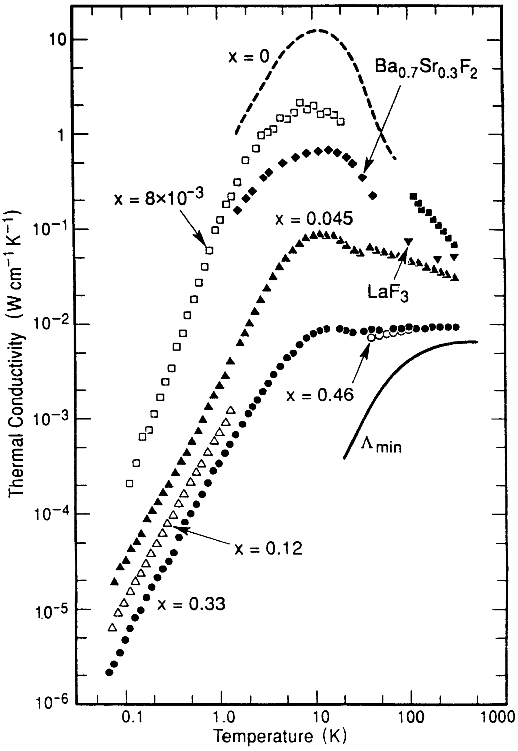

FIG. 13. Thermal conductivity of the mixed crystal $Ba_{1-x}La_xF_{2+x}$. Thermal conductivity for $x = 0$ below 30 K is shown as a dashed line. Solid line labeled Λ_{min} is the thermal conductivity calculated using Einstein's model as described in the text. Note the three data points for pure LaF_3. (Cahill *et al.*, 1992). The mixed crystal $Ba_{0.7}Sr_{0.3}F_2$ does not have glasslike lattice vibrations.

from thermal conductivity (Cahill and Pohl, 1989b).

Figure 13 also contains an example of a disordered crystal without glasslike lattice vibrations: The thermal conductivity of $Ba_{0.7}Sr_{0.3}F_2$, in which crystal the cations are distributed randomly over the cation sites, is that of a crystal with point defects.

Another example of glasslike lattice vibrations is shown in Fig. 14. $Or_1Ab_{33}An_{66}$ is a feldspar (labradorite), whose chemical composition can be described as a mixture of orthoclase (Or, which is short for $KAl\text{-}Si_3O_8$), albite (Ab, $NaAlSi_3O_8$), and anorthite (An, $CaAl_2Si_2O_8$). Its crystal structure can be approximately described as a three-dimensionally linked network of AlO_4 and SiO_4 tetrahedrons, with charge balancing alkali- and alkaline-earth ions occupying interstitial sites. Feldspars are of great geophysical interest, since they constitute 60% of the earth's crust. Thus, their very small, glasslike thermal conductivity, strikingly illustrated through the comparison with two amorphous solids, plays an important role in determining the heat flow out of the earth's interior.

The observation of glasslike lattice vibrations in the mixed BaF_2:LaF_3 crystal and in the feldspar suggests that large concentrations of interstitial ions may be important in causing these vibrations. However, glasslike lattice vibrations are also observed in disordered crystals without interstitials: The open circles in Fig. 11 show the comparison of the measured high-temperature thermal conductivity of a variety of disordered crystals with that predicted by the Einstein model. In addition to feldspar and the BaF_2:LaF_3 mixed crystals, glasslike lattice vibrations are, for example, established in yttria-stabilized zirconia, which contains vacancies in the oxygen sublattice, or in the mixed crystals of alkali halide–alkali cyanides, in which the oblong CN^- ions occupy halogen sites in the cubic lattice. All of the disordered crystals in Fig. 11 have random strains in common. However, such random strains alone are not sufficient to produce glasslike lattice vibrations either, since mixed crystals of $(BaF_2)_{1-x}(SrF_2)_x$, which also have random

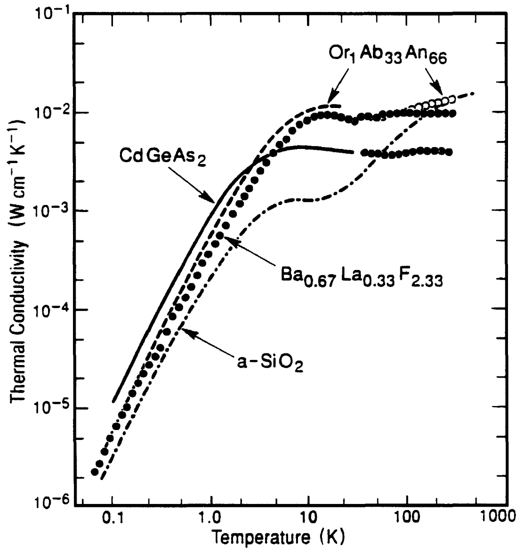

FIG. 14. Thermal conductivity of two disordered crystals, the feldspar labradorite (Or$_1$Ab$_{33}$An$_{66}$) and Ba$_{1-x}$La$_x$F$_{2+x}$, $x = 0.33$, compared with that of two amorphous solids, *a*-SiO$_2$ and CdGeAs$_2$ (Cahill *et al.*, 1992).

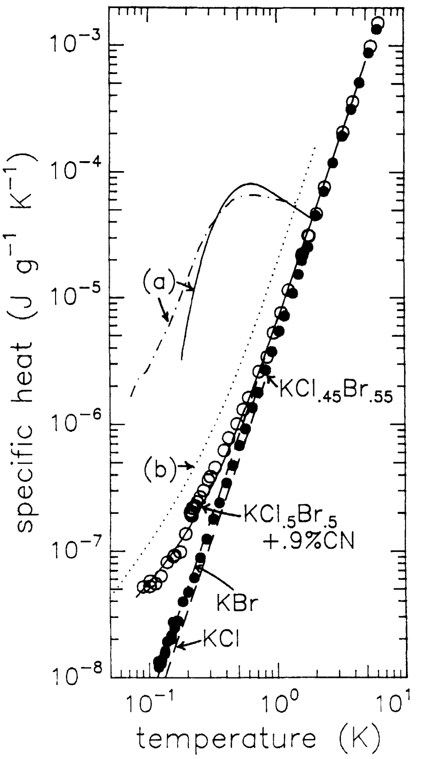

FIG. 15. The Schottky anomaly in KCl + 0.06 mol% CN [curve (a), dash-dotted line] is close to the expected contribution due to 0.06 mol% CN$^-$ (solid curve), indicating a narrow energy spectrum for the CN$^-$ tunneling states. In the similarly doped but also heavily strained crystal, (KCl)$_{0.5}$(KBr)$_{0.5}$ + 0.9 mol% CN, the specific heat is glasslike (open circles). The Schottky anomaly is replaced by a linear contribution, indicating vastly different energy spectra for the CN$^-$ ions, with a corresponding smaller contribution to the specific heat at any given temperature. The solid curve through the open circles is a fit to the data: $c_1T + (c_3 + C_D)T^3$ with $C_1 = 5 \times 10^{-7}$ J g^{-1} K^{-2}, $c_3 = 1.2 \times 10^{-6}$ J g^{-1} K^{-4}, and $C_D = 4.8 \times 10^{-6}$ J g^{-1} K^{-4} from the (KCl)$_{0.45}$ (KBr)$_{0.55}$ data. Also shown are measurements for a mixed crystal with glasslike excitations, (KBr)$_{59}$(KCN)$_{41}$ (curve b), crystalline T^3 behavior for (KCl)$_{0.45}$(KBr)$_{0.55}$ (solid circles), and Debye predictions for KBr and KCl. Both of the latter are well confirmed by experiment (see Fig. 2 for KBr). (Watson, 1995).

strains, do not have glasslike lattice vibrations, as shown in Fig. 13. The Debye model is also found to give the proper description for the low-temperature specific heat of (KBr)$_{1-x}$(KCl)$_x$ shown in Fig. 15.

Next, we show that if a crystal contains tunneling defects, like alkali halide crystals with small concentrations of CN$^-$ ions, which have tunneling states of well-defined energy splittings, then random strains can lead to a spreading of those tunneling states very much as in amorphous solids; see Fig. 15 (Watson, 1995). In a KBr or a KCl crystal containing a small concentration of KCN, the CN$^-$ tunneling states lead to a specific-heat anomaly of the Schottky type, which peaks at 0.6 K. However, if a small concentration of CN$^-$ is dissolved in the highly strained, mixed KBr:KCl crystal, a linear specific-heat anomaly arises, very similar to that found in amorphous solids or certain highly disordered solids; see for comparison the specific heat of (KBr)$_{0.59}$(KCN)$_{0.41}$, which has glasslike lattice vibrations (DeYoreo *et al.*, 1986). The comparison of the magnitude of this linear specific heat with that of the Schottky anomaly expected for the same CN$^-$ concentration [about 15 times larger than curve (a) in Fig. 15] shows that in this strained crystal most of the CN$^-$ ions have been frozen out so that they do not contribute to the specific heat at low temperatures. A very small fraction, however, has retained low-energy tunneling splittings as known in amorphous solids. This finding suggests that random strains can affect the reorientation of molecular entities with rotational degrees of freedom. The question whether this mechanism can explain the origin of the tunneling states in amorphous solids has to be left unanswered.

We return once more to Fig. 13. It illustrates how with increasing disorder the high-temperature thermal conductivity decreases and approaches the value predicted on the basis of Einstein's model. The same behavior has been found in the other disordered crystals shown in Fig. 11: The measured thermal conductivity decreases with increasing disorder without, however, ever dropping below the value predicted by Einsteins model. Although we have no explanation for this, the observations are by now sufficiently numerous to conclude that the value predicted by this model does represent a lower limit. This is our justification for calling it $\Lambda_{\min}$, the minimum thermal conductivity. Furthermore, $\Lambda_{\min}$ seems to describe closely the thermal conductivity of the amorphous phase above ~50 K (see, for example, Fig. 4). As a practical conclusion it follows that there is little hope of ever finding a disordered crystal with a thermal conductivity smaller than that of its amorphous phase.

5. CLOSING REMARKS

The concept that the elastic vibrations of solids can be described by waves, as proposed by Born and von Kármán (1912), and by Debye (1912), is inadequate for all amorphous solids, and also for a large—and growing—number of highly disordered crystals. These solids require for their description, in addition to waves, localized excitations or tunneling states at low energies. At high energies, the proper description of the vibrations is that of individual atoms vibrating with random phases, passing their energy along to their neighbors within half a period of vibration, in a random walk. This difference between crystals and highly disordered solids is illustrated schematically in Fig. 16. In this doubly logarithmic plot of the density of states of the excitations, the heavy solid line, which varies proportionally to the second power of the frequency ν, represents the elastic waves as described in Debye's model. At high frequencies, the line ends at a maximum frequency, called the Debye cutoff frequency [Eq. (8)]. For disordered solids, the density of states in the low-energy region is dominated by the tunneling states with a nearly constant value of their density of states, and a magnitude varying only within approximately one order of magnitude among chemically different solids. In the frequency regime above a few terahertz (marked by the vertical line in Fig. 16), the concept of propagating waves loses its significance and has to be replaced by short-lived vibrations of individual atoms.

Although a phenomenological description

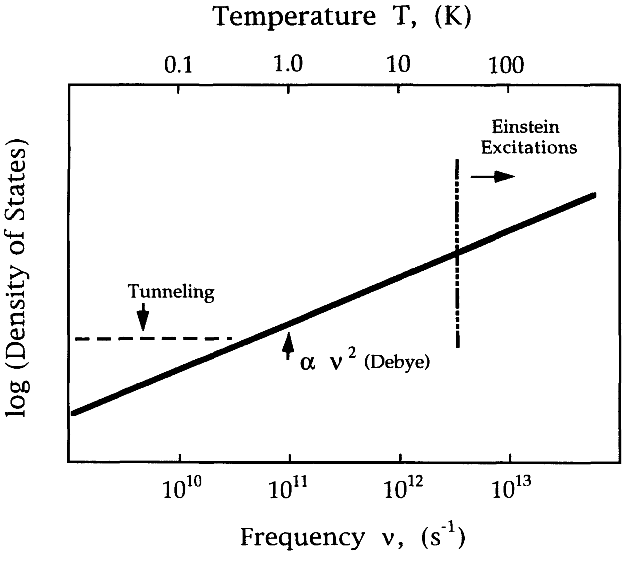

FIG. 16. Schematic summary of the present knowledge of the lattice vibration of disordered solids. The heavy solid line is based on the Debye model: All vibrations are waves, with a density of states varying as the square of the frequency ν, up to a cutoff frequency [given by Eq. (8)]. In disordered solids, the density of states is increasingly dominated by the localized tunneling states as the frequency decreases. Their density of states is nearly independent of frequency (dashed line). Above a certain frequency, traveling waves cease to exist in disordered solids and are replaced by localized excitations on the atomic scale. The excitations pass on their energy from atom to atom in a random walk. In the figure, they are labeled "Einstein Excitations." The upper horizontal scale marks the temperature at which excitations of certain frequency are thermally excited.

of the lattice vibrations of disordered solids has been created, many questions remain unanswered:

1. What is the physical nature of the tunneling entities? Specifically, can we apply the concepts developed from the study of disordered crystals to amorphous solids?
2. Why are the phenomena connected with the tunneling states so similar in all these solids, and specifically, why is their density of states so similar in all these disordered solids?
3. Which mechanism limits the high-temperature thermal conductivity of all dielectric solids to that of their amorphous phases?
4. Is there a connection between the tunneling states, which determine the properties at low temperatures, and the high-energy atomic vibrational states, which determine the heat flow at high temperatures?

It is remarkable indeed that the important and widely studied subject of the lattice vibrations of solids still contains so many unsolved mysteries.

GLOSSARY

Amorphous Solids: Solids in which the atoms are disordered topologically, i.e., their atoms lack long-range order. They can be viewed as frozen liquids.

Disordered Solids: Solids in which the atomic arrangement differs from that of perfect crystals. In this article, disordered solids are either amorphous (glassy), in which the atoms lack long-range order, or disordered crystalline, in which different atomic species are distributed randomly over well-defined crystalline lattice sites.

Elastic Waves: Sound waves, which can be either transverse or longitudinal. In a wave the motion of atoms is correlated; i.e., the atoms vibrate with fixed phase relations relative to their neighbors.

Internal Friction: A quantity describing the dissipation of vibrational energy. Defined in Eq. (3) through the decay of the vibrational amplitude. The internal friction Q^{-1} is related to the attenuation of an elastic (sound) wave by $Q^{-1} = (v/\omega)\alpha$, where v is the speed of the wave, ω is its frequency ν multiplied by 2π, and α is the absorption constant of the wave, which describes the attenuation of the elastic power carried in the wave.

Phonon: Quantum of elastic energy, analogous to the quantum of electromagnetic energy, which is called a photon. One may view a phonon as a wave packet moving through the solid with the speed of sound.

Quartz: Crystalline form of silica, SiO_2. The most common form is α quartz. The amorphous form is called vitreous silica, or briefly a-SiO_2.

Rotational Degrees of Freedom: Molecules in a gas can not only translate, but they can also rotate. The translational motion is frozen in most solids. Rotation can, however, occur. In that case, one talks about rotational degrees of freedom in the solid.

Specific Heat: The proportionality factor between the thermal energy (heat) added to a sample, its mass, and the resultant temperature rise, as defined in Eq. (2).

Stabilized Zirconia: ZrO_2 has a cubic crystal structure only near its melting point. As it cools to room temperature, its structure changes, and the crystal shatters. Through the addition of other oxides, like CaO or Y_2O_3, in small concentrations (~10 mol%), the cubic phase is stabilized to room temperature. Stabilized zirconia is used as an artificial gem stone of great hardness, resembling diamond in its optical properties.

Thermal Conductivity: The proportionality factor between the heat current density and the temperature gradient, as defined in Eq. (1).

Transducer: Any device used to change energy from one form to the other. In this article, it converts electric to elastic energy.

Tunneling: A quantum-mechanical process that demonstrates the wave nature of material particles (matter wave, wave-particle duality). Classically, a particle cannot cross into a region in which its potential energy exceeds the total energy of the particle. For example, a ball can never penetrate a solid wall. Quantum mechanically, however, the matter wave does have a nonzero probability to enter such an energetically forbidden region, just like an evanescent wave in the case of light waves.

Vibrational States: The vibrational motion of atoms is described by quantum-mechanical vibrational states.

INTRODUCTION

The subjects of viscosity and diffusion are parts (thermal conductivity is also included) of the general phenomena of transport in gases and liquids. As we discuss, viscosity is concerned with momentum transport and diffusion with mass transport. The length scale over which this transport is defined is macroscopic; hence, these phenomena are fundamentally long-wavelength properties. Thus their definitions and defining equations are part of the continuum description of matter.

When the structural relaxation time is short compared to time scales on which transport occurs, as is the case for the fluids we consider, this falls into the field of hydro-

dynamics. As we will see, the fundamental definitions of viscosity and diffusion are imbedded in the fundamental hydrodynamic equations. If the transport rate approaches and exceeds the structural relaxation time, then one enters the viscoelastic regime. We only briefly consider this. It is a subject in itself, and we only need address it here in defining the shear rates at which slowly relaxing molecules, such as polymers, can be considered as acting as simple fluids.

Although the phenomena under consideration are continuum properties, we wish to understand their origins in terms of the intermolecular interactions that govern the motions of the individual particles of the fluid. This is a problem in statistical mechanics, one for which solutions to the gas-phase transport equations have been well developed. However, these analytical solutions to the equations of motion involve only binary collisions. Ultimately, as we approach higher densities, such as those of ordinary liquids, this approximation loses its validity, and the problem remains poorly understood. We touch upon the current thoughts on how this fundamental problem may be solved in the future through the use of mode-coupling equations.

In lieu of fundamental theories, the most common approach for describing the ordinary liquid state is scaling theories. These theories incorporate an approximate description of the effects of temperature, composition, or pressure on the change in viscosity or diffusion. These are in common use, and as we shall see, they range from close to fundamental descriptions of the underlying physics to strictly phenomenological equations used to systematize data.

One of the most important relationships between viscosity and diffusion for ordinary liquids is the Stokes–Einstein equation. This equation combines hydrodynamic drag on a spherical particle with the statistical mechanics of Brownian motion to yield a simple inverse relationship between viscosity and diffusion [see Eq. (26)]. Experimental tests of this relationship indicate that it is accurate over length scales ranging from atomic to macroscopic, and it finds wide application in interrelating particle diffusivity, particle size, and solvent viscosity.

1. THEORY OF VISCOSITY AND DIFFUSION

1.1 Continuum Hydrodynamics

1.1.1 Viscosity

1.1.1.1 Simple Motivation for Continuum Transport. We first consider viscosity. Imagine two plates, parallel to one another and separated by a distance Δz and perpendicular to the z axis of a coordinate system (Fig. 1). The region between the plates is filled with a fluid (gas or liquid). If we suddenly accelerate the top plate in the y direction to some velocity V, the intervening fluid between the plates will respond by also moving. In a short time, we find that a constant force F will maintain a constant velocity for the plate of area A. The resulting steady-state velocity gradient in the fluid is linear, going from zero at the stationary plate up to V at the moving one. We can write an equation for the required force F as follows:

$$F/A = \eta \Delta V/\Delta z. \tag{1}$$

This is Newton's law of viscosity. It defines the viscosity η as a proportionality constant between the force per unit area, F/A, and the velocity gradient, $\Delta V/\Delta z$. The force per unit area is a shear stress, and the velocity gradient is a shear rate, $\dot{\gamma}$. Several qualities of viscosity are apparent from this equation. First, we find that the dimensions of viscosity are F/A times time; in SI units this is given in Pa · s, whereas in cgs units the poise is used, which is dyne·s/cm^2. The second important feature is that in a plot of shear rate versus shear stress, Eq. (1) says that a straight line will result, the slope of which is the viscosity. For all fluids we consider here, this is true, and these are designated Newtonian fluids. Non-Newtonian behavior, seen in polymer melts for example, often results in curvature on such plots. See Bird *et al.* (1960) for a further discussion.

One can immediately see that the simplified geometry we have used to define viscosity can be generalized. In particular, if we write the left-hand side of Eq. (1) as a component of the shear stress tensor, with the second index indicating the direction of the force and the first designating the plane in

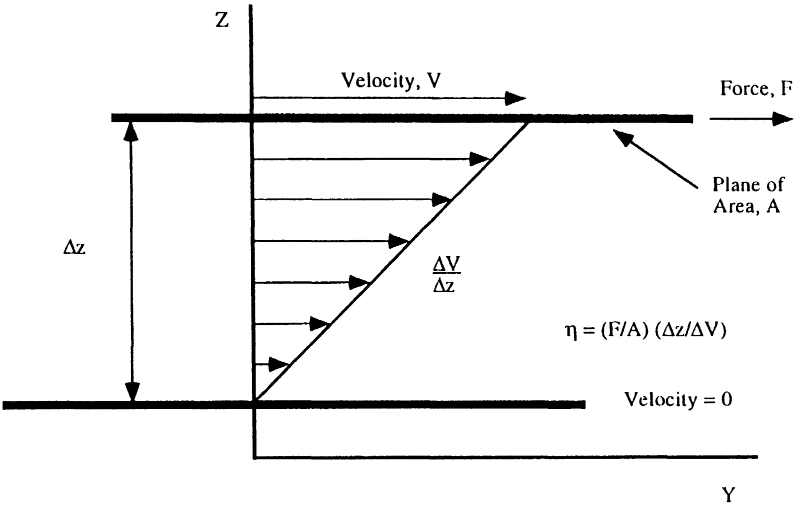

FIG. 1. Definition of the viscosity in the hydrodynamic limit. Movement of upper plane at constant velocity V leads to velocity gradient $\Delta V/\Delta z$ in the intervening fluid. The viscosity is the proportionality constant between the force per unit area and the velocity gradient produced. This defines the viscosity for a Newtonian fluid, one for which changes in the magnitude of the shear rate, equal to $\Delta V/\Delta z$, do not change the viscosity η.

which the response is measured, we can generalize the above equation:

$$\sigma_{zy} = -\eta \frac{dV_y}{dz}. \tag{2}$$

A further generalization is to write this equation in terms of the momentum flux. This will aid our understanding of the molecular origins of viscosity as well as connect us to the upcoming description of the general hydrodynamic approach to the role of viscosity in mass and momentum balances in a fluid. We write

$$\sigma_{zy} = -\mu \frac{d(\rho V_y)}{dz}, \tag{3}$$

where we have defined the kinematic viscosity μ as the ratio of viscosity to the density. Now we see that the gradient is written with respect to the momentum density ρV_y.

1.1.1.2 Navier-Stokes Equation. To understand the role of viscosity in the broader context of hydrodynamics, we need to understand the origin of the Navier–Stokes equation. This equation results from a consideration of mass and momentum balances. Imagine a cubic fluid element, and consider the mass flow into and out of its six faces. For each face the rate of mass inflow is the velocity at that point times the density. Similarly, the outflow is the velocity at the exit face times the density. For example, the net flow through the face perpendicular to the V_x direction is $\Delta y \Delta z[\rho V_x(x) - \rho V_x(x + \Delta x)]$. The total is then the sum over all three sets of faces. The resulting equation, written for the reference frame that moves with the fluid, is

$$\frac{d\rho}{dt} = -\rho(\nabla \cdot \mathbf{V}). \tag{4}$$

A similar procedure is used to determine the equation of motion. For our fictive cube, we consider the rate of momentum accumulation, which equals the rate of momentum inflow minus the outflow plus any forces acting on the system (such as gravity or pressure). Momentum flows in and out via two means: bulk fluid flow and stress transfer. The fluid-flow component depends upon the velocity at which the momentum density ρV enters and leaves. However, this situation is a bit more complex than that for mass. Each of the three components of ρV can be transferred by one of the three velocity components. Therefore, flow across all three pairs of faces contributes to the x-momentum flow, and there are similar contributions for y and z, a total of three equations with three components each. A similar situation results from consideration of the stress-transfer mechanism. This component is transferred via the stress, which we introduced earlier in Eq. (3), except that here we must additionally consider the on-diagonal stress-tensor terms. As shown above, each component of the stress tensor is itself the momentum flux. Hence our tabulation of the inflow and outflow relates to the spatial variation of this tensor at each of the faces of the imaginary cube. Thus for each component, x, y, and z, of momentum, the resulting equations contain three terms each for bulk-fluid-flow and stress-transfer momenta. We write out one of these for the x direction:

$$\begin{aligned}\frac{\partial}{\partial t}\rho V_x = &-\left(\frac{\partial}{\partial x}\rho V_x V_x + \frac{\partial}{\partial y}\rho V_y V_x + \frac{\partial}{\partial z}\rho V_z V_x\right)\\ &-\left(\frac{\partial}{\partial x}\sigma_{xx} + \frac{\partial}{\partial y}\sigma_{yx} + \frac{\partial}{\partial z}\sigma_{zx}\right)\\ &-\frac{\partial P}{\partial x} + \rho g_x. \qquad (5)\end{aligned}$$

There are two additional terms included in Eq. (5) to account for pressure forces and gravitational forces. This is one of three equations of motion. Clearly, the complete set are better written in vector notion. The result is

$$\frac{\partial}{\partial t}\rho \mathbf{V} = -(\nabla\cdot\rho\mathbf{V}\mathbf{V}) - (\nabla\cdot\sigma) - \nabla P + \rho\mathbf{g}. \qquad (6)$$

To solve this equation we need additional information, namely, the relationship between the stress-tensor components and velocity. These are of particular interest here since this is the basis for viscous effects in fluid flow. [Absent these terms one would have inviscid flow that is quite unrealistic in several ways; for example, a sphere moving in such a flow suffers no drag force (d' Alembert's paradox; Landau and Lifshitz, 1959).] We do not derive the needed relationships here (see Hirschfelder *et al.*, 1954) but give the results for two of the six independent stress-tensor components:

$$\begin{aligned}\sigma_{xx} &= -2\eta\frac{\partial V_x}{\partial x} + (\tfrac{2}{3}\eta - \kappa)(\nabla\cdot\mathbf{V});\\ \sigma_{xy} = \sigma_{yx} &= -\eta\left(\frac{\partial V_x}{\partial y} + \frac{\partial V_y}{\partial x}\right). \qquad (7)\end{aligned}$$

As can be seen, the on-diagonal terms now contain a new variable. This is the bulk viscosity κ, which describes the result of energy dissipation associated with volume (pressure) change. This term can be important when the rates of expansion and contraction are large or periodic such as in shock waves or ultrasound transmission (see Batchelor, 1967, pp. 155–156). However, it is common that the rate of shear dominates and that the bulk viscosity can be neglected. We do not consider it further. In our subsequent discussions, and in those likely to be encountered in other publications, the term viscosity is taken to mean the shear viscosity η.

Using Eq. (6), and mass balance, Eq. (4), a full description of fluid motion can be made. This includes the spatial and time derivatives of velocity, density, and pressure. Isothermal conditions are assumed, but an extension to include temperature variations is also possible (see Bird *et al.*, 1960, p. 310). Taking the case that the fluid is incompressible (a common and accurate assumption in nearly all instances, i.e., that the pressure generated during flow does not compress the fluid) and Newtonian viscosity, we obtain from Eq. (6) the celebrated Navier–Stokes equation,

$$\rho\frac{d\mathbf{V}}{dt} = \rho\frac{\partial\mathbf{V}}{\partial t} + \rho\mathbf{V}\cdot\nabla\mathbf{V} = \eta(\nabla^2\mathbf{V}) - \nabla P + \rho\mathbf{g}. \qquad (8)$$

This is the starting point for most hydrodynamic solutions to fluid flow. Indeed, a solution of this equation for steady-state flow, $dV/dt = 0$ in the absence of gravitational effects, will yield the linear velocity profile and a simple relation between viscosity and the stress and velocity gradients we discussed for Fig. 1.

A great difficulty in solving Eq. (8) comes about when the nonlinear term $\mathbf{V}\cdot\nabla V$ is nonnegligible. In most cases of interest for measuring viscosities, we can neglect the ΔP and $\rho\mathbf{g}$ terms. The condition that the nonlinear term is smaller than the remaining damping term is $\rho V^2/l < \eta V/l^2$ or $\rho Vl/\eta \ll 1$, where l is some characteristic length over which the velocity V varies. This ratio is defined as the Reynolds number

$$Re = \rho Vl/\eta = Vl/\mu, \qquad (9)$$

which plays a crucial role in hydrodynamics. When $Re \ll 1$, the Navier–Stokes Eq. (8) reduces to the simple result that is linear in the velocity, the equation on creeping flow,

$$\frac{\partial \mathbf{V}}{\partial t} = -\mu(\nabla^2 \mathbf{V}). \tag{10}$$

A direct result of the linearity of this equation is that for any given geometry and Re, it can be shown that solutions to the Navier–Stokes equation are identical; thus the solutions are appropriate to a wide range of conditions. For most situations, solutions to the Navier–Stokes equation are made in the low-Re limit. A feature of these low-Re solutions is that the flow lines (contours of constant velocity) are parallel, i.e., laminar flow. Such solutions, of course, become poorer as Re increases, and in general this would exclude values of $Re \geq 1$. However, the transition to turbulent flow is geometry specific, and the laminar flow regime can extend to higher Re numbers, perhaps as high as 10, before the onset of turbulence. Up to that point, viscosity continues to play the dominant role in the drag. As discussed later, for accurate results in most experimental viscosity measurements, turbulence should be absent.

1.1.1.3 Stokes Equation. An important solution to the Navier–Stokes equation is that for motion of a sphere in a fluid. From this we obtain the Stokes equation. It is a low-Re solution, typically $Re = 2RV\rho/\eta < 0.1$, made for steady-state flow, e.g., the terminal velocity of a falling sphere. The full derivation of this equation is outside the scope of the present work (Landau and Lifshitz, 1959; Bird *et al.*, 1960). However, we can understand the origin of the equation by noting that one obtains two forces on the sphere in considering its motion governed by Eq. (10): the force acting normal to the surface due to a pressure field set up by flow, F_n, and a force acting tangential to the surface due to stress transmitted tangentially, F_t. For the case when the fluid velocity at the sphere boundary equals that of the sphere, a nonslip boundary condition, the two net forces, integrated over the surface of the sphere, are given by

$$F_n = \tfrac{4}{3}\pi R^3 \rho g + 2\pi\eta RV,$$

$$F_t = 4\pi\eta RV;$$

thus the *total force* is

$$F = F_n + F_t = \tfrac{4}{3}\pi R^3 \rho g + 6\pi\eta RV, \tag{11}$$

where R is the sphere radius and V is its steady-state velocity. As one can see, the second term is velocity dependent and is termed the Stokes drag. The familiar form of the Stokes equation giving the terminal velocity of a falling sphere is obtained by setting the total force equal to the gravitational force, $\tfrac{4}{3}\pi R^3 \rho_S g$, on a sphere of density ρ_S.

One important feature of the Stokes-equation solution is that, to leading order, the decay of the flow field goes as $1/r$. Hence the disturbance is long ranged, and the equation is strictly applicable only to isolated spheres. A practical consequence is that the use of this equation in determining the viscosity through falling- and rolling-sphere viscometers requires an empirical correction for termination of the velocity field by various walls of a container.

1.1.2 Diffusion In the previous sections both the motion of fluids (Sec. 1.1.1.2) and the motion of particles in a fluid (Sec. 1.1.1.3) under the influence of external forces (e.g., shear or gravitational forces) have been described. However, molecular migration can be observed even without the existence of external forces. This is the subject of Brownian motion, i.e., the statistical movement of atoms or molecules. Brownian motion has been extensively studied, beginning with observations of Robert Brown in 1853 of the random incessant motions of dust pollen in solution. In the following sections we describe how Brownian motion and diffusion are related.

1.1.2.1 Continuum Transport: Fick's Laws of Diffusion. The term *mutual diffusion* (or transport diffusion) describes the process of molecular transport within systems caused by the statistical movement of atoms or molecules. This transport process becomes macroscopically visible during the process of equalizing concentration differences (e.g., of dye molecules in a solution). The reduction of a concentration gradient implies a particle flux that can be described with Fick's first law,

$$\mathbf{j}_i = -D_i \nabla c_i. \tag{12}$$

The proportionality constant between the particle flux density $\mathbf{j}_i$ and the concentration gradient ∇c_i is the diffusion coefficient D_i of the considered component i of a mixture. Although the units for $\mathbf{j}_i$ will depend upon the units of concentration (Bird *et al.*, 1960), the units for the diffusion coefficient are m^2/s in SI or cm^2/s in cgs. In general, the diffusion coefficient D_i is a function of the concentration of the component i.

The time derivative of the concentration of a certain component i in a volume element has to be equal to the total flux of this component through the surface of the considered volume:

$$\frac{\partial c_i}{\partial t} = -\nabla \cdot \mathbf{j}_i. \tag{13}$$

Using this mass balance constraint along with Eq. (12), we obtain Fick's second law,

$$\frac{\partial c_i}{\partial t} = \nabla \cdot (D_i \nabla c_i), \tag{14}$$

which describes the time derivative of the concentration for a system as it approaches its equilibrium state.

1.1.2.2 Self-Diffusion. Even in the absence of a concentration gradient, statistical fluctuations of particle positions continue. This process, called *self-diffusion,* is caused by the thermal energy of the particles. Therefore, the self-diffusion coefficient D_S arises from the same fluctuations that drive mutual diffusion, but there is no net mass transport in this case.

Because there is no macroscopic particle flux, to monitor the molecular displacement in such systems a certain portion of the molecules must be labeled in one way or another, e.g., by introducing observable isotopes into the system under study. With respect to the experimental setup, the proportionality constant between the gradient of the concentration of labeled particles and their flux density is called the coefficient of *tracer diffusivity.*

The coefficients of tracer and self-diffusion coincide if two assumptions are fulfilled: First, the molecular mobility of the molecules must not be altered by the process of labeling. Second, mutual interactions between the tracer molecules must be small enough to be negligible; i.e., the mobility of any labeled molecules must be unaffected by the existence of other (e.g., labeled) molecules. Experimentally, that requirement is fulfilled in sufficiently high dilution of the labeled species under consideration (Kärger *et al.*, 1988).

1.1.2.3 Diffusion Equation. In homogenous systems, Brownian motion is determined by the coefficient of self-diffusion only. Since in such systems the self-diffusivity is independent of the spatial position of the molecules, Eq. (14) simplifies to

$$\frac{\partial c^*(\mathbf{r},t)}{\partial t} = D_S \nabla^2 c^*. \tag{15}$$

In this equation c^* is the concentration of labeled molecules (see Sec. 1.1.2.2) and, therefore, the probability of finding a labeled particle on a certain position. Equation (15) is commonly referred to as the *diffusion equation* since that differential equation provides the probability of finding a molecule at time t at position $\mathbf{r}$ if it initially was at $\mathbf{r}_0$. With the initial condition that the concentration of the labeled molecules follows Dirac's delta function, $c^*(\mathbf{r},0) = \delta(\mathbf{r} - \mathbf{r}_0)$, the solution of the diffusion equation, Eq. (15), is found to be a Gaussian distribution of the following form:

$$\begin{aligned} c^*(\mathbf{r},\mathbf{r}_0,\mathbf{t})d\mathbf{r} &= \frac{1}{(4\pi Dt)^{3/2}} \exp\left\{ -\frac{(\mathbf{r} - \mathbf{r}_0)^2}{4Dt} \right\} \\ &= P(\mathbf{r},t). \end{aligned} \tag{16}$$

Equation (16) is commonly referred to as the *propagator P*(**r**,*t*), or *fundamental solution of the diffusion equation.* It allows one to calculate the mean square value of molecular displacement during the observation time t:

$$\langle \mathbf{r}^2(t) \rangle = \int_{-\infty}^{+\infty} P(\mathbf{r},t)\mathbf{r}^2 d\mathbf{r} = 6Dt. \tag{17}$$

Equation (17) is referred to as Einstein's equation of diffusion and provides a straightforward manner for defining molecular diffusivity.

More generalized, the exact form of Eq. (17) depends on the number of spatial dimensions k of molecular migration:

$$\langle x^2(t) + y^2(t) + z^2(t)\rangle = 2kDt. \tag{18}$$

Equation (18) coincides with Eq. (17) in isotropic systems where $\langle \mathbf{r}^2(t)\rangle = \langle x^2(t) + y^2(t) + z^2(t)\rangle$ and the dimension of diffusion, k, is equal to 3.

1.1.2.4 Diffusion as a Random Walk. On a microscopic level, the propagation of atoms or molecules can be understood as a stochastic jump process. The molecular migration becomes "random" if both the length and the direction of the elementary jumps do not correlate; i.e., this diffusion process has to be a Markovian process. In the simplest approach for deriving the diffusion equation, however, one considers only jump processes that are uncorrelated regarding their direction.

Imagine the one-dimensional diffusion of a particle that is situated at a certain position of an imaginary z axis and performs stochastic jumps of a *constant* length l toward the positive or negative direction of the z axis. The mean square displacement of the considered particle, $\langle z^2\rangle$, can be expressed as a function of the number of jumps, n, and their length l:

$$\begin{aligned}\langle z^2(n)\rangle &= \left\langle\left(\sum_{i=1}^{n} l_i\right)^2\right\rangle \\ &= \left\langle\left(\sum_i l_i^2\right)\right\rangle + \left\langle\left(\sum_{i\neq j} l_i l_j\right)\right\rangle,\end{aligned} \tag{19}$$

where l_i is the length of the ith jump in positive or negative z direction. Assuming a Markovian diffusion process where the mean displacements of all particles cancel each other, $\langle l_i\rangle = \langle l_j\rangle = 0$, and a constant jump length, $l_i \equiv l$, Eq. (19) simplifies to

$$\langle z^2(n)\rangle = nl^2 + \sum_{i\neq j} \langle l_i\rangle\langle l_j\rangle = nl^2. \tag{20}$$

The number of elementary jump processes, n, is the ratio of the total diffusion time t and the mean dwell time of the jumps, τ. Thus, it follows from Eq. (20) that

$$\langle z^2(t)\rangle = l^2 t/\tau, \tag{21}$$

which shows that the mean square displacement is directly proportional to the diffusion time if the displacements in subsequent intervals are uncorrelated.

The jump length l can be expressed using Einstein's equation, Eq. (18), for one-dimensional diffusion ($k = 1$) of the jumping particle:

$$D = l^2/2\tau. \tag{22}$$

Therefore, for Eq. (21) it follows that

$$\langle z^2(t)\rangle = 2Dt. \tag{23}$$

Equation (23) represents a definition of the diffusion coefficient equivalent to Eq. (17) or (18). Similarly to Eq. (18), Eq. (23) can be extended to three-dimensional diffusion.

For a given time interval, the mean square displacement is thus found to be directly proportional to the total observation (or diffusion) time. Molecular propagation that follows this relation is generally called *normal diffusion.* Since any confinements interfering with the diffusion process lead to a correlation of subsequent elementary jumps, the direct proportionality between mean square displacement and diffusion time breaks down; this is called *anomalous diffusion.* Depending on the nature of the confinement, quite distinct patterns of deviation from normal diffusion may be observed.

1.1.3 Stokes–Einstein Equation: Viscosity and Diffusion in Liquids The single most important relation between viscosity and diffusion in liquids is the Stokes–Einstein equation. Although its origin is from hydrodynamics, hence a continuum picture, it has been found to be an accurate equation down to the molecular length scale, and it finds wide application in relating molecular diffusion to fluid viscosity. We describe some of these throughout the text. Here we give the derivation.

Brownian motion of a single spherical body moving in an overall quiescent fluid is the target of our thinking. In the Stokes equation derivation (Sec. 1.1.1.3), we saw that such a body would experience a damping force equal to the viscous drag, $F/V = 6\pi\eta R$. The driving force for Brownian motion is thermal fluctuations. The equation of motion for a sphere of mass m can be written

$$m \frac{dV}{dt} = -F + F_R(t) = -6\pi\eta R V + F_R(t), \tag{24}$$

where $F_R(t) \propto k_B T$ is the random white-noise term that represents the incessant bombardment of the solute molecules that drive Brownian motion. The solution to Eq. (24) for the velocity correlation function is

$$\langle V(0)V(t)\rangle = (k_B T/m) \exp(-Ft/m). \tag{25}$$

The amplitude of the velocity fluctuations is proportional to the thermal energy, $k_B T$, and the decay is given by the frictional drag, m/F. For a typical 1-μm particle in water, $m/F \approx 0.1$ μs. An important consequence of Eq. (25) is that the velocity is correlated only for a short period; i.e., over long times the particle will appear to be moving randomly. This random walk is diffusion, with the magnitude of the diffusion coefficient being given by

$$D \equiv \int_0^\infty \langle V(0)V(t)\rangle dt = \frac{k_B T}{6\pi\eta R}. \tag{26}$$

This is the Stokes–Einstein equation. Despite its hydrodynamic origins, it is extensively utilized for both molecular and complex liquids in examining the relationship between single-particle (tracer) diffusion and solution viscosity. A description of particle positions in the random-walk, Brownian, regime can be found from Eqs. (25) and (26) and is given by

$$\langle \Delta r^2(t)\rangle = 6Dt, \tag{27}$$

providing a similar result for the time dependence of the mean square displacement to that derived in Secs. 1.1.2.3 and 1.1.2.4.

Experimental tests of the Stokes–Einstein equation have revealed the need to consider both the nonslip (as formulated) and slip boundary conditions for the fluid–particle interface. The slip boundary condition alters Eq. (26) by replacing the denominator with $4\pi\eta R$. We discuss this in Secs. 1.2.4 and 4.1.3.2.

Rotational motions, in addition to translational ones, also result from the incessant thermal motions imparted to individual molecules by the surrounding liquid. The randomness of the collisions results in the applicability of a diffusion equation to the description of the time-dependent rotational velocity, $\omega = d\Theta/dt$, given as

$$I \frac{d\omega}{dt} = -F_\omega \omega + F_\omega(t), \tag{28}$$

where I is the moment of inertia, F_ω the viscous drag force of a rotating sphere, and $F_\omega(t)$ the random white-noise term representing the incessant bombardment of the solute molecules that drive rotational diffusion. A solution to this equation is

$$D_\Theta \equiv \int_0^\infty \langle \omega(0)\omega(t)\rangle dt = \frac{k_B T}{8\pi\eta R^3}, \tag{29}$$

yielding an expression for the time-dependent angular displacements as

$$\langle \Delta\Theta^2(t)\rangle = 6D_\Theta t, \tag{30}$$

in exact analogy with the translational diffusion description above.

The specific study of rotational diffusion, as opposed to translational diffusion as referred to earlier, has been the subject of numerous works (Berne and Pecora, 1976). Both Alms *et al.* (1973) and Bauer *et al.* (1974) used dynamic light scattering (depolarized) to elucidate the nonsymmetric rotational relaxation mechanisms of benzene molecules in solution. Hu and Zwanzig (1974) determined the effective translation–rotation coupling constants by computer simulation for a wide range of elliptically shaped objects. Sillescu *et al.* studied both rotational and translational diffusion in highly viscous, glass-forming systems by forced Rayleigh scattering (FRS) and NMR-based diffusion techniques (Chang̈ *et al.*, 1994).

1.2 Atomistic Theories and Computer Simulations

1.2.1 Simple Kinetic-Theory Approximation As might be imagined, atomistic descriptions of the dynamics that lead to the energy dissipation mechanisms responsible for viscosity and diffusion are quite complex. Not only must the models describe the energy losses, but they must also be consistent with requirements for local equilibrium such as mass and energy balance. In the general case, such models derive from solutions to the Liouville equation (see Hansen and McDonald, 1986), which provides a full description of an N-particle system in the classical mechanics limit. However, a true solution to this equation is as yet unrealized; one instead finds solutions based upon consideration of subsets of the N-particle system. For example, the pair distribution function arises from this approach. The difficulty in solving this equation for viscosity and diffusion increases as one goes to higher and higher density. At low density, description of the dynamics through binary collisions is sufficient, but as the density increases, three-body interactions become increasingly important. It is in this regime that the current challenge in understanding the atomistic origins of viscosity and diffusion lie. Considerable theoretical and experimental efforts are now devoted to this. One theory, mode-coupling theory (Götze and Sjögren, 1992; Cummins *et al.*, 1993), which utilizes the memory function to describe the results of three-body interactions, is currently quite promising.

In the description that follows, we start with a simple description of a theory for viscosity applicable to low particle density and work our way forward considering increasingly complex treatments that will eventually include dense gases. This approach will give insight into the physical processes that lead to viscosity and diffusion without having to treat the involved mathematics necessary for more rigorous treatments. The reader is referred to several books (Hirschfelder *et al.*, 1954; Bird *et al.*, 1960; Hansen and McDonald, 1986) for more complete discussions.

Given a gas composed of hard spheres of diameter σ and mass m, at a concentration of n molecules per unit volume such that the average distance between molecules is considerably larger than σ, we obtain from kinetic gas theory the following expressions for the equilibrium properties. The average velocity is

$$\bar{u} = (8k_{\mathrm{B}}T/\pi m)^{1/2}. \tag{31}$$

The average distance traveled by a molecule between collisions is the mean free path λ:

$$\lambda = (\sqrt{2}\pi\sigma^2 n)^{-1}. \tag{32}$$

We assume that locally equilibrium is maintained during transport, making these equations an accurate description of local dynamics. Also, we consider only the local velocity u relative to the overall velocity $\mathbf{u}$. Of the ensemble of molecules, $\frac{1}{3}$ can be considered as traveling along each of three orthogonal directions, and half of each of these fractions are going in the positive direction, half in the negative one.

Now, consider the geometry depicted in Fig. 2, where we define planes N and P, separated from the reference plane O by one mean free path. Our interest is in the amount of some property, W (mass or momentum), that crosses plane O per unit area and unit time. Only $\frac{1}{6}$ of the molecules on plane N move in the $+z$ direction. The upward flux is $\frac{1}{6}\bar{u}W_N$; similarly, the downward flux is $\frac{1}{6}\bar{u}W_P$. The net flux Ψ_W of W is therefore

$$\begin{aligned}\Psi_W &= \tfrac{1}{6}\bar{u}(W_N - W_P) = -\tfrac{1}{3}\bar{u}\lambda\left(\frac{dW}{dz}\right)\\ &= -\xi\frac{\sqrt{k_{\mathrm{B}}Tm\pi}}{\pi m\sigma^2 n}\left(\frac{dW}{dz}\right),\end{aligned} \tag{33}$$

where $\xi = 2/3\pi$ and the subscripts N and P designate the values of W on the respective planes. This leads directly to equations for both the diffusion and viscosity of particles having mass m and concentration n:

$$\begin{aligned}\Psi_{(nm)} &= j_z = -\tfrac{1}{3}\bar{u}\lambda\left(\frac{d(nm)}{dz}\right) = -D\left(\frac{d(nm)}{dz}\right);\\ \Psi_{(nmv_y)} &= p_{yz} = -\tfrac{1}{3}\bar{u}\lambda nm\left(\frac{dv_y}{dz}\right) = -\eta\left(\frac{dv_y}{dz}\right).\end{aligned} \tag{34}$$

The expressions in the simple kinetic-theory (SKT) approximation for self-diffusion and viscosity are

$$\begin{aligned}D_{\mathrm{SKT}} &= \tfrac{1}{3}\bar{u}\lambda = \xi\frac{\sqrt{\pi mk_{\mathrm{B}}T}}{\pi\sigma^2}\frac{1}{\rho},\\ \eta_{\mathrm{SKT}} &= -\tfrac{1}{3}\bar{u}\lambda nm = \xi\frac{\sqrt{\pi mk_{\mathrm{B}}T}}{\pi\sigma^2} = \rho D.\end{aligned} \tag{35}$$

where $\rho = nm = pm/k_{\mathrm{B}}T$ is the density of the ideal gas and $\xi = 2/3\pi$ as in Eq. (33). This exceedingly simple model gives the correct functional form for both these transport properties.

FIG. 2. Illustration of the simple kinetic-theory approach to calculating the transport rate of the property W. For W equal to density, this yields the diffusion rate; for W equal to momentum, this yields the viscosity. A superimposed gradient in W along the vertical z axis in a dilute gas is transported by the movement of individual atoms or molecules. A molecule arriving at plane O from plane N brings with it the value of W from one mean free path away. A similar process transports the W values from plane P to O. On average, one-third of the molecules travel in each of three orthogonal directions, x, y, and z: one-sixth move along $+z$ and one-sixth along $-z$. Each molecule moves with an average thermal velocity $\bar{u}$. The transport equation is obtained by summing the $+z$ and $-z$ fluxes, as described in the text, where increasingly more complex approximations are also explained.

1.2.2 Boltzmann Development A more rigorous consideration of the nonequilibrium dynamics for hard spheres changes the values of ξ slightly. The expression in the Boltzmann (B) approximation are

$$D_{\mathrm{B}} = \tfrac{3}{8}\frac{\sqrt{\pi m k_{\mathrm{B}} T}}{\pi\sigma^2}\frac{1}{\rho},$$
$$\eta_{\mathrm{B}} = \tfrac{5}{16}\frac{\sqrt{\pi m k_{\mathrm{B}} T}}{\pi\sigma^2} = \tfrac{5}{6}\rho D, \qquad (36)$$

with $\xi_D = \frac{3}{8}$ and $\xi_\eta = \frac{5}{16}$. These equations are moderately accurate expressions for gaseous materials. As can be seen, they correctly predict that the viscosity is pressure independent and that the viscosity increases with increasing temperature. The square-root temperature dependence is not quite accurate, and consideration of more realistic intermolecular potentials helps correct this.

1.2.3 Lennard-Jones Interactions Extending the range of interaction for the binary collisions considered in the previous model now introduces an integral collision term into the equations. Typically used are potentials that are spherically symmetric, and the Lennard-Jones (6-12) potential has proven a useful way to model the interactions. The results for the derivation of the rigorous kinetic theory (see Hirschfelder *et al.*, 1954, p. 527) for the self-diffusion and the viscosity in the Lennard-Jones (LJ) interaction approximation are as follows:

$$D_{\mathrm{LJ}} = \tfrac{3}{8}\left(\frac{\sqrt{\pi m k_{\mathrm{B}} T}}{\pi\sigma^2\Omega^{(1,1)*}}\right)\left(\frac{1}{\rho}\right),$$
$$\eta_{\mathrm{LJ}} = \tfrac{5}{16}\left(\frac{\sqrt{\pi m k_{\mathrm{B}} T}}{\pi\sigma^2\Omega^{(2,2)*}}\right), \qquad (37)$$

where the terms $\Omega^{(n,n)*}$ are normalized collision integrals. These depend upon the interaction potential and are normalized to the values for a hard-sphere (HS) interaction. Hence, for hard spheres they equal unity. To utilize actual interatomic potentials, one must calculate the values for $\Omega^{(n,n)*}$. These are available in tabulated form in Hirschfelder *et al.*, (1954), Appendix *I*, for a Lennard-Jones potential. Although we give here the equations for single-component fluids, this same approach can be extended to mixtures and more complex interaction potentials. This is discussed in Hirschfelder *et al.* (1954), pp. 485–610.

1.2.4 Hard-Sphere Model—Enskog Development An extended version of Boltzmann's theory in dense gases and liquids was developed by Enskog and Chapman (Chapman and Cowling, 1939) more than 80 years ago. The Enskog theory still accounts only for binary collisions and assumes many features in common with dilute gases. Molecular chaos, as found in dilute gases, is assumed, which amounts to neglecting the correlations between successive particle collisions. Spheres collide with one another at random with velocities consistent with the Maxwell–Boltzmann distribution at that temperature. In particular, multiparticle correlations such as those seen in vortex or ringlike flows in computer simulations are neglected. Two fundamental assumptions in the Enskog theory that distinguish it from the dilute-gas theories can be stated as follows:

1. The molecules attain a finite size, which means that molecules close to the reference plane O in Fig. 2 will collide with those in the plane. This collisional transfer of momentum and energy must be accounted for.
2. Because of the higher density, the collision frequency differs from that of point particles. Both kinetic and potential energy contributions to the flux vector (mass or momentum) are included. The potential energy term arises from the collisional transfer, which is absent for low-density gases.

The Enskog theory (E) scales the Boltzmann results up to higher densities as

$$D_E = D_B/g(\sigma);$$
$$\eta_E = \eta_B[1/g(\sigma) + 3.2\phi + 12.18g(\sigma)\phi^2], \quad (38)$$

where D_B and η_B are given by Eq. (36) and ϕ is the volume fraction of particles. The quantity $g(\sigma)$ is the magnitude of the two-particle distribution function evaluated at contact and is a measure of particle collisions that are neglected in the Boltzmann approach.

The contact radial distribution function $g(\sigma)$ is related to the second virial coefficient in the expansion for the compressibility factor $Z(\phi)$ for the HS system,

$$Z = p/nk_BT = 1 + 4\phi g(\sigma). \quad (39)$$

Hoover and Ree (1964) as well as Carnahan and Starling (1969) calculated $Z(\phi)$, resulting in the following virial expansion equation:

$$Z = 1 + 4\phi + 10\phi^2 + 18\phi^3 + 28\phi^4 + \ldots; \quad (40)$$

$$Z = \frac{1 + \phi + \phi^2 - \phi^3}{1 - \phi^3}. \quad (41)$$

Substituting Eq. (41) into Eq. (39), we obtain an expression for the quantity of interest in the Enskog theory, the pair distribution function,

$$g(\sigma) = (1 - 0.5\phi)/(1 - \phi)^3. \quad (42)$$

In the dilute-gas limit, $\phi \to 0$; $g(\sigma) \to 1$, and the Boltzmann results are recovered. At higher densities, $\phi = 0.1, 0.2, 0.3$, and 0.4, we find $g(\sigma) = 1.3, 1.9, 2.3$, and 2.9, respectively.

An interesting result of the Enskog theory is that over a wide range of moderate densities the products of the diffusion coefficient and viscosity are nearly constant. This can be recast in terms of the Stokes–Einstein model, discussed in Sec. 1.1.3. We rewrite Eq. (26) as $D = k_BT/C\pi\eta R$, where C is 6 for nonslip and 4 for slip boundary conditions. Application of the Enskog model yields C = 3.55, 3.16, 2.88, 3.41, 3.50, and 3.03 at the volume fractions ϕ = 0.15, 0.25, 0.37, 0.41, 0.46, and 0.494, respectively. Hence this test shows that the Stokes–Einstein theory is not strictly obeyed by the model calculations but that solutions are closer to the *slip* boundary condition.

In practice, the Enskog theory is limited in its range of applicability to that of dense gases, not liquids. In the next section we consider corrections to the Enskog model into the fluid regime.

1.2.5 Hard-Sphere Model—Computer Simulations at High Density A critical examination of the Enskog transport theory of hard spheres was performed by Alder, Gass, and Wainwright (Alder *et al.*, 1970; Alder and Wainwright, 1970), who performed computer simulations over a wide range of densities. Several important effects were observed. First, the Enskog assumption of uncorrelated binary collision, molecular chaos, was violated at moderate densities. The velocity autocorrelation function, which should decay exponentially in time according to Enskog, was found to possess a long-time, algebraic persistence. This long-time tail results from multiparticle vortex-type flows. Second, vortex flows lead to an enhancement in diffusion, by about 30% at moderate densities. Third, at the highest densities, backscattering effects cause a marked reduction in D, as well as increase in η, upon approach to the freezing transition (Hoover and Ree, 1964) at $\phi = 0.494$. Finally, tests of the Stokes–Einstein equation can be made using values from these simulations. For $\phi = 0.15$, 0.25, 0.37, 0.41, 0.46, and 0.494, the values of C, as defined in Section 1.2.4, are $C = 4.1$, 4.3, 4.1, 4.3, 4.2, and 3.8, respectively, nearly independent of ϕ and consistent with the *slip* boundary condition.

The seminal work of Alder, Gass, and Wainwright led to considerable activity in the 1970s researching the transport behavior of HS fluids. In 1974 Dymond (1974a, 1974b) fitted the simulation results of Alder *et al.* (Alder and Wainwright, 1970) to an expression linear in the particle volume. In 1981, Woodcock and Angel (1981a, 1981b) performed HS simulations and extracted diffusivities at concentrations beyond those originally studied by Alder *et al.* (Alder *et al.*, 1970; Alder and Wainwright, 1970). One of their main findings was that the linear volume dependence of D seen at moderate densities crosses over to a free-volume (see Sec. 1.2.8) type dependence at the highest densities:

$$D = A \exp[-B/(V - 1.163V_0)]. \qquad (43)$$

It is interesting to note that the packing fraction at which the transport is predicted to cease, $\phi = 0.61$, is close to the value of random close packing (RCP) $\phi_{\mathrm{RCP}} = 0.638$, at which all the particles are touching and all particle motions necessarily stop. Woodcock and Angel also showed that experimental data on methylcyclohexane as well as model Leonard–Jones molecules are in excellent agreement with the predictions.

Accurate expressions for the transport properties of HS fluids provide a useful reference system against which measurements on real atomic and molecular liquids can be tested and modeled. However, it must be kept in mind that the theory only directly applies to *spherical* molecules that interact as hard spheres. The effects of asymmetric shapes, as seen in the next section, is to couple translational and rotational motions, resulting in reduced diffusion coefficients as compared to the HS model. Additionally, molecules are not explicitly hard spheres, typically displaying a steep short-range potential with an effective radius that can decrease slightly with increasing collision velocities, i.e., temperature. Several tests of the HS equations have been done on systems where it should best apply, noble gases such as argon and krypton (Dymond, 1974a). In these cases a linear dependence of the diffusion on molar volume was seen, with a close numerical accord of the results with the HS model. In the slightly more complex cases of nearly symmetric simple molecules such as methane and cyclohexane, the important linear dependence of D and $1/\eta$ on volume is seen, but the numerical values are not in close agreement. This situation is commonly found in many atomic and molecular liquids (Parkhurst and Jonas, 1975; Dymond and Brawn, 1979). Improvements in the HS model, to include the effects of the translation–rotation coupling, are shown in the next section to allow the extension to a wide variety of liquids.

1.2.6 Rough Hard-Sphere Model In 1975 Chandler proposed a simple extension to the hard-sphere model that includes the coupling of molecular translational and rotational degrees of freedom (Chandler, 1975). His calculations showed that the coupling provides an additional mechanism of relaxation of the velocity correlation function of a particle in a fluid. As a result, velocity correlations decay to zero more rapidly than if the coupling did not exist, leading to smaller values of D. The model is termed the *rough hard-sphere model,* described by D_{RHS} and η_{RHS}, and in this context the hard-sphere results are referred to as the *smooth hard-sphere model,* i.e., D_{SHS} and η_{SHS}.

The basic equation for the diffusion coefficients in this model is

$$D_{\mathrm{RHS}} = AD_{\mathrm{SHS}}; \qquad (44)$$

and similarly for the viscosity,

$$\eta_{\mathrm{RHS}} = B\eta_{\mathrm{SHS}}. \qquad (45)$$

The RHS model predicts that the effects of nonsphericity is such to produce $0 < A < 1$, and $B > 1$. In Chandler's derivation, the RHS model was developed as a rigorous result using the assumption of uncorrelated binary collisions, equivalent to the Enskog approximation, which has been shown above to be inaccurate at high densities. However, he suggested that the translation–rotation coupling parameters of the individual molecules, A and B, may be somewhat insensitive to the emergence of higher-order collisional correlations and suggested that the forms of Eqs. (44) and (45) be maintained with the use of the high-density computer simulation data results for D_{SHS}.

The RHS model is extensively used in the modeling of experimental diffusion and viscosity data onto the "hard-sphere" model. For instance, Chandler showed that even in a fairly spherical molecule such as CCl_4, the diffusion and viscosity data could be mapped onto the HS simulation results [Eqs. (44) and (45)] using $A = 0.54$ and $B = 1.74$. Parkhurst and Jonas (Parkhurst and Jonas, 1975) studied tetramethylisilane and benzene and found $B = 1.39$ and 1.34, respectively. Jonas *et al.* (1979) studied in detail the rather nonspherical molecule methylcyclohexane and contrasted its behavior against the more spherical cyclohexane and found $A \sim 0.3$ and $A \sim 0.75$, respectively. In addition they measured the temperature dependence of A; and while for cyclohexane the dependence was weak, for methylcyclohexane A decreased by a factor of 2 from $T = 300$ °C down to $T = 200$ °C. The marked increase of the translation–rotation coupling at low temperatures, or high densities, was attributed to the strong local caging of the nonspherical molecules.

1.2.7 Mode-Coupling Theory The discovery by Alder and Wainwright of long-time velocity correlations in dense fluids, i.e., the breakdown of the Enskog theory, has motivated numerous new theoretical approaches to describe the many-body relaxations that occur in normal liquids. Mode-coupling theory is the leading approach to deal with these phenomena in a rigorous mathematical framework. This theory finds widest application in describing behavior associated with the transition to the glassy state, but it is applicable over a wide temperature range.

We showed previously (Secs. 1.1.2.3 and 1.1.2.4) that thermally driven uncorrelated motion leads to self-diffusion. Fourier transform of Brownian diffusion, Eq. (16), leads to density correlation functions that in this case decay to zero in time via an exponential function, characterized by a single relaxation time. In dense fluids this simple picture changes in two important ways. First, the decay to zero becomes nonexponential, and second, there appear two distinct characteristic relaxation times. The initial fast rate of change of the density–density correlation is termed beta relaxation, while the long slow decay is called the alpha relaxation (see Cummins *et al.*, 1994, Fig. 1). Microscopically, the beta relaxation may be thought of as particle movement within a cage created by the surrounding molecules, whereas the alpha relaxation describes diffusional motion out of the cage. Mode-coupling theory provides a rigorous mathematical model to treat the entire relaxation spectrum. The intractable problem of treating multibody interactions directly is circumvented by recasting the problem as one of interactions between different density fluctuation modes.

In mode-coupling theory the density fluctuations are treated through a damped-oscillator equation, where a memory function describes the time correlations and controls the damping of the density fluctuations. Idealized mode-coupling theory (I-MCT) expresses this memory function in terms of linear and quadratic coupling coefficients among density fluctuation modes. For simple interactions, such as Lennard-Jones, numerical solutions for the coupling coefficients are obtained. These are, of course, temperature and density dependent, and this dependence leads to the changes in the relaxation spectra observed experimentally. For more complex interactions, asymptotic solutions lead to power laws whose exponents are obtained through fits to experimental data (Cummins *et al.*, 1993). I-MCT fails at low temperature because it predicts that at some temperature $T_C > T_g$ the alpha relaxation time will go to infinity and cause an arrest of structural relaxation. Extended mode-coupling theory (E-MCT) includes thermally activated hopping processes, which prevent this singularity, and adds another term to the memory function. For E-MCT, the alpha relaxation time continuously increases as temperature decreases.

Both viscosity and diffusion are associated with the alpha relaxation. As explained above, simple random-walk motions do not describe the behavior of very dense fluids but a nonexponential relaxation is found instead. It is common to fit this relaxation spectrum by a stretched exponential form, $\exp[(-t/\tau)^{\beta}]$, where β lies in the range $0 < \beta < 1$. These values can be associated with the fragility discussed in Sec. 1.3 (Böhmer *et al.*, 1993). Of greater interest for the present discussion is the relaxation time, τ_{α}. We can associate this time with the viscosity through use of the Maxwell relation, $\eta = \tau_{\alpha}/G_{\infty}$, where G_{∞} is the high-frequency shear modulus of the liquid. The assumptions underlying this simplified connection between viscosity and relaxation are discussed in Ferry (1980) and Cummins *et al.* (1997). Taking this approach and using the predictions of I-MCT, $\tau_{\alpha} \propto |T - T_C|^{-\gamma}$, we see that viscosity is predicted to vary as a power of the temperature difference with respect to a critical temperature. It is found that this form is an adequate representation of data at high temperatures (or low pressures; Li *et al.*, 1995), where values of γ may be obtained from fitting the viscosity data or from analysis of relaxation spectra (Cummins *et al.*, 1994). However, this covers only a few decades of viscosity change, and below T_C this fails. The T_C values have no apparent physical meaning, and this was one of the main objections to early formulations of MCT. The revised E-MCT prediction for viscosity variation with temperature has not been fully formulated, but an approximate form, including hopping transport, was recently shown (Cummins *et al.*, 1997) to fit accurately the experimental alpha relaxation spectrum over the entire experimental range. Developments in mode-coupling theory and its application to experiment are currently an active area of research, and other modifications will surely be discovered.

1.2.8 Free-Volume Theory In the absence of a rigorous theory for the intermolecular dynamics to treat real liquids, one can utilize empirical relations based upon various approximations to infer the temperature, pressure, and compositional dependence of the viscosity and diffusion. Several of these types of equations have been derived; among them is the Adam–Gibbs theory, based upon entropy theory (Adam and Gibbs, 1965), and the free-volume theory, based upon molecular diffusion via cooperative movement of intermolecular free space (Cohen and Turnbull, 1959). This latter theory is rather successful in describing the effects of pressure on the viscosity of many liquids. Its assumptions can be summarized as follows:

1. It is possible to associate a local volume of molecular scale with each molecule.
2. Molecular transport occurs only when voids having a volume greater than some critical value V_{∞} approximately equal to the molecular volume form by the redistribution of free volume.
3. No local free energy is required for free-volume redistribution.

In a dense liquid, each molecule is encaged by the surrounding molecules. Now it is asked what volume is required to allow a molecule to move a distance on the order of a molecular diameter. At a minimum this volume must equal the molecular volume. Under the assumption that movement to this new position costs no energy and that the distribution of free space surrounding each molecule is governed by entropy requirements, an equation for the diffusion as a function of temperature and relative density can be obtained. If it is further assumed that one can apply the Stokes–Einstein relationship, then this equation can also be used to describe the viscosity. The forms of the equations are as follows:

$$D \propto \exp[-\gamma V_{\infty}/(V - V_{\infty})];$$

$$\eta \propto \exp[\gamma V_{\infty}/(V - V_{\infty})]. \tag{46}$$

Equations (46) can accurately describe data over a limited temperature range (Cohen and Grest, 1979). Recently, these equations have been shown to have greater utility in treating isothermal, variable-pressure data. In this case a normalized form is used:

$$\ln(\eta) = \ln(\eta_{p=0}) - \frac{BV_{\infty}}{V_{p=0} - V_{\infty}} + \frac{BV_{\infty}}{V - V_{\infty}}, \tag{47}$$

where $\eta_{p=0}$ and $V_{p=0}$ are the ambient-pressure viscosity and volume; V_{∞} and B are fit parameters, V_∞ being the volume at infinite viscosity and B a parameter that describes the strength of the viscosity divergence as $V \rightarrow V_\infty$. This equation has been found to describe the viscosity rise correctly over a fifteen–order-of-magnitude range, from ordinary liquid to the glassy state (Cook *et al.*, 1993). Moreover, the molecular volume V_∞ obtained from fitting the equation to the viscosity data is in good agreement with other estimates of the molecular volume. This volume differs considerably from that obtained when the theory is applied to variable-temperature data (Herbst *et al.*, 1993). The variable B attains values that range from approximately 1 to 10 depending upon the fluid. In the original theory, written for hard-sphere molecules, it was expected that $\gamma \propto B \approx 1$. Indeed, for simple molecules such as isopropyl benzene (Li *et al.*, 1995) and *o*-terphenyl, values close to unity are found. For more complex molecular shapes and interactions, such as hydrogen-bonded molecules, larger values of B are found. Recently it was shown that this variation could be related to the "fragility" of the molecular liquid (Cook *et al.*, 1994), a concept originated to describe the degree of cooperativeness of motion within the liquid. Further theoretical development is needed to introduce this formally into the free-volume theory; however, even in its present form it can provide a quantitative means of describing the origin of pressure-induced viscosity changes. Its use to describe temperature effects is more problematic. The extended free-volume theory (Cohen and Grest, 1979) can provide an accurate description of the temperature-induced viscosity rise over a wide range, but this formulation is clearly inferior to the original theory when used for variable-pressure data. Reconciliation of this problem is an area for further theoretical development.

Nearly all liquids for which data are available exhibit characteristics of free-volume scaling in their pressure behavior. For example, one unusual feature in the pressure data is an inflection point in a semilogarithmic plot of the viscosity as function of pressure. Utilizing free-volume scaling, it is found (Herbst *et al.*, 1993) that this feature is a consequence of nonlinear compressibility coupled with density-dependent viscosity. The reader is referred to the original articles for a more complete discussion.

1.3 Scaling Theories for Simple Liquids

There is often a practical need to describe the viscosity changes that are caused by changes in the temperature, composition, or pressure of the liquid. As described in the previous section, current theories are inadequate to predict viscosity from first principles, and scaling theories are widely used. The reader is referred to an excellent review of these empirical equations (Monnery *et al.*, 1995). A second set of scaling relationships has arisen from a desire to ascribe a molecular or thermodynamic meaning to the viscosity. Among the widely used forms of these equations, the Adam–Gibbs formulation (Adam and Gibbs, 1965), the WLF (Williams–Landel–Ferry) equation (Ferry, 1980), and the VTF (Vogel–Tammann–Fulcher) equation (Böhmer *et al.*, 1993) are found. The WLF equation finds wide application to polymers (see Sec. 4.2.2.1). The VTF equation has received considerable attention for many fluids. This equation is as follows:

$$\ln(\eta) = A + DT_0/(T - T_0), \tag{48}$$

where A, D, and T_0 are fit parameters. The physics underlying these parameters has been widely discussed, and the reader is referred to a recent review (Böhmer *et al.*, 1993). In brief: T_0 is correlated with the *Kauzmann* temperature, a fictive temperature at which the entropy of the liquid becomes equal to that of the crystal. The parameter D is related to the fragility. This concept arose from the realization that the rate of viscosity change with temperature, the size of the heat capacity change at the glass transition, and the deviation from simple single-exponential molecular relaxations are all related (Angel, 1991). The implication is that intermolecular interactions lead to structures in the liquid that give rise to a cooperativeness of motion that is absent for hard-sphere-like fluids. Fluids range from strong to fragile as D varies from large to small. This is also mentioned briefly in Sec. 1.2.8. The parameter A is proportional to the viscosity in the high-temperature limit ($T \rightarrow \infty$). In many instances, the VTF equation can describe the viscosity change over many decades, and the resulting fits enable the definition of the fragility and the calculation of the glass transition temperature, defined in this case as the point at which $\eta = 10^{12}$ Pa s.

For some liquids the VTF equation does not fit a wide temperature range. In such instances, the low-temperature data, near the glass transition temperature, are typically used in obtaining D and T_0.

2. MEASUREMENT TECHNIQUES—VISCOSITY

As indicated in Eq. (1), the measurement of viscosity must at some level involve the imposition of a shear rate upon a fluid and a measurement of the resulting shear stress or vice versa. However, an accurate experimental realization of the conditions depicted in Fig. 1 requires rather specialized conditions of flow. As previously discussed, nonturbulent flow is required (low *Re*). In addition, there will be a minimum time, t, to set up the conditions of steady-state flow, and this leads to a requirement for a minimum strain, $\gamma = t\dot{\gamma}$. This, along with the influence of the plate edges, makes the plate-and-plate geometry depicted in Fig. 1 impractical for general use as a viscometer. In practice, viscometers having infinite strain are commonly used; examples are rotating geometries such as the Couette or cone-and-plate that attain homogeneous stress and strain fields. Nonhomogeneous fields are also useful, but their use requires that one solve the Navier–Stokes equation using certain assumptions, a typical one being Newtonian fluid behavior. The resulting equation will relate an observable, such as the amount of material that flows through a capillary with time, to the viscosity of the fluid. This explicit dependence on a flow model means that changes in the observable may not fully reflect the changes in fluid behavior. For example, change to a non-Newtonian fluid leads to an alteration of the entire velocity profile in the capillary and requires an altogether new set of equations to interpret the flow. A further complication in building any viscometer is that viscosity values can span many decades, from a few micropascal-seconds for a gas to a gigapascal-second for glassy materials. Consequently, a single viscometer capable of making measurements over the entire range is not found. Typically, each device is capable of covering a few decades of viscosity only. A change in dimensions of a given geometry or use of an entirely new device is then required to reach a new viscosity range.

In the following, we briefly review some commonly utilized geometries. We emphasize the determination of the shear viscosity of Newtonian fluids. For more detailed reviews of the techniques as well as the more generalized fields of rheology and finite-strain deformation, the reader is referred to Ferry (1980) and Macosko (1994). In most instances the compositional or temperature dependence of a fluid is measured, and these topics are covered in these two references. The reader is referred to a recent review (King, 1997) for a description of high-pressure viscometry.

2.1 Rotational Viscometers

In this section, two commonly used rotary viscometers, the Couette and cone-and-plate geometries, are described. Both devices produce homogeneous stress and strain fields. The first of these consists of two concentric cylinders with a small gap separating them. Rotation of one cylinder induces a torque in the other through the fluid filling the gap. If the ratio of the cylinder radii is near unity, the resulting velocity gradient is almost that of parallel plates. Hence, the torque on the stationary cylinder is proportional to the absolute shear viscosity, and the shear rate is given by $\dot{\gamma} = \Omega\langle R\rangle/\Delta R$, where Ω is the angular rotation speed, $\langle R\rangle$ is the average radius, and ΔR is the gap separation. The Couette geometry is especially good for study of shear rate effects on moderately viscous fluids and suspensions.

The cone-and-plate geometry consists of a stationary plate with a cone-shaped bobbin oriented perpendicular to the surface. The tip of the cone nearly touches the plate, and its cone angle, β, is small, about 6°. As the cone rotates, it induces a torque in the plate through the wedge-shaped annulus of fluid that is held in place through capillary action. The shallow cone angle gives a constant velocity gradient throughout the fluid, and the observed torque is proportional to the viscosity at a shear rate given by $\dot{\gamma} = \Omega/\beta$. The cone-and-plate geometry is advantageous for studying moderately high-viscosity fluids, particularly fluids that are viscoelastic.

Various experimental difficulties arise with the use of both geometries. For example, shear heating, cylinder-end effects for Couette flow, and fluid-edge effects for cone-and-plate geometry can complicate the experimental analysis, as discussed in detail in Macosko (1994).

2.2 Capillary Viscometers

Gravity-driven fluid flow through a narrow capillary was the basis for the earliest viscometers. The stress and strain fields are nonhomogeneous, but their variation is simple to describe. The shear rate is maximum near the wall and goes to zero at the center of the tube. For a Newtonian fluid, the resulting parabolic velocity profile leads to the familiar Hagen–Poiseuille law:

$$\mu = \frac{\eta}{\rho} = \frac{\pi g h R^4 t}{8VL}, \tag{49}$$

where μ = kinematic viscosity, η = absolute viscosity, ρ = fluid density, g = gravitational acceleration, R = radius of capillary, h = vertical distance between ends of capillary, V = volume of fluid flowing in time t, and L = length of capillary. Equation (49) yields the kinematic viscosity, requiring knowledge of the density for conversion to absolute viscosity. A more general form of the equation replaces $\rho g h$ with pressure and gives the absolute viscosity. Such pressure-driven devices are commonly used for high-viscosity fluids such as polymer melts. The shear rate can be quite high in capillary viscometers and is given by $\dot{\gamma} = 4V/\pi t R^3$. Although these viscometers might seem unsophisticated, in fact they provide some of the highest-accuracy data and are applicable for fluids ranging from gases to highly viscous polymer melts.

An important application is their use in defining the effect of small amounts of polymer upon the viscosity of a solution. For such measurements a capillary geometry described as an Ubbelohde tube viscometer is utilized (Young and Lovell, 1991). The use of such viscosity data in describing polymer conformation and molecular weight is described in Sec. 4.2.1. In polymer melts, a commonly cited quantity, proportional to viscosity, is the melt index. The capillary device used for its determination, however, does not produce a uniform velocity field. Thus the viscosity cannot be directly calculated from the melt index. True capillary geometry and various rotational or oscillatory viscometers can give viscosity values for such highly viscous melts.

2.3 Falling/Rolling-Sphere Viscometer

In the falling/rolling-sphere viscometers, the velocity of a falling or rolling sphere within the viscous liquid is monitored, and the viscosity of the liquid is extracted through the use of the Stokes equation, Eq. (11). As in capillary devices, the stress is inhomogeneous. However, the mathematical description is more complex because of spatial variations of the velocity field due to finite-sample-volume effects. This makes the shear rate in such a device very poorly defined; fortunately, the velocity of the moving object is typically slow, and with appropriate corrections these devices give accurate low-shear-rate viscosity values. Typically, the deviations from an ideal, infinite system are accounted for by an empirical correction factor that characterizes a particular geometry. Very accurate data can be obtained; accuracies better than 1% are commonly reported. Like the capillary devices, these viscometers can cover a wide range of viscosities, ranging from those of gases up to polymer melts near the glassy state. Because of their simple design and sealed geometry, they also find wide application for use at elevated pressures, as reviewed in King (1997).

2.4 Vibrational Viscometers

Damping of an oscillator immersed in a fluid can also be a sensitive measure of the fluid viscosity. Certain conditions must be met: the vibration frequency f must be well below the molecular relaxation rates, and the viscosity must be sufficiently low that the oscillation is strongly damped, i.e., the viscous penetration depth, $\sqrt{\eta/2\pi f \rho}$ where ρ is the fluid density, is small compared to the sample dimensions (see King, 1997, for a discussion of the constraints). One such device, used in the measurement of the temperature and pressure dependence of viscosity of gases and supercritical fluids, relies upon the damping of a vibrating wire (van Der Gulik *et al.*, 1988).

3. MEASUREMENT TECHNIQUES—DIFFUSION

3.1 Measurement of Mutual Diffusivity

Concentration gradients lead to particle fluxes that can be observed macroscopically. According to Fick's first law (see Sec. 1.1.2), a determination of the mutual diffusion coefficient of a certain pair of species of molecules can be based either on a measurement of both the flux density and the gradients of the concentration or on a measurement of the particle distribution at different times, supposing that the rearrangement within the sample is governed by diffusion phenomena (Crank, 1975).

Molecular concentrations can be determined by chemical as well as by various physical methods, since numerous properties such as weight, refractive index, birefringence, radioactivity, spectral absorbance, and emittance depend on the composition of the system. Therefore, a wide variety of experimental techniques for determining the mutual diffusion coefficients of systems have been developed (Jost and Hauffe, 1972; Kärger *et al.*, 1988).

3.2 Measurement of Self-Diffusivity

The random movements of individual molecules do not lead to a net transport of mass. Therefore, the displacement of the particles have to be monitored directly to determine their diffusivity. However, that requires either the labeling of a small minority of molecules (tracer methods) or the imposition of a field, varying on a molecular length scale, through which the ensemble of molecules move (NMR and scattering techniques).

3.2.1 Molecular Tracer Methods The traditional procedure of "tracer" experiments is to introduce different isotopes into the system under study. However, two major assumptions have to be fulfilled: First, the molecular mobility of the molecules must not be altered by the process of labeling. Second, in order to measure the coefficient of the self-diffusivity and not the coefficient of the mutual diffusivity (see Sec. 1.1.2), the concentration of the labeled molecules must be small enough to ensure that the mobility of any labeled molecules is unaffected by the existence of other labeled molecules.

There are several experimental techniques for monitoring the rearrangement of labeled molecules within an unlabeled matrix, like infrared spectroscopy (Klein, 1979; Klein and Briscoe, 1979) or forced Rayleigh scattering (FRS) (Hervet *et al.*, 1978; Antonietti *et al.*, 1984). Alternative ways of following the labeled species have been developed—e.g., by determining the recombination rate of free radicals from an analysis of electron-spin-resonance (ESR) spectra (Lebedev, 1967) or by measuring the variation of the local density of radioactive isotopes ("liquid scintillation counting") (Mills *et al.*, 1984). Generally, "tracer" techniques have the big advantage of being able to measure extremely slow molecular diffusivities (as small as 10^{-20} m^2/s). The often complicated process of molecular labeling sets limits in the application of these techniques.

3.2.2 NMR Mean square displacements of diffusing molecules can be directly monitored by the nuclear magnetic resonance (NMR) field-gradient technique. The self-diffusion coefficient can be calculated knowing the mean square displacement of the particles within a given time; see Eq. (17). It is required, however, that the displacements of the molecules be much larger than the mean lengths of the elementary jumps of diffusion. Up to now field-gradient NMR (FG NMR) is the only method that allows a direct measurement of molecular displacements over such large distances.

The principle of measuring molecular diffusivity using FG NMR is that the spatial position of each spin (and, hence, each molecule) is marked by its specific Larmor frequency within a well-defined, spatially inhomogeneous magnetic field. Diffusion of the marked molecules causes changes in the Larmor frequencies of the spins, which results in a measurable attenuation of the NMR signal. Recently, it has been shown (Fleischer and Fujara, 1994) that the FG NMR experiment can be interpreted in terms of a generalized scattering experiment, which implies the possibility of defining a "generalized scattering vector." The NMR field-gradient technique can cover length scales from about 100 Å (using the strong field gradients of the stray field of a cryomagnet) to a few microns. Since the accessible diffusion times vary from milliseconds up to seconds, a broad range of diffusion coefficients can be determined. This makes it possible to apply FG NMR to gases, liquids, and polymers. An excellent review of the principles and applications of the FG NMR can be found in Kärger *et al.* (1988).

3.2.3 Scattering Techniques Recent advances in laser and neutron spectroscopy have enabled scattering techniques to be widely applied in the investigations of diffusion processes. In these experiments information about the diffusion phenomena follows from an analysis of the Doppler-frequency shift of a monochromatic beam due to fluctuations in the observed systems that are caused by the motion of the molecular scatterers.

All scattering techniques measure the intensity of the scattered beam as a function of the energy difference $\hbar\Delta\omega$ and the momentum difference $\hbar\Delta\mathbf{q}$ between the incident and scattered beams. The scattering vector $\mathbf{q}$ is the difference between the wave vectors of the scattered and incident beam, $\mathbf{k}$ and $\mathbf{k}_0$, respectively, and is a function of the wavelength of the incident beam λ and the scattering angle θ:

$$|\mathbf{q}| = (4\pi/\lambda)\sin(\theta/2). \qquad (50)$$

3.2.3.1 Neutron Scattering. Among the scattering methods, neutron scattering is distinguished by the fact that the wavelength and the energy of the incident beam are respectively on the order of the atomic distance and thermal energy. The quantity measured in neutron scattering is the differential scattering cross section, $\partial^2\sigma/\partial\Omega\partial E$, i.e., the probability with which an incident neutron of energy E_0 is scattered into an angle element $d\Omega$. The motion of the individual nuclei can be studied by an analysis of the incoherent scattering process. Experimentally, one determines the so-called structure factor $S(\mathbf{q},\omega)$ from the intensity of a beam scattered into a certain angle element. For the case of incoherent scattering it can be shown (Springer, 1972) that the incoherent structure factor $S_{\text{inc}}(\mathbf{q},\omega)$ is the Fourier transform of the self-correlation function, $G_S(\mathbf{r},t)$:

$$S_{\text{inc}}(\mathbf{q},\omega) = \iint G_S(\mathbf{r},t)\exp[i(\mathbf{q}\cdot\mathbf{r} - \omega t)]d^3\mathbf{r}dt. \qquad (51)$$

Therefore, $S_{\text{inc}}(\mathbf{q},\omega)$ provides the information about the ensemble-averaged probability density that a particle has been shifted from position $\mathbf{r}_0$ to the position $\mathbf{r}_0 + \mathbf{r}$ within the time interval t.

The time scale over which molecular migration can be followed is determined by the energy resolution of the scattering equipment. In conventional neutron-scattering spectrometers (see SPECTROMETERS, NEUTRON), an energy resolution of $\Delta E_{\min} = \Delta(\hbar\omega) \approx 10^{-6}$ eV may be achieved, which corresponds to maximum observation times of about 10^{-8} s. Observation times longer by almost two orders of magnitude have been achieved by the introduction of neutron spin-echo spectroscopy. The largest scanned space scale, $r_{\max} \approx 2\pi/|\mathbf{q}_{\min}|$, is on the order of 30 to 50 nm and is determined by the minimum value of momentum transfer, or scattering vector $\mathbf{q}$, that is experimentally accessible (Mezei, 1983).

3.2.3.2 Light Scattering. Traditional light-scattering techniques using thermal sources (pre-1960) were confined to the investigation of nondiffusive phenomena because of the relatively low power and high bandwidths of conventional light sources and filters. Advances in optical and electronic detection devices together with the availability of laser light sources have eliminated these restrictions and have led to the development of "photon correlation" and "light beating spectroscopy" as powerful means for light scattering investigations.

The principle of diffusion measurements by light scattering is that fluctuations of the concentration on a molecular level lead to a line broadening of the scattered radiation with respect to the incident one. Since any fluctuations of the local density relax back to equilibrium through diffusion, studies of the line broadening can yield values of the relevant diffusion coefficients (Berne and Pecora, 1976).

Light scattering allows observation times from microseconds to several seconds, with a space scale, $2\pi/|\mathbf{q}_{\min}|$, typically on the order of a few microns. The probing lengths are generally considerably longer than the size of individual atoms or molecules. Self-diffusion can be studied by working in the limit of very high dilution (see Sec. 1.1.2.2) (Tyrrell and Harris, 1984).

Viscosities of liquids can also be determined using light scattering techniques by observing the diffusive motion of large (micron-sized) tracer particles placed in the liquid of interest. Viscosities can then be determined through the Stokes–Einstein equation given in Eq. (26). Recent detailed and accurate experiments have compared this technique to the more traditional mechanical rheometric methods and have demonstrated accuracies of order 1%.

A summary of the typical working regimes of classical techniques for measuring molecular self-diffusion is illustrated in Fig. 3.

4. MATERIALS/SYSTEMS

In the preceding sections we have dealt with concepts applicable to simple gases and liquids, the most common materials for which one would like to understand viscosity and diffusion. In the following sections we deal with systems that illustrate new concepts. In the first instance, colloidal suspensions, we encounter the effects of two-phase flow, but we also see that after rescaling, these systems can illustrate many behaviors characteristic of hard-sphere systems. They become model systems for molecular liquids when treated in this way. The second section deals with the behavior of polymers. The viscosity and diffusion of these materials is vital to their understanding, and because of their large molecular size, the mechanisms underlying their viscosities and diffusions differ substantially from those of the molecular systems covered in the main sections of this text.

4.1 Hard-Sphere Colloidal Suspensions

In this section we give a brief introduction to the subject of diffusion and viscosity of suspensions of micron-sized colloidal particles that interact like hard spheres. Conceptually such suspensions are very similar to hard-sphere atomic liquids, with the essential difference being the presence of an interparticle, or background, solvent. At low particle densities, the presence of a solvent leads to profound differences in the particle dynamics between the two systems—hard spheres move ballistically, colloidal particles execute Brownian motion. At high densities, the dominant effect in both systems that determines particle motions, and hence sample viscosities, is the direct particle–particle interactions due to the close crowding, or caging, of the spheres. Consequently, as outlined below, at high densities, many of the concepts derived originally in atomic liquids for the density dependence of the viscosity, as well as the use of the Stokes–Einstein equa-

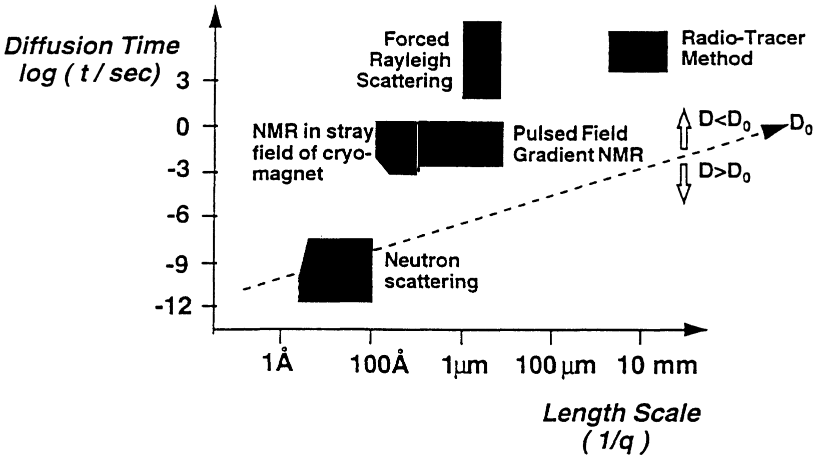

FIG. 3. Typical working regimes of classical techniques for measuring molecular self-diffusion. The dashed line has a slope of 1 and represents the trajectory of a particle diffusing according to normal self-diffusion, Eq. (26), with a certain diffusivity, D_0. A higher diffusion coefficient would displace this line downward; lower diffusivity, upward.

tion, are useful also in describing colloidal suspensions. One of the distinct advantages of studying colloidal systems is that the large particle sizes, of order 1 μm as compared to 1 nm in molecular liquids, lead to very slow dynamical processes, which are easily accessible via such commonly used techniques as dynamic light scattering (DLS) (Pusey, 1991).

4.1.1 Diffusion A single particle executes a random walk according to Eq. (27) with the Stokes–Einstein diffusion coefficient, D_0, given by Eq. (26). In semidilute suspensions individual spheres still execute Brownian displacements, albeit at a reduced diffusion coefficient, $D < D_0$, resulting from the influence of both the solvent-mediated hydrodynamic interactions and direct interactions between colliding spheres (Pusey, 1991). For concentrated suspensions it has been shown that particle motions proceed via a two-stage process. That is, there is an initial rate of diffusion for small displacements "inside" the cage of neighboring spheres, and a considerably slower diffusive process at longer times as the particles travel through the surrounding matrix (Pusey, 1991; Segrè and Pusey, 1996). As an example, Fig. 4 displays values of the (inverse) normalized short- and long-time self-diffusion coefficients, D_S^{Self} and D_L^{Self}, respectively, of suspensions of poly-(methyl methacrylate) (PMMA) spheres in *cis*-decalin (Segrè *et al.*, 1995a). The large disparity in the values at high concentrations, $\phi > 0.4$, reflects the tightening of the neighbor cages, which also shows up as an increase in the correlated short-range structure. This phenomenon is also found in simple liquids; see Sec. 1.2.7.

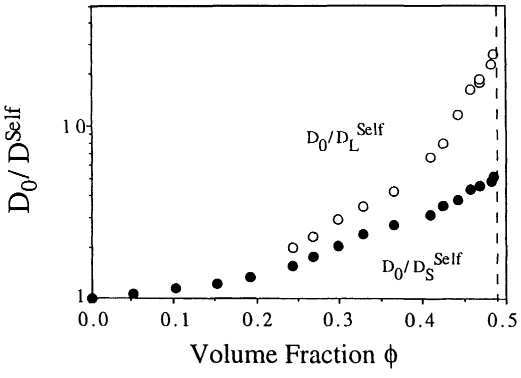

FIG. 4. Inverse normalized short- and long-time diffusion coefficients D_0/D_S^{Self} (closed circles) and D_0/D_L^{Self} (open circles) versus volume fraction ϕ. The line at $\phi = 0.494$ represents the disorder/order (freezing) transition. The considerable slowing down of D_L^{Self} represents the tightening of the neighbor cages as the volume fraction increases. Data from Segrè (1995).

Connections between the diffusion behavior of dense suspensions and molecular fluids have been the subject of numerous articles (Cohen, 1993) in recent years. Simulations of hard-sphere fluids have also exhibited two-stage diffusional processes similar to that seen in suspensions (Lust *et al.*, 1993). It is interesting to note that in suspensions, the onset of a long-time slow relaxation process occurs at a similar volume fraction ($\phi \sim 0.4$) to that at which the Enskog theory in simple liquids fails. This suggests that similar complex multiparticle correlations arise in both systems at similar densities. Further detailed comparisons, however, would benefit from more detailed relaxation spectra in simple liquids at moderate densities. At very high densities, $\phi > 0.5$, near to the glass transition, mode-coupling theories (see Sec. 1.2.7) have been developed for hard-sphere (atomic) fluids (Götze, 1991). Somewhat remarkably, these same theories also accurately account for the dynamics of very concentrated hard-sphere colloidal suspensions (van Megen and Underwood, 1993, 1994), the implication being that the effect of particle caging dominates the influence of the background solvent.

4.1.2 Viscosity When colloidal particles are placed in a solvent of viscosity η_0, the solution viscosity is found to increase. In the limit of low concentrations, Einstein found that the viscosity increase depends upon the volume fraction ϕ of the particles. He derived the linear term in ϕ, and later Batchelor (Batchelor, 1976) the ϕ^2 term, yielding

$$\eta = \eta_0(1 + \tfrac{5}{2}\phi - 6.55\phi^2). \qquad (52)$$

This expression, especially the linear term, finds wide application in expressing the viscosity of suspensions. The complete form accurately describes experimental data up to about $\phi = 0.10$. At higher densities Eq. (52) fails, and more complex theories are needed.

The viscosity in dense suspensions displays non-Newtonian behavior, with both a shear-rate and a frequency dependence. The key to understanding the behavior of the viscosity lies in examining the underlying suspension microstructure and its relaxation properties under shear (de Kruif *et al.*, 1985). The application of shear distorts the equilibrium microstructure, while Brownian motion tends to restore it. The dimensionless Peclet number, defined as the ratio of the time for a single particle to diffuse through its own radius to that needed to convect through its own radius under shear, is given by $Pe \equiv R^2\dot{\gamma}/D$. For values of the shear rate $\dot{\gamma}$ such that $Pe \ll 1$, the microstructure is only moderately perturbed, Brownian motion dominates the particle motions, and one measures the low-frequency shear viscosity η. For $Pe \gg 1$, the microstructure becomes severely distorted, and the high-frequency shear viscosity, η_∞, is found. Dense suspensions exhibit shear thinning, i.e., $\eta > \eta_\infty$, with the difference being attributed to the specific effects of Brownian motion. In practice, for submicron-sized particles, both regimes are experimentally observable. It is also worth noting that computer simulations of atomic liquids have also shown the effects of shear thinning. However, because of the small size of molecular liquids, $R \sim 0.1 - 1$ nm, experimentally unattainable shear rates of $\dot{\gamma} \geq 10^{12}$ s^{-1} would be required to see it (Evans *et al.*, 1981). For the sake of brevity we restrict the discussion in this section to the low-shear viscosity only.

In hard-sphere colloidal suspensions, the viscosity increase with ϕ has been measured under low–shear-rate conditions (Russel and Sperry, 1994; Segrè *et al.*, 1995b). At the equilibrium freezing point for monodisperse hard spheres, $\phi = 0.494$, a viscosity enhancement of about 50, relative to the background solvent, is found. At higher packing fractions the glassy state can eventually be approached. An interesting result has been obtained by de Kruif *et al.* (1985) in their studies, namely, that the results can be fitted by the relation $\eta/\eta_0 = 1/(1 - \phi_m)^2$, where $\phi_m = 0.64$, the random close-packing value at which all the particles are in direct contact and diffusion ceases. More recent studies (Phan *et al.*, 1996) have used the same fitting form and extracted $\phi_m = 0.58$, the value at which suspensions become glasslike. Overall, there is no canonical theory for this regime. Indeed, this is an area of great interest at present both for the intrinsic interest in colloidal suspensions and for the possibility that these systems can act as analogs for simple liquids.

4.1.3 Stokes–Einstein Relation Several studies have tested the validity of the Stokes–Einstein relation, Eq. (26), in concentrated colloidal suspensions (van Blaaderen *et al.*, 1992; Segrè *et al.*, 1995b). Segrè used the values of η and D_L^{Self} measured on hard-sphere-like suspensions and used the relation $D = k_BT/C\pi\eta R$ to extract the constant C, with the results shown in Fig. 5. In the dilute limit, i.e., for a single sphere, the exact relation for nonslip boundary conditions, Eq. (26), shows that $C = 6$. As shown in the figure, at the highest concentrations the measured values decrease to $C \sim 4$, which parallels what is generally also observed in dense hard-sphere/molecular fluids (see Sec. 1.2.4). These results indicate that there is no simple Stokes–Einstein equation (stick or slip) that holds over all volume fractions. This is perhaps not surprising given the assumption of an isolated sphere in the derivation of the Stokes–Einstein equation. A more complete theoretical understanding of these results, as well of viscosity of these systems in general, remains to be given.

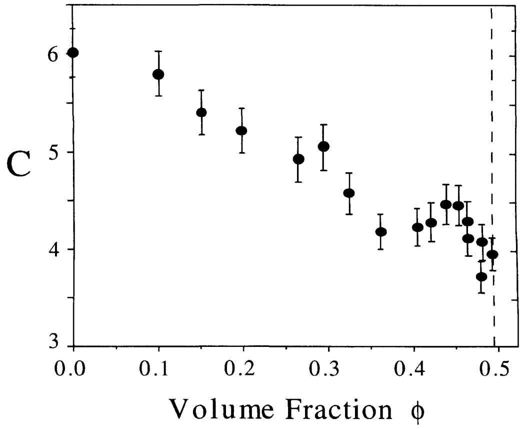

FIG. 5. Values of the constant C in the Stokes–Einstein equation [Eq. (26)] derived from measurements of the viscosity η, the long-time self-diffusion coefficient D_L^{Self}, and the particle radius R in suspensions of poly-(methyl methacrylate) (PMMA) spheres. Note the evolution from stick condition ($C = 6$) at low volume fractions to slip condition ($C = 4$) as volume fraction increases. Data from Segrè (1995).

4.1.4 Viscosity and Structural Relaxation One of the principal advantages of micron-sized colloidal suspensions as opposed to atomic liquids is that it is readily possible, using dynamic light scattering (DLS), to study accurately the dynamics of cage relaxation. Dense liquids, colloidal or molecular, do not display long-range order but possess strong short-range particle correlations on the scale of 1–3 diameters. This is exhibited in Fourier space as a strong peak in the static structure factor $S(q)$ at $q \approx q_m \approx \pi/R$. Under shear this ordering gets distorted, and its diffusional relaxation back to equilibrium plays a key role in several theories of viscosity (Geszti, 1983; de Schepper *et al.*, 1989; Götze, 1991; Brady, 1993). To study fluctuations in suspensions on this length scale is straightforward with DLS. However, it is only achievable for molecular liquids using neutron-scattering techniques, of which there are only limited results to date (Cohen, 1993). Consequently, most diffusion results in liquids concern either long–length-scale collective diffusion or self-(tracer) diffusion of isotopically labeled species. A recent DLS study in suspensions has examined directly the dynamics of structural relaxation—and characterized it by (long-time) diffusion coefficients $D_L(q_m)$. The results are shown in Fig. 6. First, the inset shows that, as a result of the cage effect, diffusion at the peak differs from single-particle self-diffusion, the former being consistently smaller. Second, for all values of ϕ up to 0.50, there is a close coincidence of the normalized viscosity and structural relation rates, consistent with the simple relation

$$\eta/\eta_0 = D_0/D_L(q_m). \tag{53}$$

Note that Eq. (53) can also be rewritten in the Stokes–Einstein-type format as $D_L(q_m) = k_BT/6\pi\eta R$. Since the long-time diffusion process is the α-relaxation, the proportionality in Eq. (53) is similar to the Maxwell relation between viscosity and τ_α as discussed in Sec. 1.2.7.

4.2 Polymers

The enormous variety of polymers and their uncounted applications have led polymer scientists to define many different types of viscosity and diffusion, and this can lead to confusion for those new in the field. The clearest division of behavior is between that of solutions of polymer molecules dispersed in a solvent (polymer solutions) and that of solvent-free systems (polymer melts). Moreover, there are five different regimes in the molar mass–concentration diagram of polymers. Figure 7 illustrates such a phase diagram for the example of a polystyrene–benzene system. At low volume fractions of polystyrene, Φ_{Polymer}, the polymer coils do not overlap one another. The threshold for overlapping coils is given by the so-called overlap-concentration c^*, which decreases with increasing molecular weight of the polymer. Systems with a polymer concentration greater than c^* are called semidilute so-

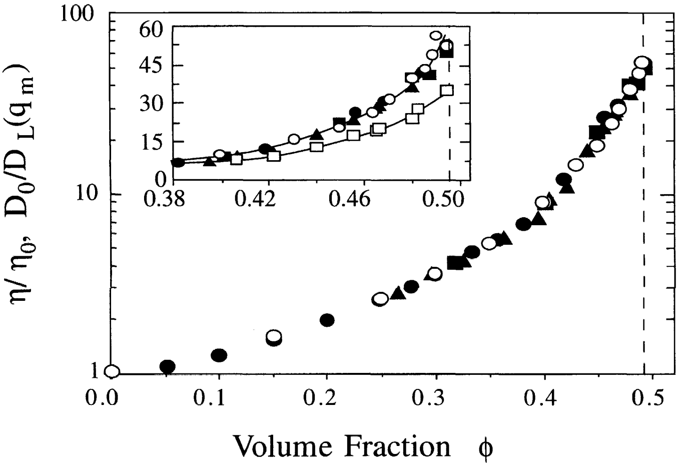

FIG. 6. Normalized low-shear viscosity η/η_0 (open symbols) and long-time peak diffusion $D_0/D_L(q_m)$ [see Eq. (53)] versus volume fraction ϕ for suspensions of poly-(methyl methacrylate) (PMMA) spheres. Inset: The same data on a linear scale at high volume fractions with in addition the open squares being measurements of the long-time self-diffusion coefficient D_0/D_L^{Self}. Note in the inset that diffusion at the peak differs from single-particle self-diffusion because of the cage effect. Note also the excellent scaling of the long-time peak diffusivity and viscosity over the entire range of volume fraction. Data from Segrè (1995).

lutions. The semidilute regime turns into the concentrated regime with the onset of polymer–polymer interactions. The corresponding concentration is abbreviated c^{**}. Both the semidilute and the concentrated regimes have to be divided into entangled and nonentangled solutions because of the onset of topological constraints for long polymer chains, as described in Sec. 4.2.2.

In the following sections we focus on dilute solutions and polymer melts only. These two regimes represent the extreme cases of the dynamic behavior of polymers, on the one hand, and are understood best, on the other hand. The semidilute and concentrated solution behavior is too complex to be treated here but can be found elsewhere (Elias, 1971).

In the description of the diffusional behavior of polymer systems, we focus on self-diffusion only. The results of self-diffusion can easily be transferred to rotational diffusion as introduced in Sec. 1.1.3 for the case of dilute, simple molecular systems. In multicomponent systems one will encounter mutual or transport diffusivities. However, relating the mutual-diffusion coefficients to the underlying self-diffusion coefficients of the species in the solutions is nontrivial and beyond the scope of this encyclopedia.

4.2.1 Dilute Solutions

Low-shear-rate viscosity in the dilute-solution regime is closely related to the polymer conformation. Since this relation is well understood theoretically, it is a useful characterization tool; for example, the molecular weight of linear polymers can easily be obtained. Also, it is a powerful tool to measure the change in polymer conformation due to solvent effects. The hydrodynamics is similar to the two-phase flow we encountered in Sec. 4.1.2, and the Einstein equation, Eq. (52), gives the essential relationship for these dilute polymer solutions. The fluid consists of dispersed polymer coils with their concentration related to the mass of polymer per unit volume of fluid, c. Furthermore, each polymer coil is characterized by a mass, the molecular weight M_W, and a size, the hydrodynamic volume V_H. We saw earlier in the Einstein equation that the viscosity enhancement due to addition of spherical particles is proportional to the volume fraction, $\frac{5}{2}\phi$. We note here that $\phi = (c/M_W)N_AV_H$, and obtain an equation for the viscosity of a dilute solution. However, by convention polymer science chooses to define a new viscosity, the specific viscosity, η_{sp}, which equals $\eta/\eta_0 - 1$ of the Einstein equation; thus, $\eta_{sp} = \frac{5}{2}(c/M_W)N_AV_H$. Recall that the Einstein equation is applicable to noninteracting particles at low concentrations. This suggests that for real systems extrapolation to zero concentration would yield the most consistent results. In polymer science this extrapolated value of the specific viscosity is named the intrinsic viscosity, $[\eta]$, defined as follows:

$$[\eta] = \lim_{c\to 0}(\eta_{sp}/c);$$
$$\eta_{sp} = [\eta]c + k_H[\eta]^2c^2. \qquad (54)$$

The second equation is simply a Taylor's expansion and is known as the Huggins equation. It provides a tool to extract an intrinsic-viscosity value from experimental data and yields a parameter, k_H, proportional to the strength of polymer–polymer interaction in a given solvent.

The intrinsic viscosity is a key property of a polymer since it is the main parameter relating solvent viscosity to polymer conformation. For example, an important scaling relationship between average molecular weight and intrinsic viscosity is the Mark–Houwink equation (Young and Lovell, 1991),

$$[\eta] = K(\bar{M}_\nu)^a. \tag{55}$$

The quantities K and a are determined experimentally and are often tabulated for various polymer-solution combinations, which provides a simple means of determining the viscosity-averaged molecular weight $\bar{M}_\nu$ of a sample. The underlying molecular origin of the Mark–Houwink equation is seen in the Flory equation (Young and Lovell, 1991)

$$[\eta] = \Phi R^3/M_W, \tag{56}$$

where Φ is a constant and M_W is the weight-average molecular weight. This form of the equation can be used to probe the effective size of the polymer, R^3, under changing solvent conditions. For example, recent high-pressure viscosity measurements have shown that for certain water-soluble polymers the intrinsic viscosity changes significantly, indicative of a collapse of the polymer chain (Cook *et al.*, 1992b). This is in contrast to hydrocarbon solvents where no change is found (Cook *et al.*, 1992a). These effects arise from the unique role that hydrogen bonding plays in the solvation of nonionic water-soluble polymers (Sun and King, 1996).

Diffusion of individual polymer coils in dilute solutions is often measured via dynamic light scattering. The diffusion coefficient of the polymer coils is connected to their effective radius and the viscosity of the solvent through use of the Stokes–Einstein equation. The effective size of the polymer coil is typically reported as V_H, the hydrodynamic volume, as discussed above. Expansion and contraction of this volume can be related to the solvent–polymer interaction strength (Sun and King, 1996).

The diffusivity of the polymer coils in the dilute regime can be directly observed via field-gradient NMR if the NMR signal from the solvent molecules can be suppressed. This can be achieved, e.g., by use of deuterated solvents, which are invisible compared to the protonated polymers during ^{1}H NMR experiments.

4.2.2 Melts A flexible polymer chain is capable of assuming an enormous number of possible configurations by rotations of its chemical bonds. Therefore, a macroscopic deformation of a polymer causes complex structural rearrangements that extend from single chemical bonds to the displacement of whole polymer chains. The corresponding time scales span from a few picoseconds up to several days. This feature, specific for macromolecules, causes their mechanical properties to be very distinct from other materials: As a function of shear rate, the polymer can behave either as a liquid or as a rubber, depending upon the kinematics of the deformation, the temperature, and the molecular weight of the polymer. This behavior is called viscoelasticity. Although the phenomenon of viscoelasticity is too complex to be completely explained in this section (see, e.g., Ferry, 1980), two of its features have to be discussed because of their strong impact on the viscosity and the diffusion of polymer melts.

For polymer melts a continuous range of behavior ranging from viscous to elastic is encountered as the frequency of investigation is scanned from low to high. This effect becomes especially important for the understanding of the viscosity of polymer melts. The second remarkable feature of the dynamics of long polymer chains arises from the fact that these one-dimensional objects cannot cross each other. Therefore, the molecular rearrangement becomes restricted because of the onset of topological constraints, known as entanglements, between the polymer chains. Entanglements prevent the chains from displacing laterally beyond a certain distance; i.e., each polymer chain can be assumed to be confined within a tube that only allows displacements of the chains along their own backbone. The diameter of this tube represents an additional length scale that determines the transport in melts.

4.2.2.1 Viscosity of Melts. Because of the viscoelastic behavior, the complete description of the viscosity of polymer melts is well beyond our discussion. However, we can focus on the viscous component alone and consider the behavior in the low-shear limit. We find then that polymer melts exhibit two characteristic behaviors. First, since we are only considering here polymers that do not form crystals, as the polymer melt is cooled, the viscosity continuously rises and the glassy state is formed. Transitions into the glassy state for polymer melts are quite common; a good example of such a material is polystyrene. This increase in viscosity with decreasing temperature can be scaled through use of the Williams–Landel–Ferry (WLF) equation:

$$\log\left(\frac{\eta}{\eta_{T_g}}\right) = \frac{-C_1(T - T_g)}{C_2 + (T - T_g)}, \tag{57}$$

where C_1 and C_2 are constants and η_{T_g} is the viscosity at the glass transition. Values for the constants are tabulated; for example, see Sperling (1992).

The second important characteristic of polymer melt viscosity is its dependence on molecular weight. Here, a remarkable effect is that two different scaling relations are found: for $M < M_C$,

$$\eta = K_L M^{1.0}, \tag{58}$$

and for $M > M_C$,

$$\eta = K_H M^{3.4}.$$

For chains shorter than a critical molecular weight, M_C, the viscosity in the limit of zero shear is directly proportional to the molar mass after corrections are made to achieve a constant free-volume state, i.e., after adjusting for chain end effects. In contrast to this, it is experimentally found (Berry and Fox, 1968) that chains with a molecular weight above M_C scale with $M^{3.4}$.

The threshold molecular weight M_C is a material-dependent property. Empirically, it was found that M_C is roughly equal to $2M_e$, where the entanglement molecular weight M_e is the molar mass of that fraction of a chain between two entanglements. The entanglement length is an important concept in describing the full complexity of polymer viscoelasticity (Ferry, 1980; Kremer and Grest, 1995). The proportionality factors, K_L and K_H, are empirical constants valid for the low (L) and high (H) molecular-weight limits (Sperling, 1992).

4.2.2.2 Diffusion of Melts. It is obvious that topological constraints strongly influence the molecular mobility of polymer chains. Similar to the behavior of the viscosity discussed in the previous section, entanglements clearly distinguish the translational dynamics of unentangled chains from that of entangled ones. In this section we begin with a brief description of the Rouse model (Ferry, 1980) for unentangled chains, followed by a discussion of the effects of topological constraints on the diffusion of entangled polymers.

The Rouse model provides a reasonable description of the translational dynamics of unentangled polymer chains in the melt. In his attempt to understand the dynamics of chains in solution, Rouse argued that a chain could be considered as a series of beads connected by Hookean springs, where each spring constant is $3k_BT/b^2$; b is the separation of the beads. The position of each bead chain is determined by a set of coordinates $\{R_1, R_2, \ldots, R_N\}$, and each bead experiences an averaged frictional drag, the monomeric friction coefficient ξ. Therefore, the central assumption of this model is that the dynamics of a chain is governed by localized interactions along the chain. That assumption causes the Rouse model to fail at describing the translational dynamics in solutions, mainly because it neglects the effects of intramolecular hydrodynamics and excluded-volume interactions. However, it is well suited for understanding the dynamics of unentangled chains in the melt where long-range interactions are assumed to be screened.

According to the Rouse assumption, the motion of each bead can be described by a Langevin equation [see Sec. 1.1.3, Eq. (24)] with the frictional drag equal to the effective spring force $(3k_BT/b^2)(2R_n - R_{n+1} - R_{n-1})$. Consequently, the motion of the beads is similar to the Brownian motion of coupled oscillators, and the whole system can be described in terms of normal-mode coordinates where each mode behaves independently of the other. Solving the Langevin equation yields a spectrum of N relaxation times where each relaxation time τ_i corresponds to one normal mode. The major consequence of this approach is that the diffusion coefficient D_S is inversely proportional to the number of monomers, N:

$$D_S = k_BT/\xi N, \tag{59}$$

if the diffusion time t is long compared to the relaxation time of the longest relaxation mode,

$$\tau_1 = \frac{b^2}{3\pi^2 k_B T}\frac{1}{\xi N^2}. \qquad (60)$$

Entangled polymer melts show a totally different dynamic behavior than this and have challenged polymer science for some time. The breakthrough for understanding the dynamics of entangled polymer melts was made by de Gennes about 25 years ago when he introduced his reptation model (de Gennes, 1971). In this model, a polymer chain is imagined to undergo one-dimensional translational motion in the presence of a fixed network of obstacles. The motion is performed by a flow of a series of kinks along the contour of the chains, which can be visualized by the motion of a snake. After this qualitative understanding, Doi and Edwards (1978) theoretically described the snakelike motion of an entangled chain within a fixed tube to account for the effects of entanglements. This tube model allowed the qualitative prediction of most of the behavior of entangled melts. However, it should be mentioned that some of the experimental findings are not in agreement with the predictions of the Doi–Edwards theory but support more recent models and refinements of the Doi–Edwards theory. We briefly discuss those deviations at the end of this section.

The theoretical description of the reptation movement of an entangled chain by Doi and Edwards assumes that the chain performs a Rouse diffusion within a temporally fixed tube. The motion of the chain occurs by the curvilinear propagation along an average trajectory that Edwards called the primitive path. Edwards defined the primitive path as the shortest distance connecting the ends of the chains that has the same topology as the chain itself (Doi and Edwards, 1986); i.e., each primitive path can be imagined as a short cut along the random walk of the chain coil. The tube is created by the topological constraints set up by neighboring chains. According to Straube, the length of the primitive path, a, can be interpreted as a measure of the tube diameter d (Straube and Heinrich, 1984):

$$a = \sqrt{C_\infty N_E}\,b \approx 1.7d, \qquad (61)$$

where C_∞ is the characteristic ratio describing the stiffness of the polymer chain and N_E, the entanglement chain length, is the number of monomers between two entanglements.

The major result of the Doi–Edwards theory for describing the movement of an entangled chain is that the diffusivity of the center of mass of the polymer coil depends more strongly on the molecular weight than for unentangled chains:

$$D_S = k_B T/3\xi\, N_E/N^2. \qquad (62)$$

Comparing the equations for the diffusivity of unentangled and entangled chains [Eqs. (59) and (62), respectively] proves that the diffusivity of the center of mass of a reptating chain is equal to the diffusivity of an unentangled chain reduced by a factor of 3 (accounting for the crossover from three-dimensional Rouse diffusion to one-dimensional diffusion along the tube) and reduced by the ratio of N/N_E accounting for the influence of the entanglement density. Equation (62) is valid for diffusion times t that are longer than the so-called reptation time, t_{Rep}, i.e., longer than the time a reptating chain needs to propagate over a length equal to the contour length of the tube:

$$t_{\mathrm{Rep}} = \frac{a^2\xi}{2k_B T}\frac{N^3}{N_E^2}. \qquad (63)$$

The Doi–Edwards model is capable of describing most of the observed behavior of entangled polymers, especially the rubbery mechanical response. However, a variety of experimental observations are not qualitatively consistent with the simple reptation/tube picture. These include, e.g., the nonexponential decay of the stress relaxation (Ngai *et al.*, 1986), the 3.4 ± 0.2 exponent of Eq. (58) (3.0 is predicted by the Doi–Edwards theory), and the time dependence of the segmental diffusion of the chains within the tube that is stronger than the -0.5 prediction of the Doi–Edwards theory (Appel *et al.*, 1994). These experimental results support more recent theories assuming that the entangled chains have a considerably larger freedom for lateral motion than the strict reptation picture allows (Ngai *et al.*, 1986; Schweizer, 1989; Herman, 1992). The use of molecular dynamics and Monte Carlo computer simulations to address such questions is restricted because of their limitations to relatively small densities (Kremer and Grest, 1990).

If the lengths of the polymer chains, N, are comparable with the entanglement chain length N_E, the model of a temporally stable tube is not valid any more. Because of the diffusion of the surrounding chains, fluctuations of the tube occur that result in an increase of the effective tube diameter. Graessley described this process as lateral jumps of a primitive path step that occurs if an entanglement is released because of the diffusion of the neighboring chains and called this mechanism "constraint release" (Graessley, 1982). The effective diffusivity in this region of the chain length is found to be sum of the diffusivities according to the reptation model, $D_{S,\mathrm{Rep}}$, and the "constraint release" mechanism, $D_{S,\mathrm{c.r.}}$:

$$D_S = D_{S,\mathrm{Rep}} + D_{S,\mathrm{s.r.}} = \frac{k_B T}{\xi}\left(\frac{N_E}{3N^2} + \frac{\alpha N_E^3}{N^4}\right). \tag{64}$$

The factor α in Eq. (64) is an empirical value that represents the number of neighboring chains forming a constraint; its value is usually found between 3 and 5.

Figure 8 illustrates the theoretical dependence of the self-diffusivity of polymer melts as a function of their molecular weight. For molecular weights below the entanglement molecular weight M_e, the self-diffusion coefficient scales with M^{-1}. At very high molecular weight, the topological constraints described by the reptation model and the Doi–Edwards theory result in a scaling of the self-diffusivity with M^{-2}. Near the critical molecular weight, M_c of Eq. (58), additional fluctuations of the tube as explained by Graessley's constraint-release model result in an even stronger dependence of the self-diffusivity on the molecular weight. If the propagating chains are forced to remain within a tube, two degrees of freedom are lost for the process of migration. According to the Doi–Edwards theory, this loss results in a sudden reduction of the self-diffusion coefficient of the Rouse model at the entanglement molecular weight to $\frac{1}{3}$ if the dependence according to the reptation model is extrapolated to the entanglement molecular weight.

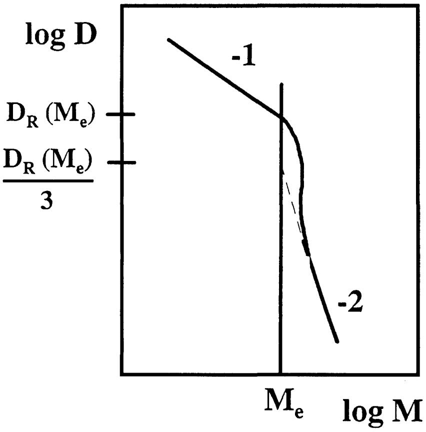

FIG. 8. Theoretical dependence of the self-diffusivity of polymer melts as a function of their molecular weight. The entanglement molecular weight M_e is indicated. Note that the crossover from three-dimensional Rouse diffusion below M_e to one-dimensional diffusion within the tubes (constraint release and reptation) above M_e is connected with a reduction of the molecular mobility to $\frac{1}{3}$ as a result of the reduced degree of freedom of the confined chains.

The dependence of the self-diffusivity on the molecular weight has been extensively studied. However, because of the broad range of molecular mobility to be covered and the drastic reduction of the diffusivity if the molecular weight exceeds its critical value M_e, only a few techniques are suited to perform such experiments. Figure 9 shows the result of pulsed field-gradient NMR measurements on different molecular weight fractions of poly(dimethyl)silioxane at a temperature of 60 °C (Appel and Fleischer, 1993). Note that the range of diffusivity covers about five orders of magnitude. The crossover from Rouse diffusion below M_e to constraint release and reptation above M_e is clearly visible. An interesting finding of those experiments is that reptation diffusion within stable tubes is only performed if the molecular weight exceeds the entanglement molecular weight, M_e, by about a factor of 8 to 10; i.e., tube fluctuations are found over a rather broad range of molecular weight.

GLOSSARY

Absolute Viscosity: Equivalent to **Shear Viscosity.** Compare with **Kinematic Viscosity.**

Anomalous Diffusion: Molecular migration that does not follow the direct propor-

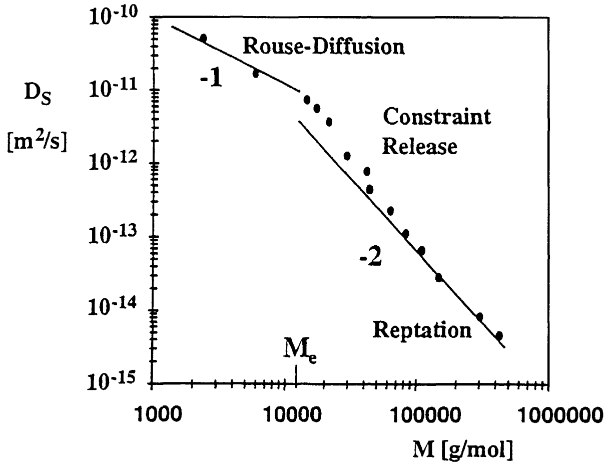

FIG. 9. Self-diffusion coefficients in the melt for different molecular weight fractions of poly(dimethyl)siloxane at $T = 60$ °C as measured by pulsed field-gradient NMR. The three different diffusion regimes (Rouse diffusion, constraint release, and reptation) can be clearly distinguished. Note that the crossover into the M^{-2} regime covers a large range of molecular weight; i.e., temporarily fixed tubes are only established if the molecular weight exceeds the entanglement molecular weight M_e by a factor of 8 to 10. Data from Appel *et al.* (1993).

tionality between mean square displacement and diffusion time because of correlations between the directions of successive elementary jumps.

α-Relaxation: Long, slow relaxation time observed in dense liquids. Its value is related to viscosity. Identified with diffusional motion of a particle out of the surrounding cage of near neighbors.

Boltzmann Theory: Relates the viscosity and diffusion for a dilute gas to the molecular mass and radius. A square-root temperature dependence for both viscosity and diffusion is predicted for a hard-sphere fluid. Extension to a Lennard-Jones fluid requires integration of the interparticle forces and leads to more realistic temperature dependence.

Bulk Viscosity: Coefficient describing energy dissipation due to expansion and contraction of a fluid. Except for specific conditions (see text), its contribution is negligible compared to shear viscosity.

Constraint Release: Theory for describing the diffusional behavior of entangled polymers near the entanglement molecular weight.

Critical Molecular Weight: Threshold molecular weight of polymers above which the viscosity strongly increases because of entanglements of the polymer chains.

Doi–Edwards Theory: Theory describing dynamic behavior of entangled polymers by assuming that a polymer chain is confined within a temporally fixed tube that is set up by neighboring chains.

Einstein Equation: Equation describing the viscosity increase of a solid/liquid mixture as a function of the volume fraction of solid.

Enskog Theory: Extension of the Boltzmann theory to higher density liquids but retaining assumption of uncorrelated binary collisions thus limiting its applicable density range.

Entanglement Length: Length of the fraction of a polymer chain between two entanglements.

Fick's Laws: Laws relating the particle flux to concentration gradient (first law) and describing the time derivative of the concentration for systems that are apart from their equilibrium state (second law).

Free-Volume Theory: Theory relating the diffusion and viscosity to the free volume available for molecules to move. Finds application to variable pressure data over wide ranges of both viscosity and density.

Hard-Sphere Model: A model for gases and liquid systems that assumes the molecules are identical hard spheres.

Intrinsic Viscosity: Limiting viscosity increment due to addition of polymer to a dilute solution.

Kinematic Viscosity: Ratio of absolute viscosity to density.

Markovian Process: A statistical process where the instantaneous movements are independent, for both length and direction, of those having occurred at earlier times. Describes particle motions, such as a random walk or Brownian diffusion.

Mode-Coupling Theory: Recently developed theory to describe the viscosity and diffusion in liquid and glassy systems at densities beyond those accessible to the Boltzmann and Enskog treatments.

Mutual Diffusion: Diffusion process caused by the gradient of the concentration of a certain species. Same as transport diffusion.

Navier–Stokes Equation: Fundamental hydrodynamic equation relating the bulk and shear viscosity to the pressure and velocity gradients in the fluid. It leads to several important relations: Stokes–Einstein equation, Einstein equation, Stokes equation, etc.

Reptation Model: Theory describing the migration of entangled polymer chains. Assumes that the lateral freedom of chain movement is restricted within a tube. Since longitudinal freedom of movement is unrestricted, polymer chain propagates in a snakelike movement along its own backbone.

Reynolds Number: Dimensionless ratio that describes the relative importance of the nonlinear inertial term to the shear, viscous-damping term in the Navier–Stokes equation. $Re \ll 1$ for laminar, or creeping, flow situations, $Re \gg 1$ for turbulent motions.

Rotational Diffusion: Description of the random motions of the orientation of molecules in solution.

Rough Hard-Sphere Model: Simple extension of the (spherical) hard-sphere model to account for the coupling of rotational and translational diffusion in asymmetric molecular systems.

Rouse Model: Theory describing diffusional behavior of unentangled polymer chains. Approximates polymer chain to a bead–spring model and reduces dynamic behavior of the bead–spring system to a superposition of relaxation modes having certain relaxation times.

Self-Diffusion: The random motion of individual species—atoms, molecules, colloids, polymers—caused by their thermal energy.

Shear Viscosity: Coefficient relating the shear stress to shear rate of a fluid. Contributions due to bulk viscosity are typically negligible; hence shear viscosity is usually equated with viscosity itself.

Specific Viscosity: Normalized solution viscosity utilized in polymer science. Defined as the ratio of the solution viscosity to the solvent viscosity minus unity.

Stokes Equation: Description of the drag on a sphere as it moves through a fluid. Assumes low-velocity flow, i.e., small Reynolds number.

Stokes–Einstein Equation: Relation between self-diffusion of a sphere in a fluid and the viscosity.

Structural Relaxation: Relaxation of the correlated structure between neighboring particles; found in both molecular and colloidal liquids. Strong influence on viscosity of systems.

Transport Diffusion: See **Mutual Diffusion.**

Viscoelasticity: Term describing the shear-rate–dependent viscous and elastic response of a material. Typical feature of entangled polymers and colloidal systems.

VTF Equation (Vogel–Tamman–Fulcher): Empirical equation relating the temperature-induced viscosity change to three material-dependent coefficients. Two of these coefficients find wide application in interpreting glassy state behavior.

WLF Equation (Williams–Landel–Ferry): Empirical equation relating the temperature-induced viscosity change to two material-dependent coefficients. This equation finds wide application in polymer science, where it plays an important role in describing viscoelastic behavior.

10.1
Introduction

The visible part of the electromagnetic spectrum extends from about 400 to 750 nm. At longer wavelengths, the retina loses sensitivity, whereas at shorter wavelengths, the lens of the eye absorbs most of the incident radiation. The ultraviolet spectrum extends from 400 to 180 nm. At wavelengths shorter than 180 nm atmospheric oxygen strongly absorbs light. Wavelengths between 180 and about 1 nm are classified as vacuum ultraviolet; wavelengths shorter than this are classified as X-rays.

A spectrometer is an instrument for discriminating among different wavelengths of light, producing a record of intensity as a function of wavelength or frequency from a particular source. Spectrometers are commonly used as tools in chemical analysis, atomic and molecular physics, astronomical measurements, and shaping and filtering optical radiation in both the time and the frequency domains.

Dispersion of light by a prism was reported by Johannes Marcus Marci in 1647. In 1666, Isaac Newton used a prism to disperse a beam of sunlight onto the wall of a darkened room; by using a lens to focus the light from the prism, he was able to disperse the visible spectrum over a length of about 25 cm. The first observations of spectral lines occurred 140 years later, when W. H. Wollaston and, independently, Joseph Fraunhofer restricted the entrance aperture of Newton's basic device with an entrance slit, allowing images of that slit to be formed as single separate colors. This innovation allowed the first observation of the ''Fraunhofer lines'' of the solar spectrum. Fraunhofer cataloged several hundred of these lines for use as in defining colors of the visible spectrum so that the refractive index of glasses at those colors could be more carefully defined. Fraunhofer also ruled the first diffraction grating and using it, he measured for the first time the wavelength of the yellow light from the sodium D lines. In addition, he was the first to observe stellar and planetary spectra using a prism placed in front of an astronomical telescope.

Forty years later, in 1859, Gustav Kirchhoff and Robert Bunsen developed the first practical spectroscope and showed that it could be used for chemical analysis. They demonstrated that atoms have characteristic absorption and emission spectra and recognized that the absorption and emission lines were identical in

ISBN: 978-3-527-40773-6

wavelength for a given atom; the appearance of a spectral line in absorption or emission depended only on the temperature of the sample. These developments mark the origin of optical spectroscopy as a branch of both analytical chemistry and chemical physics.

In 1862, G. G. Stokes used a quartz prism as a dispersing element and a fluorescent screen as a detector to make the first observations of ultraviolet atomic emission spectra. Although Stokes was unable to make wavelength measurements, he was able to observe spectra out to 186 nm. Extension of spectroscopic measurements into the vacuum ultraviolet was made by Victor Schumann in 1893. Using a fluorite prism and an evacuated spectrograph, Schumann was able to extend ultraviolet measurements to 120 nm, where absorption by the fluorite prism limited its useful range.

The production of diffraction gratings was greatly advanced in the late nineteenth century by the work of Henry Rowland on the development of an accurate ruling engine. Rowland also invented the concave grating – a grating ruled on a spherical mirror blank, which greatly simplified the construction of spectrographs. Using these gratings, Rowland was able to make accurate measurements of wavelengths of the ultraviolet spectrum down to 210 nm. In 1906, Theodore Lyman used such a concave grating to extend measurements in the vacuum ultraviolet down to 50 nm.

Theoretical understanding of atomic and molecular spectra had to await the rise of quantum mechanics in the early twentieth century. Beginning with the work of Niels Bohr, it became clear that spectra in the visible and ultraviolet regions depended on the internal electronic structure of atoms and molecules, and that the absorption and emission of radiation in this region corresponded to transitions of electrons between allowed energy levels.

10.2
Design Considerations

There are two figures of merit for any spectrometer, and generally they are mutually exclusive. They are *resolution*, the ability to distinguish between wavelengths of light that are nearly the same, and *luminosity*, the ability to accept light from a source and transmit all of it to the detector. Because improvement of one of these properties is generally at the expense of the other, a real spectrometer is always a compromise between the two.

10.2.1
Luminosity or Étendue

The light gathering power of a spectrometer is a function of both the area of the entrance aperture and the solid angle with which the instrument can accept incident light. The product of these two quantities is referred to as the *étendue of the instrument*. Terms that are often used synonymously are "throughput" and "luminosity." The étendue is defined as $L = a\Omega$, here a is the area of the entrance aperture and Ω is the solid angle subtended by the aperture stop of the instrument at the entrance aperture. For an optical system without losses (e.g., from scattering or absorption), L remains a constant through the system.

10.2.2
Resolution

The resolution of an instrument is the ability to discriminate between two adjacent wavelengths (or frequencies) of light. Resolution is most easily understood in the case of a monochromator, which transmits a certain range of wavelengths and rejects all others. The minimum attainable bandwidth of the instrument is its resolution, $\Delta\lambda$. A closely related quantity is the resolving power, R, defined as

$$R = \frac{\lambda}{\Delta\lambda} \qquad (10.1)$$

In a dispersive instrument, the maximum possible resolution is most conveniently calculated as the product of the reciprocal angular dispersion $d\lambda/d\theta$ and the diffraction-limited angular resolution $\Delta\theta$ from the aperture stop imposed by the dispersing element; the angle θ is the deviation of the dispersed light. For a nondispersing spectrometer, the resolution in wavenumber units is the reciprocal of the difference in optical retardation of rays.

The resolution desired depends on the experiment to be performed. Ideally, the resolution of the spectrometer will be matched to the line width of the sample to be examined. For solids or liquids at moderate temperatures, absorption lines have a width of several nanometers or more, and the resolution requirements on the spectrometer are modest. For gases, the width of an absorption or emission line is usually limited by the Doppler width, which is typically 2×10^{-6} times the wavelength. A high-resolution spectrometer is therefore defined as one whose resolving power is Doppler limited, that is, $R \geq 5 \cdot 10^5$.

10.2.3
Dispersion

The angular dispersion of a grating or prism is the change of the displacement angle with wavelength, $d\theta/d\lambda$. The linear dispersion of a spectrometer is the change of the distance along the focal plane with wavelength $dl/d\lambda$; this will determine the physical separation of two spectral lines at the slit or detector. A more frequently used quantity is the reciprocal linear dispersion, $d\lambda/dl$, also called the "plate factor."

10.2.4
Efficiency

The product of the resolving power and the étendue (the "resolution-luminosity product") is sometimes referred to as the *efficiency of the spectrometer*. It is a property of the instrument in question and, sometimes, the wavelength of operation. For a grating spectrometer operating at a given wavelength, for example, the efficiency is fixed, but it is possible within limits to trade resolution for throughput by opening the entrance and exit slits.

10.3
Elements of a Generic Spectrometer

There are several elements which are common to most spectrometers, and these are illustrated in Figure 10.1.

10.3.1
Entrance Aperture

The *entrance aperture* is used to define the source of light to be analyzed. In a prism or grating spectrometer, it is ordinarily a

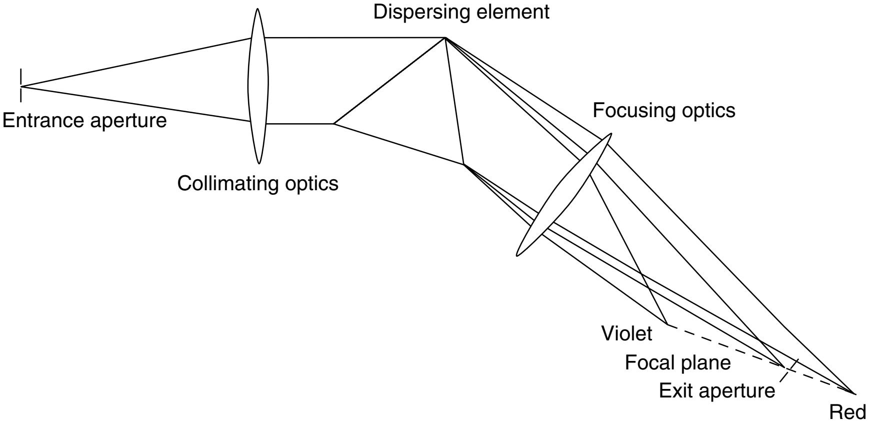

Fig. 10.1 A minimum deviation prism spectrometer, illustrating the elements common to most spectrometers.

slit, although a more complicated shape is sometimes used to enhance throughput. In an interferometric spectrometer, the entrance aperture is usually circular.

10.3.2
Collimating Optics

Collimating optics take the rays of light from the entrance aperture, which are typically diverging, and make the rays collinear. This is generally desirable so that all of the rays strike the dispersing element at the same angle; if they do not, often either the resolution is degraded, or the focus of the instrument changes with wavelength, or both. The collimating optics may be either refractive or reflective (i.e., either lenses or concave mirrors), although mirrors are generally used in modern instruments because of their lack of chromatic aberration.

10.3.3
Wavelength Selecting Element

The kind of wavelength selector in a spectrometer is usually classified as dispersive or nondispersive. Dispersive elements separate the wavelengths along some spatial dimension, while nondispersive elements pass some wavelengths and reject others without altering the optical path of the transmitted light. The most commonly used dispersing elements are the prism and the diffraction grating, although some interferometers, such as the Fabry–Perot, are also used in a dispersing mode. The most versatile nondispersing spectrometer is the Michelson interferometer, which is the basis of the modern Fourier transform spectrometer. Other examples of nondispersive elements are filters, which are used in simple colorimeters or in imaging spectrometers.

10.3.4
Focusing Optics

The focusing or condensing optics (in spectrographs often called the *camera* optics) take the collimated light passed by the wavelength selecting element and focus it onto an exit aperture (or several apertures) or a detector.

Together with the collimating optics, the focusing optics form an image of the entrance aperture at the exit aperture. The usual goal of spectrometer design is to make the collimating and focusing optics sufficiently aberration-free that the performance of the spectrometer will be limited only by the wavelength selecting element. As with the collimating optics, either lenses or mirrors may be used, with the preference being given to mirrors for most instruments.

10.3.5
Exit Aperture

The exit aperture must be matched to the image of the entrance aperture in such a way that it provides maximum discrimination of the wavelengths of interest while providing maximum allowable throughput of light. In a conventional grating or prism monochromator, for example, the exit aperture is a single exit slit in the shape of the image of the entrance slit.

10.3.6
Detector

The detector transforms the light into either a permanent image or an electronic signal. In addition to the requirement that it must be sensitive in the wavelength region of interest, the detector is chosen so as to minimize unwanted noise and provide a reproducible (ideally linear) response. Spectrometers are often distinguished from one another on the basis of the method of detection: an instrument which allows a spectrum to be observed visually is a *spectroscope*, one which makes a photographic record is called a *spectrograph*, and the term *spectrometer* refers to an instrument which records the spectrum photoelectrically. If photometric accuracy is of paramount importance, the device is called a *spectrophotometer*. In this chapter, the term *spectrometer* is used as an inclusive term covering all these types of instrument.

10.4
Prism Spectrometers

The earliest spectrometers were prism spectrometers, and the most commonly used grating spectrometer designs have their origins in prism spectrometers. Prism spectrometers, although they have generally poor optical performance in comparison with most modern designs, have the advantages of being inexpensive, rugged, easy to align, and technically undemanding.

10.4.1
Dispersion

Light incident on a prism with an angle α (measured normal to the face of the prism, as shown in Figure 10.2) will be refracted according to Snell's law, $\sin\alpha/\sin\alpha' = n_{\text{prism}}/n_{\text{air}}$, where n_{prism} and n_{air} are the refractive indices of air and the prism material at the wavelength of the incident light. On exiting the prism, the light will be refracted again by an angle β, for a total deviation θ of the beam of light. The deviation θ of the beam depends on the refractive index n of the prism, while the dispersion of the beam, $d\theta/d\lambda$, depends on the *change* of refractive index of the prism material with wavelength, $dn/d\lambda$. The angular dispersion of a prism is defined as the change of the angle of deviation θ with

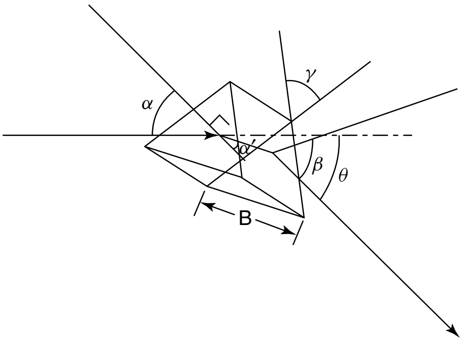

Fig. 10.2 Coordinates used in describing the dispersion of a prism.

wavelength and is given by the formula

$$\frac{d\theta}{d\lambda} = \frac{d\theta}{dn}\frac{dn}{d\lambda} \tag{10.2}$$

The first factor may be evaluated by differentiating Snell's law, while the second factor is a property of the material of the prism. If the angle of incidence α is nearly equal to the angle of departure and the refractive index of air is taken as 1, $d\theta/dn$ is given in terms of the apex angle γ of the prism as

$$\frac{d\theta}{dn} = \frac{2\sin(\gamma/2)}{\sqrt{1 - n^2\sin^2(\gamma/2)}} \tag{10.3}$$

The linear dispersion of the spectrometer $dl/d\lambda = fd\theta/d\lambda$ is the angular dispersion times the focal length of the condensing optics. Note, however, that the focal length of the condensing optics can often change considerably over the spectrum as a result of the chromatic aberration of the condensing lens.

10.4.2
Resolution

The angular resolution of a prism spectrometer, in the absence of optical aberrations of the lenses, will be determined only by the prism itself. It may be written in terms of the reciprocal angular dispersion as

$$\Delta\lambda = \frac{d\lambda}{d\theta}\Delta\theta \tag{10.4}$$

where $\Delta\theta$ is the diffraction limit imposed by the wavelength of light and the aperture of the prism itself. The resolving power for a prism at minimum deviation (Figure 10.2) is given in terms of the base B as (Sawyer, 1963)

$$R = B\left|\frac{dn}{d\lambda}\right| \tag{10.5}$$

10.4.3
Luminosity

The effective area of the aperture stop of a prism instrument is the product of the area of the prism face and the cosine of the angle of incidence. The solid angle of acceptance of the instrument will be this area divided by the square of the focal length of the collimating lens. The product of this acceptance angle and the area of the entrance slit will constitute the luminosity.

10.4.4
Specialized Designs

The design of a prism spectrometer depends on whether a large flat focal

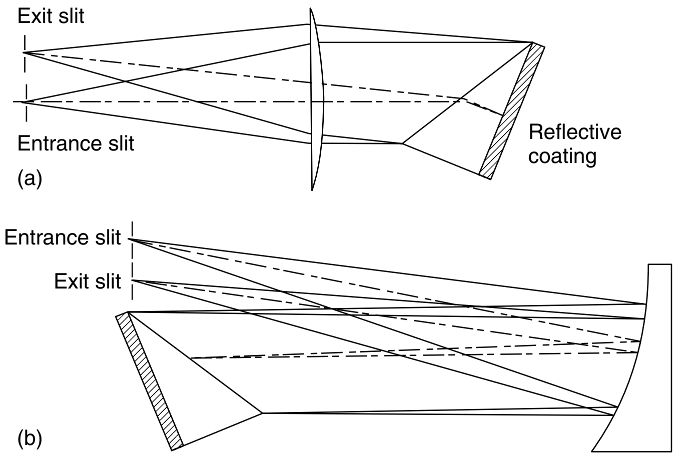

Fig. 10.3 Littrow mount prism spectrometers, (a) using lenses for imaging and (b) using an off-axis parabolic mirror for imaging. The entrance and exit slits would ordinarily be placed as close together as possible.

plane is most desirable (in the case of a spectrograph) or whether it is deemed necessary to scan the wavelength easily by rotating the prism (as in the case of a spectroscope or a spectrometer).

To minimize reflection losses, the total deviation of the light as it passes through the prism is kept to a minimum. This consideration is in conflict with the requirement that the base of the prism must be large to maximize both dispersion and resolution, and usually a 60° angle for the apex of the prism is chosen as a compromise between these two requirements. A typical minimum deviation spectrograph is illustrated in Figure 10.1. Light is collimated and focused by lenses in this design. If the lenses are of the same refractive index as the prism, then the focal surface is, to a first approximation, a plane that passes through the entrance slit (James and Sternberg, 1969).

A more compact design is the Littrow configuration, as shown in Figure 10.3(a). Here the prism is replaced by a prism having half the original apex angle whose rear surface is coated with a reflective coating. Light passes forward and then backward through the prism, and a single lens serves as both the collimating and focusing optic. The entrance and exit slits may be offset horizontally or, more frequently, vertically. This arrangement lends itself to scanning by simply rotating the prism, or an image of a spectrum may be formed as in the minimum deviation instrument. A variation which employs reflective optics is also used (Figure 10.3b). The mirror used to image the slit is chosen to be an off-axis paraboloid to minimize the astigmatism and spherical aberrations associated with a spherical mirror used off-axis. There are so many variations on the Littrow design that any spectrometer which disperses light back along the original path is often referred to as a *Littrow mount*.

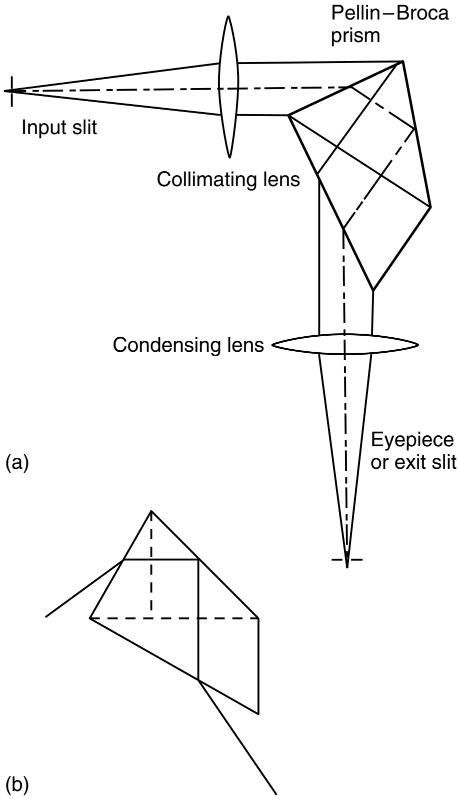

Fig. 10.4 (a) A Pellin–Broca spectrometer. Light is refracted at a constant 90° angle as the prism is rotated. (b) A Pellin–Broca prism, illustrating its conception as a composite of three separate prisms.

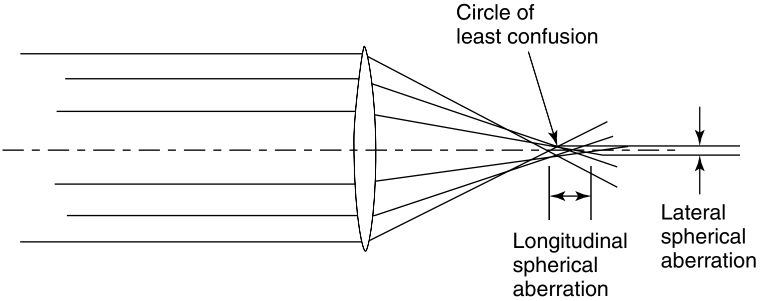
One of many *constant deviation* mounts of a prism is the Pellin–Broca spectrometer, illustrated in Figure 10.4(a). This design has the advantage that the prism may be rotated in such a way that the minimum deviation beam is always refracted at right angles to the incident beam. As indicated in Figure 10.4(b), the Pellin–Broca prism may be viewed as a pair of 30–60–90° prisms joined by a 45° total internal reflection prism.

10.4.5
Aberrations

The aberrations of the imaging optics that limit the resolution of a prism spectrometer include spherical aberration, coma, astigmatism, curvature of field, and, in some designs, chromatic aberration.

10.4.5.1 Spherical Aberration

In a spherical lens, the rays passing through the center of the lens do not focus in exactly the same point as the rays, which pass through the outer portion of the lens, as illustrated in Figure 10.5. The rays from the various parts of the lens converge to a minimum spot size, the *circle of least confusion*, which determines the resolution limit of a spherically figured lens. To a good approximation, a pair of plano-convex lenses used as collimating and condensing optics will



Circle of least confusion
Longitudinal spherical aberration
Lateral spherical aberration

Fig. 10.5 Spherical aberration in a lens.

provide the best form for reducing spherical aberration, with the plane side of the lens facing the image in each case.

10.4.5.2 **Coma**

Coma is an aberration, which affects only off-axis rays. As illustrated by Figure 10.6, coma is a result of rays passing through different annular rings of the lens being imaged, not into points, but into small circles of different size and located at different centers. The change in size with the changing focal point results in a *comatic flare* of the image resembling the shape of a comet tail, which is the origin of the term. Coma increases rapidly with the off-axis angle, severely restricting the size of the focal plane for wide-aperture spectrographs.

10.4.5.3 **Astigmatism**

Similar to coma, astigmatism is an off-axis aberration. If the rays striking the lens are off-axis in the vertical direction, the rays in the vertical plane will form a focus at a different point than those in the horizontal plane. The former will be focused into a line tangent to a circle about the principal optic axis (the tangential focus) and the latter into a line pointed toward the optic axis (the saggital focus). Astigmatism, which spreads a point source into a line parallel to the slit, will not necessarily

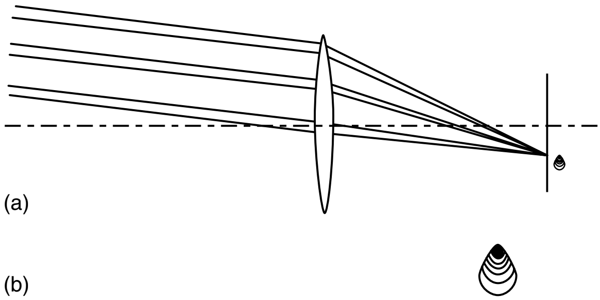


Fig. 10.6 Coma produced by a simple lens. (a) Off-axis marginal rays are imaged into different positions than the central ray. (b) Annular sections of the lens are imaged into circles whose size and position depend on the distance of the annuli from the center of the lens.

degrade the resolution, although it will reduce the brightness of the image; astigmatism, which spreads a point source perpendicular to the direction of the slit, will degrade both the throughput and the resolution.

10.4.5.4 **Curvature of Field**

The focal surface of an optical system is not usually planar, but instead is a curved surface. Whether this curvature is a problem depends in part on whether the curvature is fixed or changes according to the setting of the prism, and in part on whether the instrument is intended for use with an exit slit, an array detector, or a photographic plate. If the curvature changes with the prism angle, as it may with a minimum deviation mount, the prism cannot be rotated without defocusing the instrument, and the instrument is suitable only as a fixed prism spectrograph. If, on the other hand, the curvature and focus remain constant with the prism angle, the prism can be rotated to scan the spectrometer.

10.4.5.5 **Chromatic Aberration**

The high dispersion of a glass which makes it suitable for use as a prism means that lenses made from the same material will have different focal lengths at different wavelengths. If the spectrometer is to be used with photographic detection, as in the minimum deviation spectrograph of Figure 10.1, this is not a problem, because the plateholder can be adjusted once for optimum focus and fixed in that position. For a constant deviation mount such as the Pellin–Broca mount of Figure 10.4, both the collimating and the focusing lenses must be corrected for chromatic aberration if the spectrometer is to remain in focus as the prism is rotated.

10.5
Grating Spectrometers

Most modern ultraviolet and visible spectrometers are based on the diffraction grating, which offers improved resolution, luminosity, and dispersion compared with prism instruments of comparable size and expense. These may be classified as plane grating spectrometers, of which the Czerny–Turner spectrometer is an example, and concave grating spectrometers, which include the Eagle and Seya–Namioka mounts. The concave grating design is usually preferred whenever the number of optical surfaces must be minimized, as in the vacuum ultraviolet region, because the concave grating serves as both the dispersing element and the imaging optics. Plane grating instruments must rely on concave mirrors to image the spectrum; these mirrors lead to absorption losses at each optical surface, but the additional design freedom afforded by the imaging optics allow far greater control over aberration corrections than is possible for concave gratings. Accordingly, plane grating instruments are used whenever absorption losses at the mirrors are negligible and a high quality stigmatic image is desirable, as in the visible and near infrared.

10.5.1
Dispersion

Diffraction of light by a grating is determined by the grating equation:

$$m\lambda = a(\sin\alpha + \sin\beta) \tag{10.6}$$

where m, the order of diffraction, must be an integer; λ is the diffracted wavelength; α is the angle of incidence of the light with respect to the normal; and β is the angle of diffraction with respect to the normal. The reciprocal angular dispersion, $d\lambda/d\beta$, is given as $a \cos \beta/m$; the tuning of wavelength as the grating is turned is twice this number. The linear dispersion at the focus of the spectrometer is the angular dispersion times the focal length of the condensing optics.

10.5.2
Resolution

As with a prism, the resolution of a diffraction grating is the product of the dispersion and the diffraction-limited angular resolution imposed by the aperture of the grating. Unlike prism instruments, however, the dispersion is independent of the material of the grating, and so the resolution of a grating may be stated in several rather simple ways. Taking the ruled width of the grating as W and the angular resolution of light leaving the grating as $\Delta\beta = \lambda/(W \cos \beta)$, the resolution of the grating is found to be

$$\begin{aligned} \Delta\lambda &= \frac{d\lambda}{d\beta}\Delta\beta \\ &= \frac{a}{m}\cos\beta \cdot \frac{\lambda}{W\cos\beta} \qquad (10.7) \\ &= \frac{a}{m} \cdot \frac{\lambda}{W} \end{aligned}$$

The resolving power, in turn, is given by

$$\begin{aligned} R &= \frac{\lambda}{\Delta\lambda} \qquad (10.8) \\ &= m\frac{W}{a} \end{aligned}$$

which is just the order of diffraction times the number of grooves in the grating. Clearly, for a grating spectrometer to achieve its maximum resolving power, the entire width of the grating must be illuminated.

If $\alpha \approx \beta$, the resolution can be rewritten in terms of the wave number $\tilde{\nu}$ as

$$\begin{aligned} \Delta\tilde{\nu} &= \frac{\partial\tilde{\nu}}{\partial\lambda}\Delta\lambda \qquad (10.9) \\ &= \frac{1}{W \cdot 2(\sin\alpha)} \end{aligned}$$

which is just the reciprocal of the optical path difference of rays on opposite sides of the grating.

10.5.3
Luminosity

The solid angle of acceptance of the grating, Ω, is given to a good approximation by the equation

$$\Omega = \frac{A\cos(\alpha)}{f^2} \qquad (10.10)$$

where A is the area of the grating, α is the angle of incidence, and f is the focal length of the collimating optics. The luminosity of a grating spectrometer is thus equal to the product of Ω and the area a of the entrance slit, or

$$L = \frac{Aa\cos(\alpha)}{f^2} \qquad (10.11)$$

The "speed" of a spectrometer is often quoted in terms of its focal ratio, $F = f/d$, where d is the maximum diameter of the aperture stop dictated by the size of the grating. Thus, a spectrometer with a focal length of 1 m and a grating whose diagonal measures 12.5 cm will have a speed of $f/8$. This number obviously does not accurately measure the luminosity of the instrument as it is ordinarily used; it does, however, specify the minimum aperture of any external optics that are guaranteed to illuminate the entire surface of the grating. The luminosity of a spectrometer varies as the inverse square of the focal ratio.

10.5.4
Design and Manufacture of Gratings

Until recently, all gratings were ruled mechanically by inscribing parallel grooves on an optically polished master blank. The tolerances involved in the manufacture of such gratings generally require interferometric control of the ruling engine to compensate for mechanical errors in the lead screw; typically, modern ruling engines use a frequency stabilized laser for this purpose. Eliminating periodic errors in the rulings is extremely important, because periodic errors will result in diffraction at angles other than the design angle. The grating "ghosts" produced in this way can cause lines to appear at apparent wavelengths far removed from the true wavelength, creating problems ranging from nuisance to disaster depending on the experiment being performed.

More recently, gratings have been produced by holographically recording the groove pattern on a photosensitive surface. The main advantage of a holographic grating is the absence of the inevitable periodic errors that are found in mechanically ruled gratings. The principal advantage claimed for ruled gratings is a greater control over the shape of the groove and, consequently, a more sharply defined blaze angle and higher efficiency. These issues have been addressed in some detail theoretically (Loewen *et al.*, 1977). Gratings for use in the visible and ultraviolet are available with groove spacings from 300 grooves/mm to 4800 grooves/mm.

10.5.4.1 Transmission Grating

Conceptually, the simplest grating is the transmission grating. Transmission gratings may be fabricated either by imprinting a transparent substrate with closely spaced lines or by ruling a transparent substrate with shaped grooves. As schematically shown in Figure 10.7, the transmission grating is simply an extension of multiple slit interference to a very large number of slits. If two waves emerging from adjacent slits have a total path length which differs by an integral number of waves, constructive interference will occur and the intensity will be nonzero. For an angle of incidence α with respect to the grating normal and an angle of diffraction β, this condition requires $m\lambda = a(\sin\alpha + \sin\beta)$. This equation is always satisfied for $\alpha = -\beta$; therefore, transmission straight through the grating is allowed with $m = 0$ for all wavelengths. In addition, a wavelength may be diffracted at angles corresponding to nonzero integral values of m.

10.5.4.2 Reflection Grating

A more commonly used type of ruled grating is the *reflection grating*, which is typically ruled on a polished glass optical flat coated with a thin film of aluminum. Once again, the condition for constructive interference is that $m\lambda = a(\sin\alpha + \sin\beta)$. The reflection grating is preferred over the transmission grating for much the same reasons that mirrors

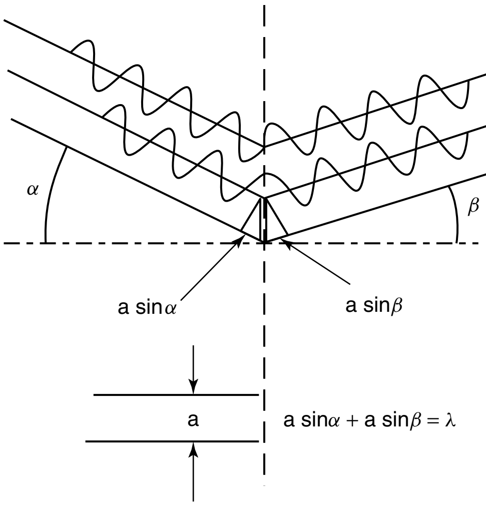

Fig. 10.7 Multiple-slit interference as observed in a segment of a transmission grating. If the waves are out of phase by an integral number of wavelengths, constructive interference will occur and intensity will be maximum.

are preferred over lenses as imaging optics: low absorption and scattering losses, high efficiency in the ultraviolet, and insensitivity to the homogeneity of the substrate.

By controlling the shape and angle of the diamond ruling tool, it is possible to control the shape of the grooves in such a way that light striking the grating normal to the face of the groves is diffracted with very high efficiency. When a grating is viewed at this angle, the grating appears to blaze with color, and this angle of highest efficiency is referred to as the *blaze angle* of the grating.

Ruled gratings are not ordinarily sold as originals, but are instead used as masters to produce replica gratings. This process allows a single ruling to be duplicated inexpensively, greatly reducing the cost of diffraction gratings in commercial spectrometers.

10.5.4.3 **Echelles**

If the grooves of a grating are ruled so that the sides are flat, the grating will have a sharply defined angle of maximum efficiency where the angle of diffraction coincides with the specular reflection from the groove facets. Such a grating is called an *echelle* or an *echelette*. It is ruled very coarsely so that the shape of the grooves can be controlled accurately, and therefore it is used in a high order of diffraction (typically $m = 100$). The free spectral range of such a grating is relatively small, so additional dispersing optics must be used to separate overlapping orders.

10.5.4.4 **Holographic Gratings**

Gratings may also be produced optically, without the use of a ruling engine. In this process, a pair of light beams is used to produce a pattern of interference fringes at a surface that has been coated with photoresist. Although the earliest such gratings predate the invention of the laser, the process did not become practical before the availability of high powered ion lasers (Hutley, 1982). Such gratings are generally referred to as *holographic gratings*.

Two intersecting coherent beams of light will produce interference fringes within their volume of intersection with a spacing D given by

$$D = \frac{\lambda}{2\sin(\theta/2)} \tag{10.12}$$

where θ is the angle of intersection. If a grating blank is placed at an angle ϕ to the bisector of θ, fringes will be produced with a spacing a of

$$a = \frac{\lambda}{2\sin\theta\sin\phi} \tag{10.13}$$

The blank, previously coated with a thin layer of photoresist, is subsequently developed to produce a corrugated surface with the spacing of the interference fringes. This surface is generally coated with a reflective metal layer and used as a reflection grating.

10.5.5
Plane Grating Spectrometers

10.5.5.1 Aberrations

Plane grating spectrometers almost invariably use spherical concave mirrors or, less frequently, paraboloids to image the entrance slit into a spectrum. Similar to lenses, the mirrors that form images in a typical grating spectrometer are subject to spherical aberration, coma, astigmatism, and curvature of plane; and, as is the case with prism instruments, the practical resolution of a grating spectrometer is frequently limited by optical aberrations. The only major aberration, which is completely removed using reflective optics, is chromatic aberration. As these aberrations usually define the limits of performance of an instrument, much of the design of grating spectrometers involves arranging the optics in such a way that aberrations induced by one optical element are corrected in part by others.

Spherical Aberration The rays reflecting from the center of a spherical mirror do not focus in exactly the same point as the rays, which are reflected from the outer portion of the mirror. As with a lens, the rays from the various parts of the lens converge to a minimum spot size, the *circle of least confusion*, which determines the resolution limit. For a spherical mirror, the diameter of this circle is $f/64F^3$, where F is the focal ratio and f is the focal length of the mirror. Thus, a 1-m focal length instrument with a 125 mm × 125 mm diffraction grating will have a spherical aberration amounting to 86 μm at the focal plane if uncorrected. If the same grating were placed in a 2-m focal length instrument, the uncorrected spherical aberration would be only 11 μm. For a parabolic reflector, the spherical aberration is zero: all rays parallel to the principal optical axis focus to a diffraction-limited point (about 4 μm for the above example of a 1-m focal length instrument with a 125 mm × 125 mm grating).

Coma Coma in a mirror, as in a lens, affects only off-axis rays. As with a lens, annular rings of a spherical mirror images off-axis rays into circles whose radius increases with the radius of the annular ring. The comatic flare is often more pronounced in reflective imaging systems than in systems which use lenses, because geometrical constraints require the entrance and exit slits to be placed off the principal optical axes of the imaging mirrors. For a spherical mirror, collimated light is imaged into a pattern whose height and width are given as (Harwit and Sloane, 1979)

$$H = \frac{3}{16}\frac{\theta f}{F^2}\left(1 - \frac{d}{2f}\right) \tag{10.14}$$
$$W = \frac{1}{8}\frac{\theta f}{F^2}\left(1 - \frac{d}{2f}\right)$$

where f is the focal length, F is the focal ratio, d is the distance from the mirror to the aperture stop (i.e., the grating), and θ is the angle the incident light makes with respect to the principal optical axis of the mirror. For the case of a 1-m focal length instrument with a 125-mm diffraction grating, the uncorrected coma at the ends of a 20-mm slit would increase the size of the image by about 10 μm. If the instrument is required to form an extended image of the spectrum, the coma would increase with the off-axis angle: at the edge of a 250-mm focal plane, the coma would increase to 100 μm.

The increase of comatic flare with the aperture of the imaging optics is the most serious practical problem preventing the design of a high resolution Ebert or Czerny–Turner grating spectrometer with a low focal ratio, because a wide collection aperture inevitably involves a large off-axis angle which limits the resolution due to unacceptably large coma.

Astigmatism Similar to a simple lens, a spherical mirror forms an astigmatic image if illuminated off-axis, as illustrated in Figure 10.8. The tangential and saggital foci, f_T and f_S, for a spherical mirror illuminated with collimated light at an

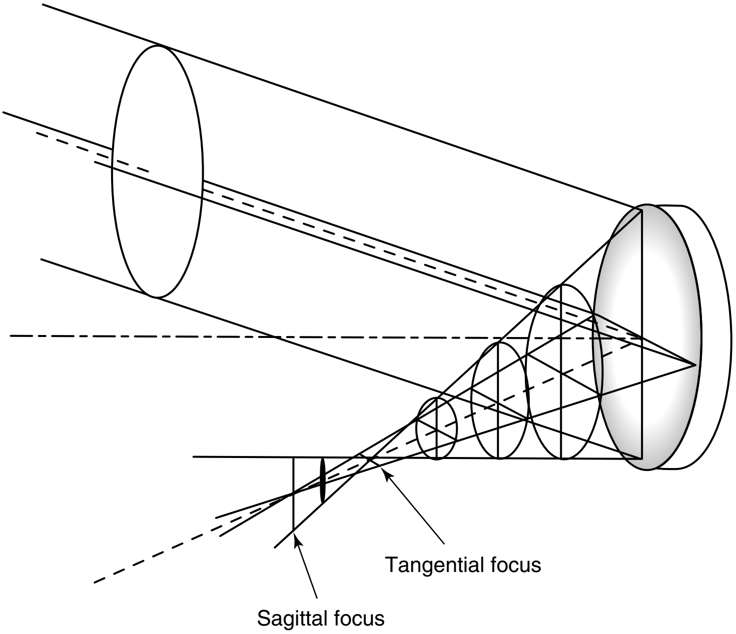

Fig. 10.8 Astigmatism of a spherical mirror. Off-axis rays of collimated light converge in different positions to form tangential and saggital foci.

angle θ to the principal axis are given as (Jenkins and White, 1976)

$$f_T = f\cos\theta \tag{10.15}$$

$$f_S = \frac{f}{\cos\theta}$$

While a paraboloidal mirror eliminates spherical aberration, it significantly exaggerates astigmatism, limiting its useful angular aperture.

Curvature of Field The focal surface of a spherical mirror is not in general a plane; this fact becomes important if an extended spectrum is to be imaged onto a photographic plate or an array detector. The exact curvature of the surface is determined by the curvature of the condensing optics, the distance of the condensing mirror from the grating, and the angle of the light with respect to the principal optical axis. It has been known since the work of Fastie (1952b) that, if the grating in an Ebert or Czerny–Turner spectrometer is placed at a distance of $2f/\sqrt{3}$ from the center of curvature of the condensing mirror, the focal surface is very nearly a plane. Reader (1969) has identified two other nearby positions which offer further corrections to the field curvature. The "corrected flat field" offers a somewhat flatter field than the Fastie position and insures that the focal plane is nearly perpendicular to the direction of propagation of light. Reader's "superflat field" provides the most nearly flat focal surface but inclines the plane slightly with respect to the direction of propagation. For the 1-m Czerny–Turner spectrometer, the offset of the grating from the Fastie flat-field position to the corrected flat-field position is 10 mm; the distance from the Fastie position to the superflat field position is 26 mm (Scheeline *et al.*, 1991).

10.5.5.2 **Types of Plane Grating Spectrometers**

Ebert-Fastie A particularly simple grating spectrometer was designed by Hermann Ebert in 1898. Dismissed and ignored by the spectroscopic community as flawed and impractical, Ebert's design was reinvented and improved in 1952 by William Fastie, who demonstrated its simplicity and optical superiority over any other instrument in use at that time (Fastie, 1952b, 1952a, 1991). The mount uses a single spherical mirror as both collimator and condenser, as illustrated in Figure 10.9(a). The grating is invariably mounted with its grooves aligned vertically, so Figure 10.9(a) is a view from above the spectrograph.

There are two implementations of the Ebert–Fastie mount: in the original design, the entrance and exit slit were placed side by side on either side of the grating (the "horizontal" Ebert mount, Figure 10.9b), while in some later versions, the slits were placed above and below the grating (the "vertical" Ebert mount, Figure 10.9c). The former has the advantage that the curvature or tilt of the image remains unchanged as the grating is rotated; the latter has the advantage of reducing stray light and thus simplifying the internal layout of the optics. In either case, both the entrance and exit slits must lie in the same plane to keep the instrument in focus over all angles of the grating; this point has been misunderstood in some commercial implementations of the Ebert mount.

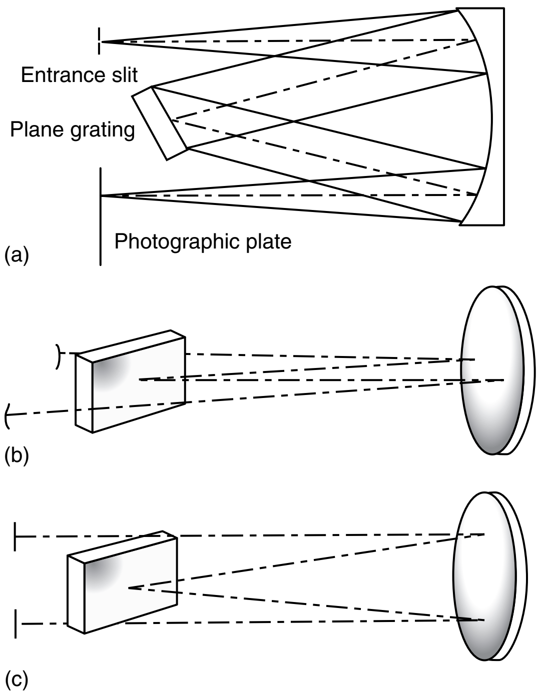

Fig. 10.9 The Ebert–Fastie grating mount, illustrating (a) a top view of an Ebert spectrograph, (b) a perspective view of a "horizontal" Ebert spectrometer, and (c) the "vertical" Ebert spectrometer.

Both designs have the effect of partially compensating for both spherical aberration and coma. In addition, Fastie has shown that the use of curved entrance and exit slits can reduce or eliminate astigmatism. The optimum shape for the slits of the horizontal Ebert spectrometer involves a pair of slits with a common center of curvature located on the line passing through the center of the grating and the center of curvature of the mirror.

Czerny–Turner If the single mirror of the Ebert–Fastie spectrometer is replaced by two independent mirrors, one for collimation and one for focusing, the Czerny–Turner spectrometer is obtained. The most commonly used design for this spectrometer is one in which two spherical mirrors are placed side by side as illustrated in Figure 10.10. This mount has all of the optical virtues of the Ebert mount (Czerny and Turner, 1930), but the extra degree of freedom afforded by the additional mirror allows superior correction of the image aberrations.

Shafer *et al.* (1964) and Reader (1969) have demonstrated that the performance of the Czerny–Turner spectrometer can be optimized by using mirrors of different focal lengths as collimator and focusing mirror. These authors have shown how the residual coma, astigmatism, and spherical aberration are affected by the choice of focal lengths. Reader has also provided equations for the focal surface of the focusing mirror in terms of the focal length and the distance of the mirror from the grating. Because of its high performance and flexibility, the Czerny–Turner mount in its many varieties forms the basis of most commercial spectrometers.

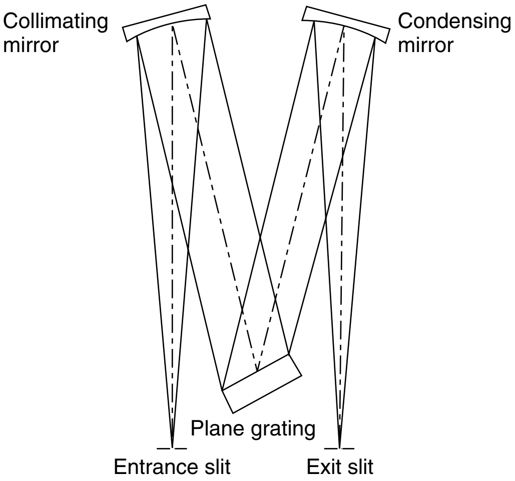

Fig. 10.10 The basic Czerny–Turner grating spectrometer.

Newtonian The most straightforward way to reduce the off-axis aberrations of coma and astigmatism is to bring the optical path as close to the principal optical axis as possible. This is the principle behind the Newtonian telescope, for instance, and it is possible to design a spectrometer based on this principle. A small plane diagonal mirror is used to bring the rays from the center of the entrance slit onto the principal optical axis of the collimating mirror, and a second plane diagonal mirror diverts the image of the spectrum from the condensing mirror to the focal plane. The problem of reducing optical aberrations then becomes the same as reducing optical aberrations in an astronomical telescope. Variations on this approach use the Schmidt or Cassegrain telescopes as collimator or condenser.

10.5.6
Concave Grating Spectrometers

If a grating is produced on a concave spherical mirror blank, the concave grating thus formed serves as both the dispersing element and as the image-forming optics. With rare exceptions, it is the only element in the optical train of a spectrometer in which it is used. There is one major advantage and one major disadvantage that follow from this choice: the advantage is that absorption losses at optical surfaces are considerably reduced, whereas the disadvantage is that the opportunity to correct optical aberrations is severely limited.

Concave grating spectrometers are of two general types: those which form images on the Rowland circle and those which do not. The former mounts include the Paschen–Runge mount, the Eagle mount, and some grazing incidence spectrometers. The latter include the Seya–Namioka and related mounts, the Wadsworth mount, and several modern designs which employ specially designed holographic gratings which compensate for certain aberrations.

10.5.6.1 Optical Aberrations of Concave Mirrors

The concave grating is ruled on a spherical mirror, and so inherits the spherical mirror's optical aberrations. Chief among these is astigmatism, because the grating is always used off the principal optical axis. In the vertical plane (i.e., the plane in which the light is dispersed), meridional rays will be focused according to the equation

$$\frac{1}{r_1}+\frac{1}{r_2}=\frac{2}{R} \tag{10.16}$$

where R is the radius of curvature of the spherical surface and r_1 and r_2 are the distances from the grating to the entrance and exit slits. The condition for horizontal focus, on the other hand, is

$$\frac{\cos\alpha}{R}-\frac{\cos^2\alpha}{r_1}+\frac{\cos\beta}{R}-\frac{\cos^2\beta}{r_2}=0 \tag{10.17}$$

where, as usual, α and β are the angles of incidence and diffraction at the grating.

For wide-aperture concave gratings, spherical aberration can also become a problem. In such a grating, rays diffracted from the extreme ends of the grooves do not come to a focus in exactly the same line as meridional rays. The effect of spherical aberration increases as the fourth power of the vertical acceptance angle, requiring a compromise between luminosity, which increases with the square of the aperture, and resolution, which decreases as the fourth power of the aperture.

10.5.6.2 Rowland Circle Mounts

If both the grating and the entrance slit are placed on a circle whose diameter is the radius of curvature of the concave grating, as indicated in Figure 10.11, then images of the slit will also be formed on this circle at diffraction angles which satisfy the grating equation, $m\lambda = a(\sin\alpha+\sin\beta)$, just as a plane grating. The horizontal focal equation for the concave grating is solved by setting

$$\frac{\cos\alpha}{R}-\frac{\cos^2\alpha}{r_1}=0 \tag{10.18}$$

and

$$\frac{\cos\beta}{R}-\frac{\cos^2\beta}{r_2}=0 \tag{10.19}$$

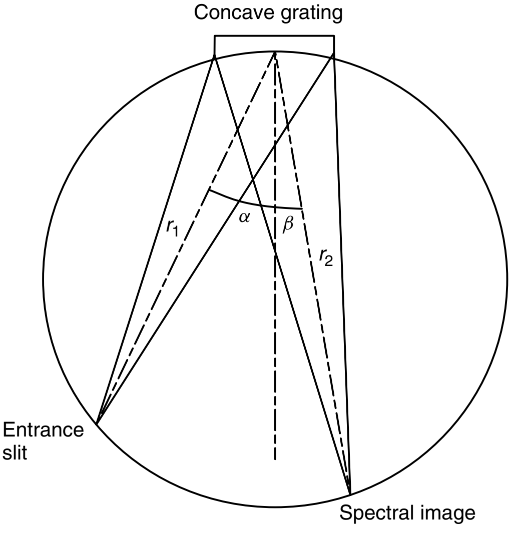

Fig. 10.11 The Rowland circle. Conjugate images of a concave grating are formed on a circle whose diameter equals the radius of curvature of the grating.

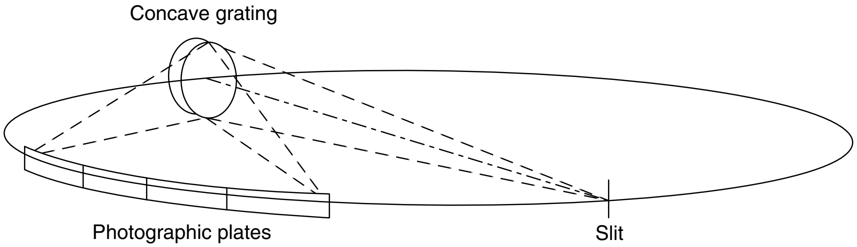

Fig. 10.12 The Paschen–Runge mount of a concave grating, illustrated for use as a spectrograph.

Paschen–Runge The most straightforward design using the Rowland circle is the Paschen–Runge spectrograph, illustrated in Figure 10.12. Here an entrance slit is placed at one point on the Rowland circle and photographic plates are located at points all around the circle wherever the spectrum is to be obtained. Using an instrument of this type, it is possible to cover the entire visible and ultraviolet spectrum at high resolution in a single exposure. The instrument occupies a very large area, and in addition is very difficult to isolate from building vibrations. As a result, it is used mostly in specialized circumstances requiring a high information bandwidth; an example would be to record the spectrum of a unique or precious sample such as a rare isotope.

Eagle Mount Among the many more compact mounts based on the Rowland circle, the Eagle mount is probably the most widely used (Eagle, 1910). In this mount, the entrance slit, grating and exit slit or plateholder are placed along a single optical axis, as shown in Figure 10.13. Variations of this mount place the plateholder in the same horizontal plane with the grating and entrance slit. In the Eagle mount, the plateholder is a segment of the Rowland circle, and it

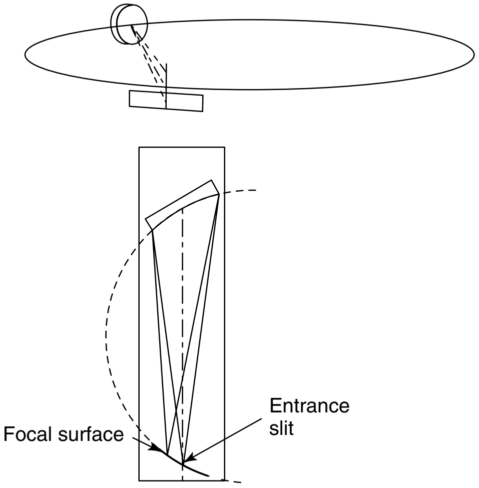

Fig. 10.13 The Eagle mount of a concave grating. The Rowland circle is indicated in both the perspective and the top view.

must be readjusted to fall on the focal surface of the grating each time the grating angle is changed. Moreover, the distance between the grating and the entrance slit must also be changed as the grating is rotated to keep the instrument in focus. Accordingly, the Eagle mount is not well suited for use as a scanning spectrometer. However, it functions very well as a high resolution spectrograph, and the compact design makes it suitable for a vacuum instrument.

Grazing Incidence Even the single surface of the concave grating produces unacceptable absorption losses at wavelengths shorter than 50 nm when used at normal incidence. At these wavelengths, use is made of the fact that short wavelength light striking a surface tangentially is reflected much more efficiently than light striking the same surface at normal incidence. This observation led to the *grazing incidence* mount of the concave grating, which is yet another mount making use of the Rowland circle. In this mount, the angle of incidence ranges from 60° to slightly less than 90°, and the angle of diffraction is only slightly less and on the opposite side of the grating normal.

At such high angles of incidence, the aberrations of the grating are quite pronounced. It has been shown that, in grazing incidence, the optimum width of a concave grating is much smaller than that for normal incidence; increasing the width above the optimum value degrades resolution without significantly increasing the central intensity of emission lines. Similarly, the useful length of a grating groove is limited by astigmatism.

10.5.6.3 Non-Rowland Circle Mounts

Seya–Namioka Other mounts of the concave grating are not based on the Rowland circle, but instead employ fixed entrance and exit slits while the grating is rotated about a point (Miyake, 1959). Such a mount is substantially simpler to use as a scanning monochromator than one based on the Rowland circle, and considerable effort has been made to find the best design to maintain focus of such an instrument as the grating is rotated.

Seya (1951) designed such a mount based on the requirement that the grating pivot about the center of its face. This design was refined by Namioka (1959), who used the condition that there be a minimum change of focus as the grating is rotated. The difference between the angle of incidence and the angle of diffraction is found to be 70°15′, and the distance of the slits from the surface of the grating is 0.8156 times the radius of curvature of the grating.

The Seya–Namioka solution of the focal equation for the concave grating involves taking

$$\frac{\cos\alpha}{R} - \frac{\cos^2\alpha}{r_1} + \frac{\cos\beta}{R} - \frac{\cos^2\beta}{r_2} = F(r_1, r_2, \alpha - \beta, \alpha + \beta) \qquad (10.20)$$

and setting F and its first three derivatives with respect to $(\alpha + \beta)$ equal to zero at some particular angle of incidence. While this condition does not guarantee a good focus over a wide range, the simplicity of the design makes it highly useful as a scanning vacuum monochromator.

Wadsworth A different kind of non-Rowland circle mount was devised by

Wadsworth to produce a stigmatic image using a concave grating. The grating is illuminated with collimated light from a concave mirror just as in a plane grating spectrometer, and the concave grating produces a stigmatic image at the focus. The image is brighter than the astigmatic image produced by the various Rowland circle mounts, provided the additional loss due to absorption at the first mirror surface can be tolerated. The focal surface is not flat, however, and both the focus and the curvature of the focal surface change as the grating is rotated, making the mount inconvenient as either a scanning spectrometer or a spectrograph. As a result, the Wadsworth mount is not widely used.

Compensated Holographic Yet another class of mounts has been designed around holographically recorded concave gratings which are specifically designed to compensate for one or more of the aberrations inherent in concave gratings. These aberration-corrected holographic gratings are not recorded with collimated light sources, and so the projection of the grooves onto a chord will not be equally spaced as is the case with a ruled grating or an ordinary concave grating. The greatest flexibility in correcting aberrations is achieved by allowing the focal surface of the grating to depart from that of the ruled concave grating.

10.6
Interferometric Spectrometers

10.6.1
Michelson

The Michelson interferometer, which has in the past four decades seen a rapid rise in popularity for use as a Fourier transform infrared spectrometer, has seen relatively little use as in the visible and ultraviolet regions. The reason for this is threefold: First, the requirement that the mirrors be kept in alignment to within a fraction of a wavelength during the full scan is a much more stringent condition in the ultraviolet than in the infrared. Second, the signal/noise ratio is not usually detector limited in the visible or ultraviolet, so that the multiplex advantage of a Fourier transform spectrometer is less important than in the infrared. Finally, the requirement for resolution of $0.001\ \mathrm{cm}^{-1}$ or better, which is important in the infrared and can most easily be achieved with a Fourier transform instrument, is less important in the visible or ultraviolet because of the much greater Doppler width.

Despite these obstacles, the Fourier transform spectrometer has seen some limited use in the shorter wavelength regions. There are two strategies for maintaining alignment during a scan. One of these involves passive stabilization of the fixed and moving mirrors using a self-aligning optical element. This may be either a corner cube or a cats-eye mirror, each of which is designed to reflect light back along the original path or parallel to it. The other strategy makes use of active stabilization: a monochromatic source such as a single frequency laser is passed through the interferometer, and the interference fringes are monitored to provide a feedback signal which corrects the tilt of one of the mirrors.

In addition to its use as a Fourier transform spectrometer, the Michelson interferometer has achieved considerable popularity in the measurement of the

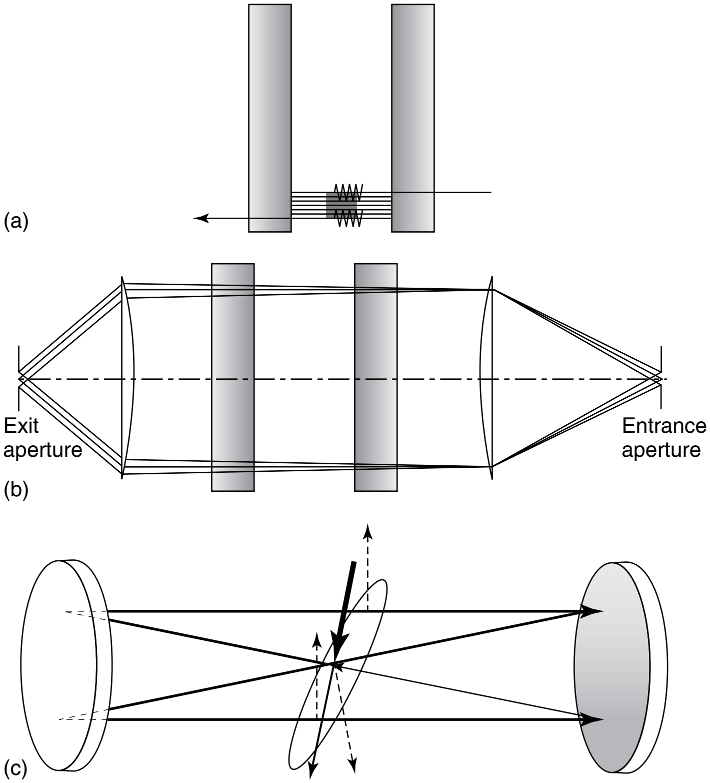

Fig. 10.14 The Fabry–Perot étalon. (a) The path of light indicating the resonance condition. (b) Illumination of the interferometer for use as a spectrometer. (c) The internally coupled confocal Fabry–Perot.

wavelength of single frequency lasers. In this application, the Fourier transform is unnecessary, as the wavenumber of an unknown laser can be obtained simply by counting the fringes during a sweep of the interferometer and comparing the number with the fringes from a laser of known frequency (Kowalski *et al.*, 1978; Fox *et al.*, 1999).

10.6.2
Fabry–Perot

The highest resolution spectrometer commonly used in the visible and ultraviolet is the Fabry–Perot interferometer or étalon (Fabry and Perot, 1899). Invented in 1899, the basic Fabry–Perot interferometer consists of a pair of partially reflective flat plates held parallel at a fixed distance d from each other (Figure 10.14a). This arrangement forms a resonant cavity which passes through light if the wavelength satisfies the condition $m\lambda = 2d\cos\theta$, where θ is the angle between the incident ray and the normal to the plate surface and m is an integer. At wavelengths which do not satisfy this condition, light is reflected. For a Fabry–Perot interferometer with perfectly flat plates and no absorption losses, the transmitted intensity is described in terms of the incident intensity I_0 and the reflectance r by the Airy formula:

$$I(\lambda) = \frac{I_0(1-r)^2}{1 - 2r\cos\left(\frac{4\pi d}{\lambda}\cos\theta\right) + r^2} \tag{10.21}$$

The Fabry–Perot interferometer can be used as the dispersing element of a spectrometer by using suitable collimating and condensing optics, as indicated in Figure 10.14(b). The entrance aperture is circular, and spectrometer produces at the output focal plane a set of concentric rings.

The resolving power R is given as

$$R = \frac{m\pi\sqrt{r}}{1-r} \tag{10.22}$$

while the free spectral range is found to be simply

$$\Delta\lambda = \frac{\lambda}{m} \tag{10.23}$$

The ratio of the free spectral range to the resolution, called the *finesse* of the Fabry–Perot interferometer, is given as

$$F_r = \frac{\pi\sqrt{r}}{1-r} \tag{10.24}$$

where the symbol F_r is used to emphasize that this is the part of the finesse due to the reflectance. The finesse is the most straightforward figure of merit for the Fabry–Perot interferometer, because it is the width of adjacent peaks of the instrument function divided by their separation. If absorption losses are considered, the peak intensity passed by the interferometer drops to

$$I_{\max} = I_0(1 - (A/(1-r))^2 \tag{10.25}$$

where A is the absorption coefficient of the reflectors.

If the interferometer plates are not perfectly flat, there will be both loss of intensity and a degradation of the resolution compared with the formulas above, and the instrument function will be a convolution of the Airy formula with these additional losses (Jacquinot, 1960). A contribution to the effective finesse can be determined from the surface irregularities if they are known: if the irregularities are characterized by a width Δd, then the finesse is limited to $F_d = \lambda/(2\Delta d)$. For example, if the surface imperfections are of the order $\Delta d = \lambda/200$, the flatness finesse F_d will be limited to 100. Increasing the reflectance to improve the reflectance finesse above this value will only introduce additional absorption and scattering losses.

In a similar way, a nonzero size for the entrance aperture of the collimating optics will result in a loss of resolution which can be cast into the form of a lower finesse. The solid angle of acceptance Ω will restrict the resolving power to a maximum value of $R_\Omega = 2\pi/\Omega$, so the aperture-limited finesse will be

$$F_\Omega = \frac{R_\Omega}{m} = \frac{2\pi}{\Omega m} \tag{10.26}$$

A variation on the plane-mirror Fabry–Perot is one which uses concave spherical mirrors placed so that their focal points coincide. This *confocal* Fabry–Perot has as its condition for constructive interference that $m\lambda = 4d$; consequently, it has a free spectral range (and resolving power) which is twice that of a plane Fabry–Perot of the same spacing. In addition, the confocal Fabry–Perot has a luminosity which exceeds that of the plane interferometer, since the interference condition is independent of the angle of incidence.

A Fabry–Perot interferometer is ordinarily used in an order $m = 10^5 – 10^6$, so that a modest finesse of 10–20 can easily produce a resolving power of a few million. However, the free spectral range is correspondingly limited so that this instrument is ordinarily used for uncluttered and isolated spectra, such as the nuclear hyperfine splitting of single atomic emission lines.

The combination of high resolution and luminosity make the Fabry–Perot interferometer the instrument of choice for monitoring and stabilizing high-resolution lasers such as dye lasers or diode lasers. One particularly useful configuration is an ‘‘internally coupled’’ confocal interferometer, Figure 10.14(c) (Reich *et al.*, 1986). The ‘‘internal coupling’’ refers to the means of coupling light into the cavity via a nearly transparent beam splitter placed near the common foci of the two spherical mirrors that make up the cavity. This method of coupling the light in and out of the cavity eliminates the need for specialized partially reflective dielectric coatings on the mirrors, greatly increasing the useful spectral range of the device: a single instrument can typically be operated without modification from the mid-infrared into the visible spectrum.

10.7
Hybrid and Compound Instruments and Imaging Filters

There are a large number of innovative designs for spectrometers which do not fit neatly into any of the categories above. Some of these are compound instruments with more than one dispersing element; others are hybrids which make use of diffraction gratings in what are essentially interferometers.

10.7.1
Order-Sorter for a Grating Spectrometer

The most common type of compound instrument involves a low-resolution spectrometer which serves as a predisperser or order-sorter for a high-resolution spectrometer with a limited free spectral range. As an example, consider a grating spectrometer employing a 300 groove/mm grating blazed at 65°. A 250-mm-wide grating of this type will produce a resolving power of 750 000 in the tenth order when used to observe a wavelength of 600 nm. It will also, however, diffract light at 545 and 666 nm in the ninth and eleventh orders, and these orders must be removed to record an absorption spectrum. This is usually accomplished by illuminating the slit of the grating spectrometer with a small prism monochromator centered at the wavelength of interest. The prism instrument can, at the modest resolution required to separate the adjacent orders, be designed to have high throughput so that the luminosity of the overall instrument is only slightly reduced.

10.7.2
Harrison Echelle

If the grating of the Czerny–Turner spectrometer is chosen to be an echelle, the spectrometer can be very efficient and deliver very high resolution. The disadvantage of such an arrangement is that the echelle must operate in a high order (typically $m = 50–100$ in the visible), and wavelengths from many overlapping orders are diffracted at the same angle. To separate the orders,

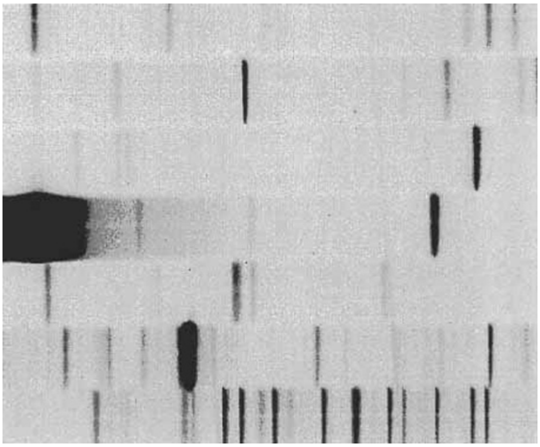

Fig. 10.15 A portion of an echelle spectrogram. Wavelength is dispersed horizontally within an order, while adjacent orders are separated vertically.

some other dispersing element must be used. One ingenious solution to this problem is to use a prism placed immediately in front of the grating as an order-sorting cross disperser. The prism-grating pair can be matched in such a way that the spectrum appears as short strips of adjacent orders as illustrated in Figure 10.15. A second solution which produces much the same result is to replace the condensing mirror of the echelle spectrometer with a concave grating whose grooves are perpendicular to those of the echelle.

10.7.3
Fabry–Perot/Grating Instrument

A second such tandem instrument is the Fabry–Perot interferometer in series with a grating spectrometer. In this case, it is the grating instrument which acts as a low-resolution order-sorter for the much higher resolution étalon. If the free spectral range of the étalon is matched to the resolution of the grating spectrometer, the maximum theoretical resolution is increased by a factor of the finesse of the Fabry–Perot. The instrument can be used either as a scanning spectrometer, by scanning the grating and the interferometer synchronously, or it can be used as an imaging spectrograph, in which case the image is a two-dimensional pattern of Fabry–Perot rings superimposed on the spectrometer slit.

10.7.4
Double and Triple Monochromators

In many instances, a tandem spectrometer combination is not intended to increase the resolution but rather to improve the signal/noise ratio. Double or triple monochromators are used to reduce scattered light from a prominent emission line and so improve the ability to observe a nearby faint feature. The exit slit of the first monochromator serves as the entrance slit of the second monochromator, which is scanned synchronously with the first. If the dispersion is additive, the entrance slit of the first and last monochromator determine the spectral resolution to a first approximation, while the central slit determines the rejection of scattered light. A typical use of such a spectrometer would be to observe low-frequency Raman or Brillouin scattering in the presence of a nearby exciting line. If the dispersion is subtractive, the double monochromator is essentially a sharp cutoff bandpass filter whose width is determined by the width of the central slit. The subtractive dispersion arrangement has the advantage in time-resolved experiments that all rays are transmitted through the instrument in the same time interval, because any optical retardation of a marginal ray through one monochromator is cancelled by the other.

10.7.5
Imaging Filters

Imaging spectrometers have long been of interest to astronomers, but they are also useful for any application requiring position-sensitive wavelength discrimination. One promising technology for imaging spectrometers is the acousto-optic tunable filter. These devices make use of Bragg diffraction by acoustic waves in an optoelastic medium. These acoustic waves are produced by a piezoelectric element in contact with the optoelastic element; and by tuning the acoustic excitation frequency, it is possible to tune the transmitted wavelength. Filters with a resolving power of a few hundred have been demonstrated that are tunable through much of the visible and into the near infrared (Georgiev *et al.*, 2002).

10.7.6
The Sisam Spectrometer

A hybrid instrument originally described by Connes (1959) attempted to capture the advantages of Michelson interferometer without the necessity of implementing the Fourier transform. The instrument consists of a Michelson interferometer in which the two mirrors have been replaced by diffraction gratings. The most significant technical problem with this arrangement is that the gratings are required to rotate in tandem; otherwise, the resolution of the instrument is degraded. This problem was effectively solved by Till *et al.* (1975), who constructed an optical system in which the two diffraction gratings were mounted back-to-back on a single rotating platform. Although the availability of fast and inexpensive computers has eliminated the main advantage of the Sisam spectrometer, it remains a useful design for highly specialized tasks; chief among these is the high resolution detection of a weak emission signal in the presence of a much stronger signal.

10.8
Detectors

10.8.1
Ideal Detector

The ideal detector would have unit quantum efficiency (that is, one photoelectric or photochemical event per photon), no dark current or readout noise, zero response time, and a flat response over a wide spectral range. In addition to these features, a detector which can increase the *information bandwidth* either by multiplexing a signal or by allowing parallel detection of several signals will improve the performance of a spectrometer enormously. Naturally, no single detector type embodies all of these features, and different compromises among the various desirable properties of detectors must be made depending on the nature of the experiment and the spectral region to be covered.

10.8.2
Types of Detectors

Photographic Plate The first detector used for making a permanent record of a spectrum was the photographic plate. Photographic plates can be obtained which cover the spectral region in the near infrared to about 1200 nm or through the vacuum ultraviolet. Photographic plates are especially suitable for high resolution measurements because of the ease of superimposing a wavelength calibration on a spectrum using an emission source which produces known wavelengths. In addition, the information bandwidth of a photographic plate is extremely high: if a single emission line is 10 μm wide (a typical width), a 250-mm-wide photographic plate has an advantage of 25 000 over a spectrometer using a single photoelectric detector with comparable quantum efficiency. If the spectrometer is of the Harrison echelle type, the advantage becomes even greater and can easily reach several million. This advantage is mitigated somewhat by a relatively low quantum efficiency (typically 0.01 or lower) and is severely compromised by the highly nonlinear response of photographic emulsions. The main difficulty with photographic detection is, however, the inconvenience of waiting several hours between performing an experiment and measuring the recorded spectrum. In addition, there is no way of adapting photographic recording to exploit modern time-dependent techniques. Despite these inconveniences, there are certain spectrograph designs such as the Paschen–Runge mount, for which the photographic plate has no cost-effective replacement.

Photomultipliers The photomultiplier tube (PMT) is the detector of choice for most spectroscopic applications. This detector consists of a vacuum tube containing a photoemissive surface (a *photocathode*) which ejects electrons when exposed to light. These electrons are accelerated by an electric field toward elements of a *dynode chain*, each of which will emit several electrons when struck by an energetic electron. The photocathode determines the spectral sensitivity and quantum efficiency of the photomultiplier, while the dynode chain serves to amplify the signal of a single photoelectron to a measurable signal. Photomultipliers can be obtained commercially with useful sensitivity from 200 to 900 nm. Quantum efficiency is typically 0.1–0.3 at peak sensitivity, and the internal amplification of the photomultiplier boosts the signal by a factor of about 10^6.

The photomultiplier produces a burst of current in response to each photon, and this feature may be used to count photons in favorable circumstances. The rise time of a pulse of electrons is a few nanoseconds, while the transit time is approximately 10 times that value; accordingly, the counting rate of photomultiplier pulses may range upward of several million per second before overlapping pulses begin to become a problem. The photon noise is simply the square root of the number of photons, so that the signal/noise ratio is about 10^3 for a 1-second sampling time under these circumstances. The dark count in selected photomultipliers may be as low as 10 counts per second, leading to photon noise limited behavior at count rates as low as a few hundred per second.

The impact of the availability of these detectors on spectrometer design cannot be overstated. In the infrared, even the best detectors have responses which are limited by the noise of the detector itself. In consequence, infrared spectrometers have always been designed to provide maximum efficiency of detecting a small signal in the presence of a large amount of noise. This has routinely been achieved by multiplexing the signal, leading to the popularity of Fourier transform or Hadamard transform spectrometers in the infrared. In the visible and ultraviolet regions, such techniques do not provide any great benefit because the detectors are of such high quality.

An additional advantage of electronic detectors such as photomultipliers is that they can be used for *phase sensitive detection*. If the source of light incident on a spectrometer is modulated (either in amplitude or in wavelength), the signal emerging from the spectrometer will also be modulated. A modern lock-in amplifier can then be used to amplify only that part of the signal from the detector that has both the same frequency as the source modulation and a constant phase with respect to that modulation. This scheme of detection can greatly reduce the bandwidth of the noise spectrum, improving the signal/noise ratio by several orders of magnitude.

Photodiode Several types of solid state detector have become available recently. Most of these depend on the ability of a photon to promote an electron in a semiconductor from one energy level to another where it is more mobile. The simplest of these is the photodiode, which is the solid state equivalent of an unamplified vacuum tube photocell. Each incoming photon with an energy in excess of the semiconductor band gap promotes one electron from the valence band to the conduction band, and this may be detected in the form of a change in potential or a change in current. The difficulty with this device is that the current carried by a single electron is well below the noise level of an ammeter, so the device is insensitive to a low light level. A typical silicon photodiode produces $1\ \mathrm{A\ W^{-1}}/$ of incident radiant power compared with $10^5\ \mathrm{A\ W^{-1}}$ for a good photomultiplier. At a radiant power of 10^{-12} W, the signal/noise of a photomultiplier is about 10^4 times higher than a photodiode.

The two advantages the photodiode have over the PMT are speed and infrared sensitivity. The photodiode can be configured so as to have a very large frequency bandwidth (cutting off at frequencies above 1 GHz). Silicon photodiodes have peak quantum efficiency in the red of 0.8 or better, retaining quantum efficiency as high as 0.1 out to 1000 nm. Indium gallium arsenide (InGaAs) photodiodes are sensitive to wavelengths as long as 1700 nm.

Avalanche Photodiode One improvement on the photodiode that makes it suitable for low light level detection is the avalanche photodiode (APD). This device has a built-in amplification similar in principle to the photomultiplier: the diode is run at a high reverse bias so that a photoelectron is accelerated by the applied field, ejecting a cascade of secondary electrons. This internal amplification boosts the current produced by a factor of about 100, improving the overall signal/noise ratio by a factor of 50. The amplification is high enough to allow APDs to be adapted for use in photon counting, and photon counting units with matched amplifier/discriminators are now available. With a quantum efficiency of 0.8 and a dark count as low as 25 counts/s, the APD is becoming competitive with the photomultiplier, especially at wavelengths longer than 800 nm.

Diode Array A second technique for improving the performance of the photodiode is to place a large number of photodiodes (128 up to 2048) in a linear array at the focal plane of a spectrometer. This tactic improves the information bandwidth of the instrument as a whole by a factor up to the number of parallel detectors. In spectrometers employing a diode array, sensitivity is further improved by the use of an image intensifier to amplify the image of the spectrum before it is imaged onto the diode array. The exit aperture is fixed at the size of a single photodiode, which is ordinarily 25 μm wide and up to 1 mm high.

The availability of inexpensive solid state array detectors such as the diode array and charged coupled device (CCD) has prompted a dramatic miniaturization of laboratory spectrometers. Instruments based on the Czerny–Turner mount are now commercially available which easily fit in the palm of the hand and weigh less than 300 g, including the detector and readout electronics. These offer coverage of the visible and UV spectrum at a resolving power of roughly 10^3.

CCD A different type of array detector is the CCD, which is commonly employed in video cameras. The CCD is similar to the photodiode in that the photon is used to promote an electron, producing an electron–hole pair. Instead of using the electron to produce a current, however, the CCD captures the electron on a small capacitor (a "gate"), allowing many electrons to accumulate before the charge packet is converted to an output voltage and digitized. Each pixel consists of such a gate, and a single CCD chip may contain several million pixels arranged as a rectangular array. The advantage of a CCD is that, by accumulating a charge over an exposure of several seconds or minutes, the integrated signal may be made to surpass the readout noise, even though the light level is low. For best performance, therefore, the dark current must be kept to a minimum, so that the dark current does not saturate the gate before the pixel is read; this is most often accomplished by cooling the CCD chip. Like the diode array, a CCD fixes the spectrometer exit aperture at the size of a single pixel. This size ranges from 25 μm × 25 μm down to 9 μm × 9 μm for CCDs, which are presently available commercially.

The simplest use of a CCD is to place it in the focal plane of the instrument in place of a photographic plate (Florek *et al.*, 1996). The CCD is becoming a sufficiently popular detector, however, that customized spectrometers are now being designed to take advantage of the properties of this detector (Scheeline *et al.*, 1991; Den Hartog and Holly, 1997; Furenlid and Cardona, 1988).

Conventional front-illuminated CCDs are silicon-based devices, and so are limited in their blue and ultraviolet sensitivity due to the absorption of short wavelength light by silicon before the photon can penetrate to the gate. This problem has been partly overcome by the use of thinned back-illuminated CCDs, with the result that CCDs are now available with useful sensitivity throughout the ultraviolet. As with photodiodes, CCDs based on indium gallium arsenide are now becoming available; these InGaAs detectors are sensitive from about 900 nm well into the near infrared.

Glossary

Aberration: The Gaussian approximation for a ray passing through a lens or reflected from a spherical mirror is that the angle of deviation θ is small enough for $\sin\theta$ to be replaced by θ. Any departure from this approximation is an *optical aberration*. For practical purposes, any departure from geometric optics that causes a point source to be imaged into a nonpoint image is an aberration.

Dark Current: Current from a photodetector, which is present even in the absence of illumination.

Information Bandwidth: The speed with which information channels may be recorded. In a spectrometer, the information bandwidth may be increased either by increasing the efficiency of recording a single wavelength or by recording several wavelengths simultaneously.

Monochromator: An instrument used to isolate a single wavelength of light.

Polychromator: An instrument capable of isolating several monochromatic rays simultaneously from an incident beam.

Spectrograph: An instrument which produces a graphical record (usually a photograph) of an optical spectrum.

Spectrometer: Any instrument that measures the intensity of light as a function of wavelength.

Spectrophotometer: A spectrometer specialized for accurately recording the intensity of light.

INTRODUCTION

The term VLSI (very large-scale integration) refers to one stage of the continual process of putting more and more functions and individual components into a small area of single-crystal silicon. These devices and the techniques that are used to achieve this are the subjects of this article. There is not a hard rule on how the level of integration is described or on how many individual components are necessary to qualify an integrated circuit as VLSI. Circuits of various levels of complexity are referred to as either small, medium, large, very large, or ultra-large integration. This is according to a convention of using ULSI to describe devices with 2–64 million individual components (Broydo and Osburn, 1987). VLSI devices are described as having 0.06–2 million components in this convention, with each new category having a factor of 2^5 (32) more devices than the previous generation. Most of the state-of-the-art large circuits commercially available, such as memories and microprocessors, now have on the order of 10 million transistors, which would make them ULSI devices. The largest circuits that have been reported are the 1-gigabit memory circuits, which have over a billion (10^9) transistors (Horiuchi *et al.*, 1995; Sugibayashi *et al.*, 1995). The term VLSI is commonly used to describe these integrated circuits, and the content of this article is applicable to all of the levels of integration. The techniques of the most modern devices are emphasized in this article.

The integrated circuit was first proposed by Jack Kilby in 1957 (Kilby, 1976) as a way of connecting more than one device to form

a circuit. However, the widespread application of this technique and the economies of scaling of these devices did not become a reality until the late 1960s. Over the last 20 years, the scale of integration has doubled every 18 months. Two types of circuits, memories and microprocessors, have been most successful in taking advantage of the new levels of integration. This trend of putting more components and functionality on a single integrated circuit has been coupled with an enormous increase in the number of circuits produced per year. The result of all of the production improvements and the considerable economies of scale have resulted in the wide-scale application of integrated circuits in a growing number of consumer products. Integrated circuits now permeate the life of nearly everyone in modern society. The integrated circuit is used in electronic devices including telephones, calculators, computers, televisions, kitchen appliances, automobiles, video games, door knobs, and many others. The current rate of production of transistors is estimated to be 10^{17}/year, which equals about 4000 transistors per person per day for every man, woman, and child on Earth. The changes in the way of life we have witnessed in telecommunication, transportation, and information storage and retrieval have all been influenced by the widespread application of the VLSI technology.

In Fig. 1 is shown the relationship of the wafer, chip, and component sizes that illustrates the dimensions involved in ULSI manufacturing. This figure shows the scope of the topics that are discussed in this article. The device, circuit, and wafer dimensions are all the key indicators of the progress being made. Figure 2 shows the design rules and density trends for DRAMS (Komiya, 1993). This figure illustrates how the levels of integration have been growing over the last 10 years and the projection for this trend to continue into the future. The wafer sizes and the chip sizes are steadily increasing as the feature size gets smaller, as seen in Fig. 3. The result of all these trends in the complexity of the devices is that the ability to control yield-limiting defects becomes the single most important parameter to determine viability of a technology. The yield-limiting defects come in two varieties: process parameters that are out of the acceptable range and random defects due to particles or missing or extra features. The techniques to deal with these defects are quite different. These techniques, along with device structures and manufacturing techniques, are presented in this article. All of these compo-

nents are critically important aspects of the ULSI technology.

1. PRINCIPLES OF OPERATION

1.1 Metal-Oxide-Semiconductor (MOS) Field-Effect Transistors (FET)

The most common type of active element used in VLSI devices is the metal-oxide-semiconductor (MOS) field-effect transistor (FET). This device is the most commonly used on account of the simplicity of operation, the low power consumption, and the favorable properties of the device as it is reduced in size. It is this scaling feature that has allowed the tremendous reduction in device size and increase in complexity. The basic operation of a MOS transistor is schematically indicated in Fig. 4. This figure indicates the four terminals of the device: source, gate, drain, and bulk. The current flows from the source to the drain in an n-channel MOS device depicted here, with the current flow regulated by the voltage on the gate. This is the basic operation and is described by

$$I_{ds} \propto \mu W/LD(V_{gs} - V_t)^2, \quad (1)$$

where μ is the electron mobility, W is the transistor width, L is the length of the transistor gate, V_{gs} is the voltage on the gate, D is the gate oxide thickness, and V_t is the threshold voltage of the transistor. The importance of the gate oxide thickness and the gate length can be seen in this expression. Decreasing either of these parameters results in an increase in the drive current. In the operating region where the gate voltage is below the threshold voltage, the current volt-

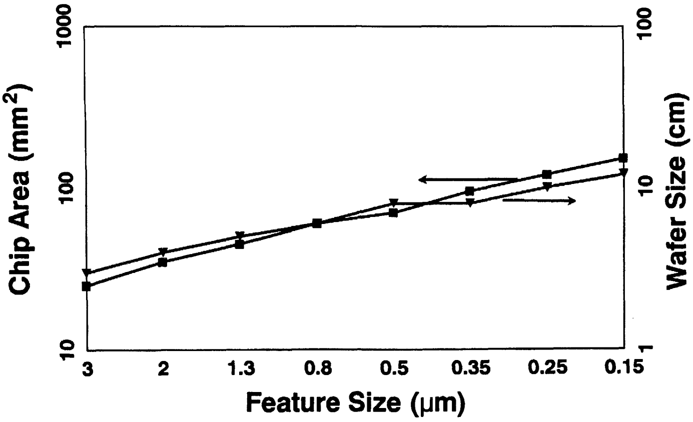

FIG. 3. Chip and wafer size trends for memory devices as a function of the minimum feature size (from Komiya, 1993).

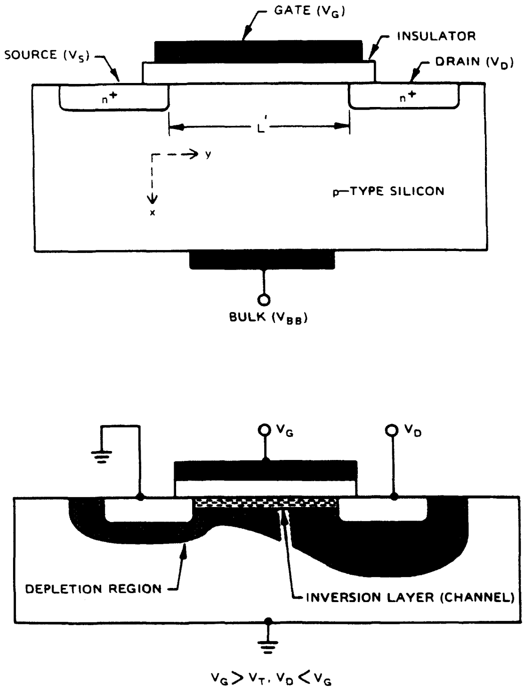

FIG. 4. Cross section of MOS transistor showing the components and the charge distribution in the linear region (from Beadle *et al.*, 1984).

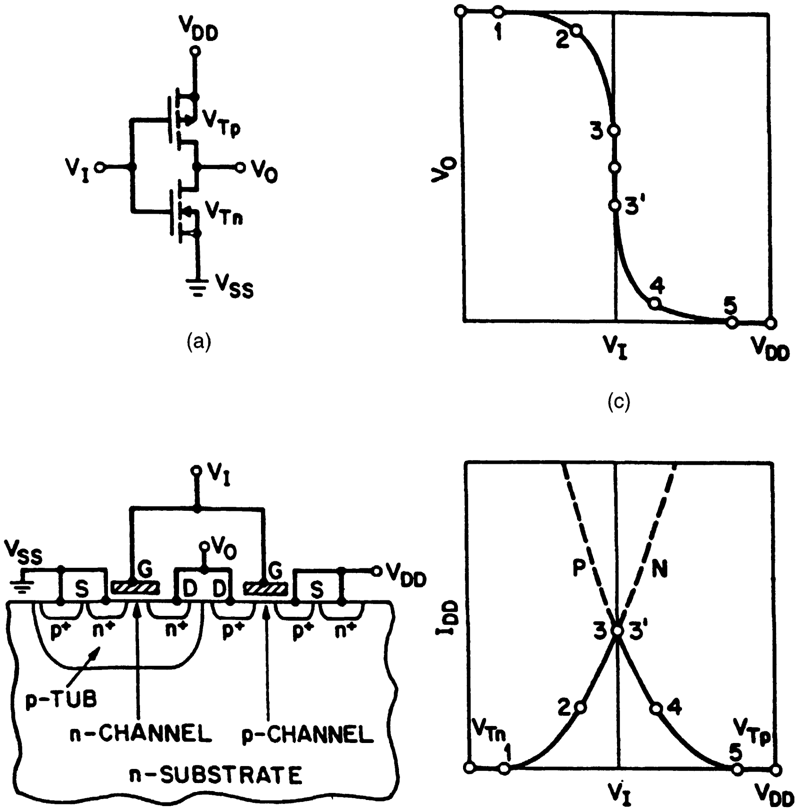
age relationship is dominated by diffusion effects, and the drain current varies exponentially with the gate voltage. This is referred to as the subthreshold region of operation. The ratio of the current with the device on (I_{on}) to the current with the device off (I_{off}) is typically on the order of 10^6 to 10^8 for these devices. See TRANSISTORS, FIELD-EFFECT for a more detailed description of the operation of this device.

This basic transistor can be used in many different configurations, but the simplest building block of most digital circuits is the inverter. The inverter takes the input signal and produces an output signal that is the opposite state. The most common technology used for modern VLSI circuits is called complementary MOS (CMOS). CMOS technology uses NMOS transistors as described above and a PMOS or *p*-channel transistor, which operates just like the NMOS transistor, but the S/D region consists of p-type silicon and the channel region is *n* type. This gives the *p*-channel transistor a current that is exactly like the NMOS transistor except that the polarity is the opposite type. The basic inverter structure for the CMOS circuit is shown in Figs. 5(a) and 5(b). The most important characteristic of this circuit is that the steady-state current drawn by the inverter is only the "off" current of the individual transistors. This allows for a very low use of power in these circuits and is the primary reason why the CMOS type of circuit methodology is used in VLSI devices. Figures 5(c) and 5(d) show the voltage and current drawn by the inverter during the transition from one state to another.

1.2 Bipolar Transistors

Bipolar transistors are electronic devices with two *p-n* junctions in very close proximity that produce three distinct regions in the silicon described as the emitter (E), base (B), and collector (C) regions. A bipolar transistor can either be an *npn* or *pnp* according to the type of doping for the respective regions. A cross-sectional view for the basic *npn* and *pnp* bipolar transistor structure is shown in Fig. 6. The two distinct junctions formed are the emitter-base junction and the base-collector junction. Under equilibrium conditions, there is no net current flow across either of these junctions. When an external voltage is applied to the transistor, either of these junctions may be forward or reverse biased. When the E-B junction is forward biased in the *npn* transistor, a large number of electrons are injected into the *p*-type base region as a result of the forward bias applied to the *p-n* junction. If the distance between the emitter and collector is small enough, then most of the electrons will diffuse to the reverse-biased C-B junction. This effect is the essence of the bipolar transistor action, which is the large current flowing through a reverse-biased junction due to the close physical proximity of a forward-biased junction. The practical outcome of this transistor action is the ability to produce an amplifying effect on small currents or "current gain." This current gain is defined by the change in the emitter current (I_E), which consists of the electrons that reach the collector plus those that flow out of the transistor through the base (I_B), as the base current is changed. Two parameters that describe this transistor action are the common-base current gain,



(a) (b) (c) (d)

CMOS inverter showing the (a) circuit schematic, (b) device cross section, (c) output vs input voltage of inverter, and (d) current through inverters a function of input voltage (solid curve); *I–V* characteristics of *n*- and *p*-channel transistors (dashed curves). The numbers correspond to different points on the inverter transfer characteristic.

$$\alpha = \delta I_C/\delta I_E, \tag{2}$$

and the common-emitter gain,

$$\beta = \delta I_C/\delta I_B. \tag{3}$$

And with the total-current relation $I_E = I_C + I_B$, we get the relationship between the two gains as

$$\beta = \alpha/(1 - \alpha). \tag{4}$$

Typically, the value of α is very close to unity and the value of β is on the order of 100–200. A more detailed discussion of the physics of the transistor can be found in TRANSISTORS, BIPOLAR.

2. STRUCTURES AND DEVICES

2.1 Complementary MOS (CMOS)

The basic structure for building the transistors and interconnects consists of building successive layers of insulating, conducting, and semiconducting materials. The individual layers are patterned by the lithographic techniques and etching techniques described later in this article. The basic structure of the transistor is shown in Fig. 7. The basic device structure is formed by the combination of the basic steps shown in Fig. 8. The basic elements of any silicon device consist of various combinations of these steps. The CMOS device cross section is shown in Fig. 9(f), and the sequence of steps used to form the transistors is shown in Fig. 9. This shows

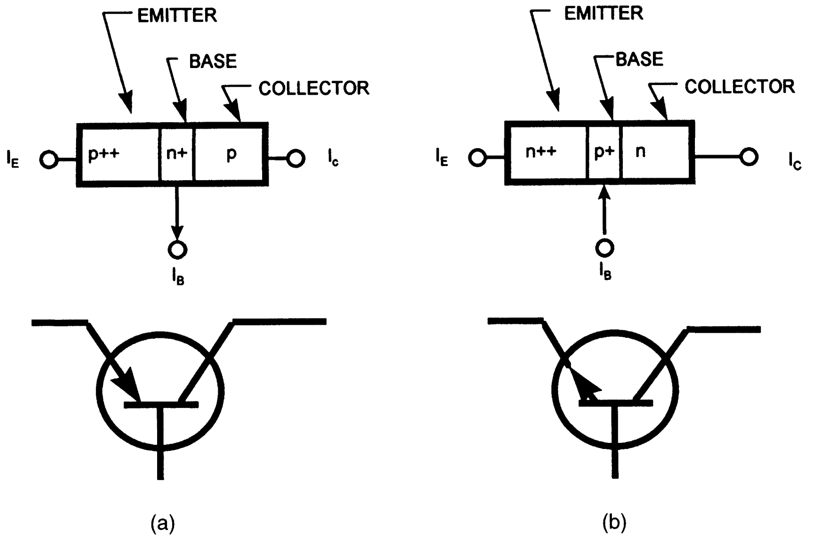


FIG. 6. Parts of the bipolar transistor and symbols used to denote (a) *pnp* and (b) *npn* transistors.

the two types of transistors (NMOS and PMOS) formed in a *p* tub and an *n* tub, respectively. The starting material for this process is an *n*-type silicon wafer with a lightly doped *n*-type epitaxial layer that is sometimes denoted with the Greek letter *ν*. The process consists of masking the implants using the patterned nitride layer shown in Fig. 9(a) as an ion implant (I^2) mask. This nitride layer is also used as an oxidation mask to form an oxide layer in the region of the *n* tub. This oxide layer is then used to mask the implant of the boron ions to form the *p* tub as is shown in Fig. 9(b). The oxide is then stripped in a wet etch, and the tub dopants are diffused into the silicon with a high-temperature anneal. The anneal is performed in a dilute oxygen ambient so that there is no loss of dopant [Fig. 9(c)]. The field oxide is then grown by a local oxidation process, which is then followed by a gate oxide formed and a polysilicon gate deposited and patterned [Fig. 9(d)]. The gate is then used as a mask for the source and drain implants of boron and arsenic. The boron is implanted in all the source and drain regions, but the arsenic is selectively implanted into the NMOS regions [Fig. 9(e)] to form the *n*+ source and drains for the NMOS and *p*+ source and drains for the PMOS transistors. The last step in Fig. 9(e) is to passivate the devices with an insulating layer of phosphorus-doped SiO_2 to insulate the devices electrically from the subsequent metal layers. Phosphorus-doped glass is used because the phosphorus prevents the diffusion of sodium and other mobile ions, which cause serious problems if they penetrate to the active regions of the transistors. These devices are then connected through the gate level or the metallization levels to form the inverters and other circuits as described in Sec. 1.

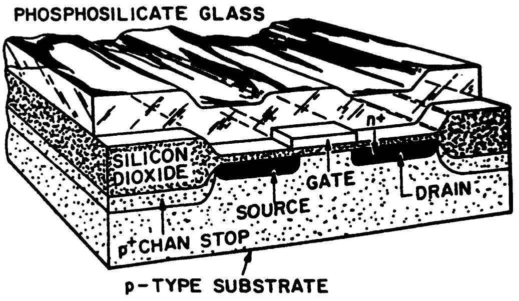

FIG. 7. Cross section of an NMOS transistor showing the structure and the individual parts (from Beadle *et al.*, 1984).

2.2 Bipolar

Bipolar devices are processed such that the structure is formed vertically into the silicon and with the critical dimensions for

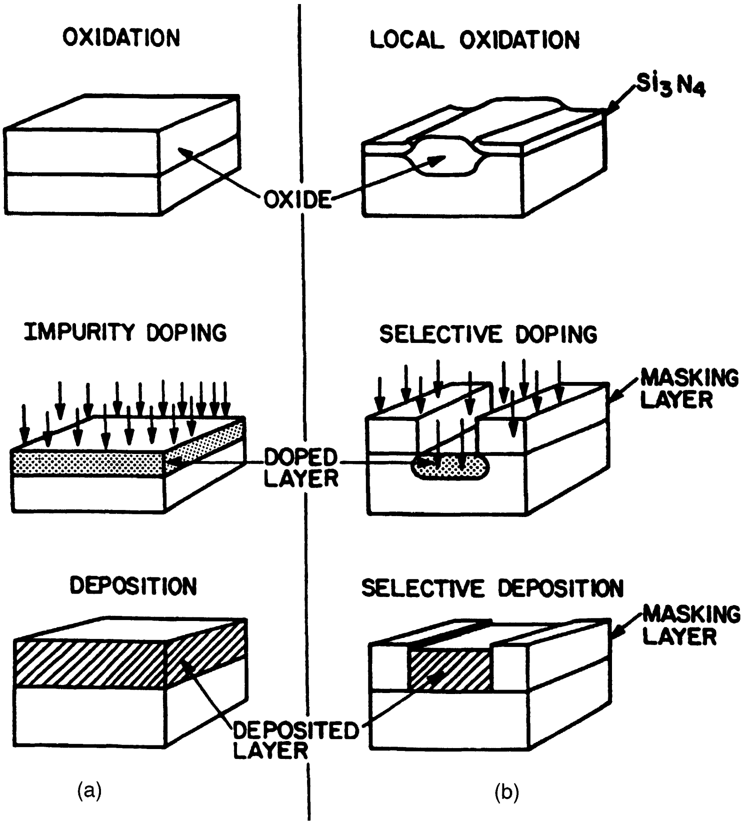

FIG. 8. Techniques in silicon processing to create either (a) uniform layers or (b) selective layers in silicon.

gain and performance in the vertical direction. The cross-sectional view of a bipolar structure is shown in Fig. 10(f), indicating the individual parts of the device. The formation sequence is similar to that of the CMOS process except that the base doping and thickness are critical parameters for the operation characteristics of the bipolar device. This requires the deposition of an epitaxial silicon layer to form a relatively lightly doped region of silicon in which the base of the transistor is formed. The doping levels of the bipolar transistor determine the gain of the device. The relationship between the doping level and the gain is determined by calculating the density of electrons and holes in each part of the bipolar devices. The gain is related to the doping in the emitter and the base of the device through the relationship

$$\beta \sim N_E/Q_B, \tag{5}$$

where N_E is the emitter doping, and

$$Q_B = \int_0^W N(x)dx, \tag{6}$$

where W is the width of the base. Q_B is called the Gummel number of the base. Equation (5) illustrates how the gain of the device is increased by maintaining a high emitter doping and a low base doping.

The most common structure for bipolar devices in VLSI/ULSI technology is the oxide-isolated device. The basic structure of this device is shown in Fig. 10(f). In the VLSI and ULSI applications, it is usually used in conjunction with a CMOS technology sometimes referred to as BiCMOS.

3. MANUFACTURING TECHNIQUES

3.1 Implantation and Dopant Diffusion

Diffusion of dopant through the silicon lattice is a process of random motion of particles in three dimensions. The dopant is dif-

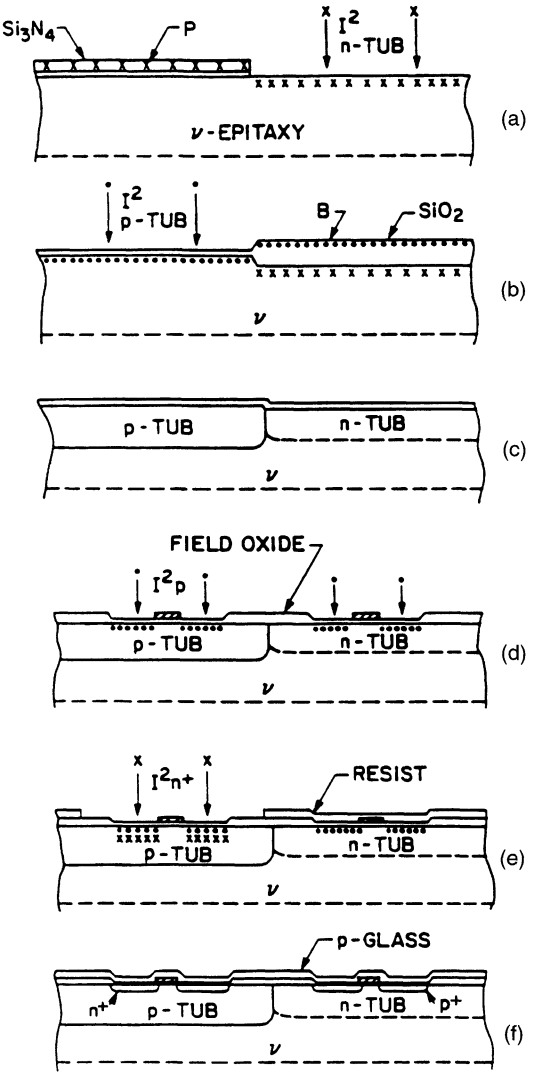

FIG. 9. Basic process sequence to make the CMOS device structures.

fused in the region of the device structure where it is necessary to produce the proper dopant profiles for device operation. The typical dopant species used in silicon VLSI are boron, for forming acceptor sites, and either arsenic, phosphorus, or antimony for forming donor sites. These dopants are used to form the *p*- and *n*-type regions of the semiconductor. The usefulness of each of the dopants is determined by a combination of the solid solubility, diffusion coefficients, and the compatibility of these dopants with the thermal cycles and materials used in the rest of the manufacturing process. Most of the impurity doping for modern VLSI devices is done through ion implantation of dopants, using ion accelerators that implant ions into silicon at energies somewhere between 10 and 300 keV. Table 1 shows the range of various ions illustrating the range that can be implanted. The implant energy would be chosen to place the dopant in the silicon such as to produce the correct distribution for the device characteristics required. The dopant will experience subsequent heat cycles that will diffuse the dopant into the silicon.

The dopant diffusion rates will vary considerably depending on the particular dopant and are the result of the random motion in three dimensions. The diffusion mechanism of these dopants is through an interaction between the dopants and point defects. Point defects can be vacancies in the crystal lattice, interstitials, or interstitial defects. Interstitials are atoms residing in between the lattice sites, and interstitial defects consist of two atoms that are in interstitial sites with a substitutional site between them.

The diffusion of these impurities can be described by Fick's laws regardless of what diffusion mechanism is involved. Fick's first law relates the number of particles passing through a unit area per unit time to the concentration gradient:

$$J_n = -D\frac{dn}{dx}. \tag{7}$$

Fick's second law of diffusion is based on the assumptions of conservation of matter and that diffusion is only a function of distance x and time t. If you also assume that the diffusivity at a given temperature is constant, then you get Fick's second law, which is

$$\frac{\partial N(x,t)}{\partial t} = D\frac{\partial^2 N(x,t)}{\partial x^2}. \tag{8}$$

The solutions of this equation depend on the boundary conditions, but one solution assuming a constant surface concentration is

$$C_s = C(0,t)\exp(-x^2/4Dt), \tag{9}$$

where C is the concentration of dopant and

C_s is the concentration at the surface, which is held constant.

Another important aspect of diffusion is the temperature dependence of the diffusivity. The experimentally determined temperature dependence of the diffusivity is

$$D = D_0 \exp(-E_a/kT). \tag{10}$$

Equation (10) is the same as the equation describing heat conduction through a solid. The term E_a is the activation energy and k is the Boltzmann constant. D_0 is related to the

atomic jumping frequency or the lattice vibration frequency of the solid.

These simple equations describe the diffusion of impurities when the impurity concentration is low (smaller than the intrinsic carrier concentration n_i) and the conduction gradient is not large. If the concentrations are higher than n_i, then more complicated interactions with the point defects and different impurities causes the diffusion to become more difficult to model, and it is not simply represented by Fick's laws. This is called extrinsic diffusion. The extrinsic effects can also be caused by reactions at the surface of the silicon.

3.2 Thermal Oxidation

Thermal oxidation is the technique of forming a SiO_2 layer on a silicon surface by exposing the silicon to an oxidizing ambient at an elevated temperature. The typical method for forming this film is to insert the silicon wafers in a cylindrical quartz tube in a resistance-heated furnace that contains a source of either oxygen gas or water vapor. The temperature of oxidation is typically in the range of 800–1200 °C. The chemical reaction occurring on the surface of the silicon causes the silicon on the surface to be converted into SiO_2 with the ratio of the thickness of SiO_2 to silicon consumed equal to 2.3.

The properties of thermally grown SiO_2 are probably the single most important factor in the progress made in VLSI/ULSI technology. It is the interface of the Si/SiO_2 in the gate of the MOS transistor that determines the important electrical characteristics of the MOS device. The ability to grow defect-free films that can reliably withstand the high electric fields and resist damage from the other processing steps also determines the rate of development of the ULSI technologies.

3.3 Lithography

Lithography is the process through which a pattern is delineated in a layer of material in which the physical properties can be changed through exposure to photons, electrons, or ions. The most common application is to use a photosensitive material called a photoresist. This is a material that can be developed like a photosensitive emulsion to form regions in which the resist remains on the surface and other regions where the resist is removed. The area where the resist is removed exposes the layers below to chemical etching or doping. A schematic diagram of the basic projection-reduction optical lithography system is shown in Fig. 11. This consists of a light source with a mask and lens arrangement to focus an image onto the resist surface. This is the most common technique used for ULSI technologies today.

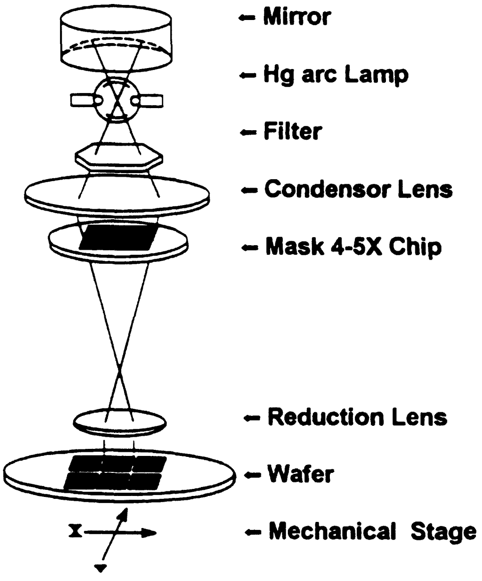

FIG. 11. Schematic of a reduction step-and-repeat projection system.

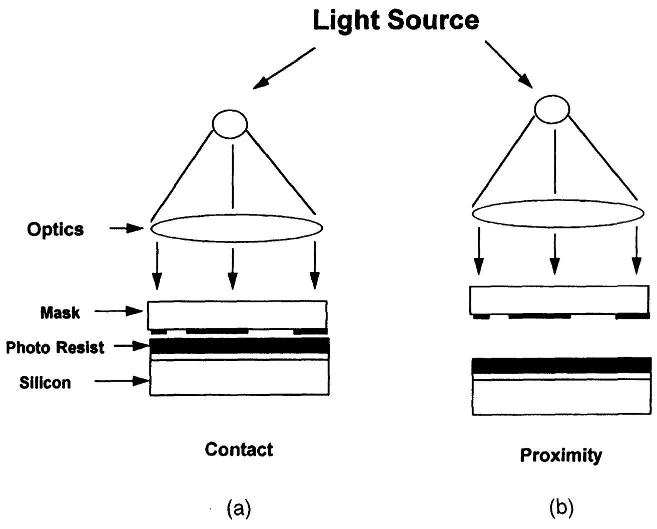

FIG. 12. Proximity and contact lithography.

The optical lithography techniques can be classified into three categories: contact, proximity, and projection. The contact and projection systems are schematically shown in Figs. 12(a) and 12(b). The disadvantages of contact and proximity systems are defect generation and the inability to make the fine features on the masks.

The most commonly used light source is ultraviolet (UV) light, formed in high-pressure mercury-vapor light arc sources that produce high-intensity emission in the wavelength range of 300–600 nm. The optical lithography generations are usually referred to by the particular lines of the emission spectrum that are used. Figure 13 shows the output spectrum of the high-pressure mercury arc source indicating the g, h, and i lines of this spectrum. The shorter the wavelength of the light, the finer the image size is. As the even shorter wavelengths become needed to pattern the very small features, the light sources will change to deep UV (DUV) light sources that use an excimer laser to produce the light at a wavelength of 248 nm. Beyond the use of 248 nm, the next optical wavelength that will be used will be 193 nm.

These optical lithography systems become increasingly difficult to manufacture at the shorter wavelengths and may become prohibitively difficult so that another lithography technique may be used. Possible alter-

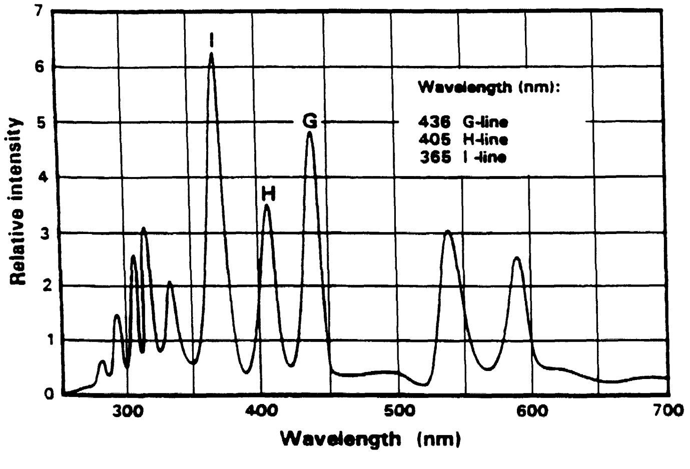

FIG. 13. Spectrum of high-pressure mercury-arc source indicating the high-intensity lines used for optical lithography.

natives such as using synchrotron radiation as a source of x rays are under development and may be useful in the future.

Another lithography technique that has its use in VLSI technology is electron-beam lithography. Electron-beam lithography uses accelerated electrons instead of photons to expose resist and to create the pattern. The use of electrons instead of photons allows the ultimate feature size to be reduced to below 0.1 μm. The disadvantages of *e*-beam lithography are the relatively more expensive equipment and the slow writing time for the technique. This means that this technique is used for prototyping and laboratory devices but is not commonly used for production of ULSI products. See MICROLITHOGRAPHY for more information on these techniques.

3.4 Deposition

The deposition of thin films of material to make very uniform and defect-free films of metals, insulators, and semiconductors is an essential part of the manufacture of silicon devices. The most important materials for manufacture of VLSI devices are polysilicon, silicon dioxide, silicon nitride, aluminum, various refractory metals such as titanium and tungsten, and metal compounds such as WSi_2 and $TiSi_2$. These materials are deposited by two basic techniques: chemical vapor deposition (CVD) and physical vapor deposition (PVD). There are also some applications that are combinations of CVD and PVD.

3.4.1 Chemical Vapor Deposition (CVD) Chemical vapor deposition (CVD) [see CVD (CHEMICAL VAPOR DEPOSITION)] is a process of depositing a film by causing a chemical reaction of a gas mixture or a decomposition of a gas. This is done at high temperatures on the wafer surface. The process can be performed at atmospheric pressure or at low pressure and is then denoted as APCVD or LPCVD, respectively. The general configuration of a CVD deposition system illustrating the various configurations is shown in Fig. 14 with the illustrations of the hot-wall reduced-pressure reactors and the continuous-deposition atmospheric reactors.

There are also several ways to enhance the deposition of films using light or plasma energy to enhance the deposition rate or film quality. These are referred to as photo-CVD and plasma-enhanced chemical vapor deposition (PECVD). Two configurations for the plasma-deposition reactors are shown in Fig. 15. The relative advantages of each deposition technique depend on the particular material properties of the thin film and the trade-offs that must be made between particle generation, step coverage, and the cost of deposition. More detailed explanations of the chemical processes can be found in CVD (CHEMICAL VAPOR DEPOSITION).

3.4.2 Physical Vapor Deposition (PVD) There are several important films used in VLSI technology that are applied using physical vapor deposition. Physical vapor deposition is done under a vacuum using a sputtering or an evaporation technique. The sputtering techniques (see SPUTTERING) used usually involve the acceleration of argon atoms through a potential gradient and the collision of these ions onto a target material at the cathode of the ion acceleration cham-

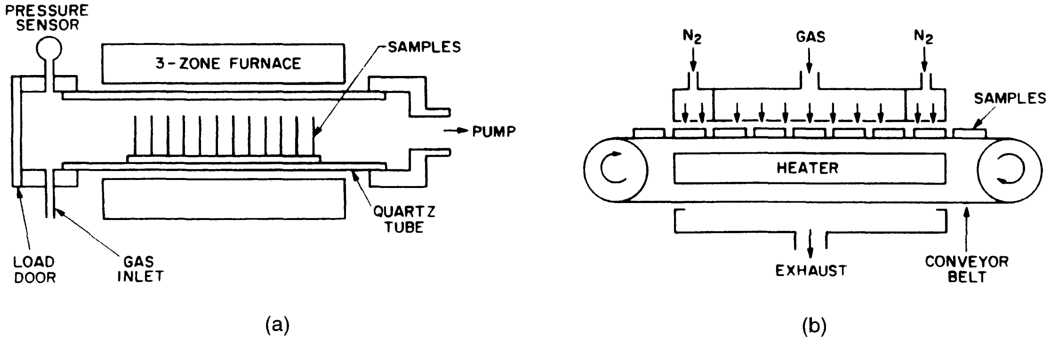

FIG. 14. Diagrams of two types of CVD reactors used to deposit dielectrics: (a) hot-wall, reduced-pressure reactor; (b) continuous atmospheric-pressure reactor. (From Sze, 1988.)

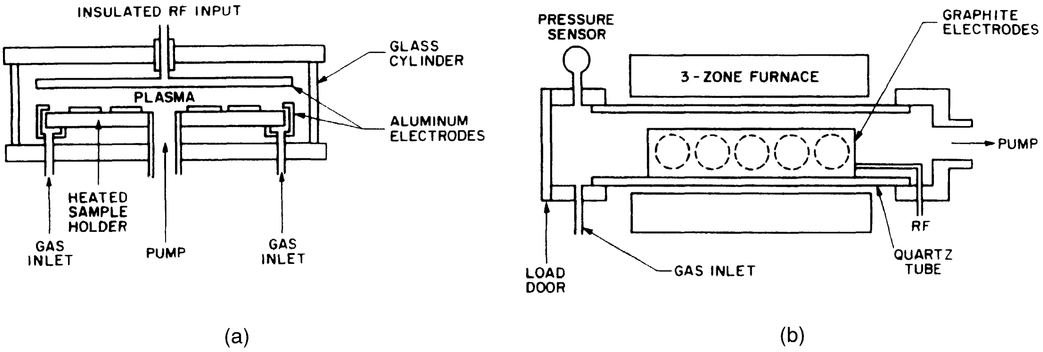

FIG. 15. Diagrams of plasma-deposition reactors: (a) parallel-plate, (b) hot-wall. (From Sze, 1988.)

ber. The ion causes the atoms of the target material to be dislodged, and the dislodged target atoms travel through the vacuum until they impinge upon the substrate that is receiving the film deposition. The ion energy must be sufficient to dislodge the atoms. A measure of the efficiency of this process is called the sputter yield. This number represents the number of atoms sputtered from the surface per incident ion. This number varies from about 0.5 to 1.5 depending on the material and the geometry of the targets.

Vacuum evaporation techniques are used when the source material can be easily heated above its melting point in a vacuum chamber allowing a direct evaporation of the material onto the surface receiving the thin-film deposition. Aluminum can be deposited this way. The rate of evaporation of the material depends on the temperature and the vapor pressure of the evaporated material. See THIN-FILM DEPOSITION.

3.5 Etching

Etching is the removal of material from the wafer surface either selectively, such as where photoresist is used as an etching mask, or globally, such as for cleaning a film or removing a layer of material.

3.5.1 Wet Etching Wet etching consists of the wafers being immersed in a liquid reagent to achieve a controlled chemical reaction that results in the particulate being suspended in the liquid or the material dissolved. The selective etching techniques needed to make modern high-density VLSI and ULSI circuits have become one of the critical enabling techniques for the progress of processing the features needed for these devices. Wet chemical etching is widely used for cleaning and for global removal of films, but the definition of the smallest features in modern devices is almost always done with a dry etching technique.

3.5.2 Dry Etching Figure 16 illustrates the difference between a pattern produced by wet etching, which is isotropic, and one produced by dry etching which is anisotropic. This is the reason the dry etching techniques allow the definition of the very smallest features. The wet-etched pattern allows for etching to occur under the masking layer, resulting in loss of control of the patterned feature size.

Dry etching techniques cover many different chemistries and equipment geometries, choice among which is determined by the selectivity, etch rates, uniformity, reproducibil-

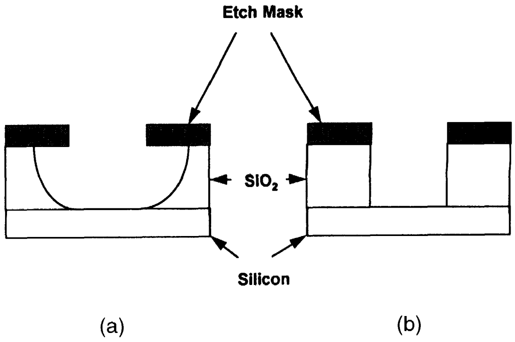

FIG. 16. Cross-sectional diagram of (a) the isotropic etch typical of a wet-etch process and (b) the anisotropic etch achieved by dry etching techniques.

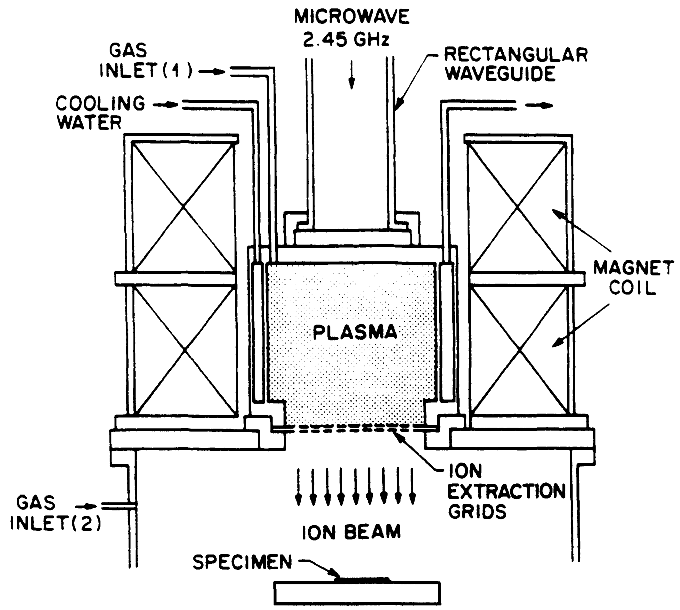

FIG. 17. Reactive ion-beam etcher using an electron cyclotron-resonance chamber as an ion source (from Sze, 1988).

ity, and cost. All of these factors are part of the decision made on what the final etch would be for a particular step in the process. Most commonly used dry-etching techniques use a low-pressure gas in the form of a plasma, leading to the term "plasma etching" or more commonly "reactive ion etching" (RIE). A schematic of the chamber of a RIE system is shown in Fig. 17. The particular gases used in the RIE of various materials are shown in Table 2 (Sze, 1988), which illustrates the variety of chemical reactions necessary to obtain the correct etch characteristics. More details of these etching techniques can be found in PLASMA ETCHING.

3.5.3 Chemical Mechanical Polishing

A technique that has recently come into use in the VLSI silicon industry is the application of chemical mechanical polishing (CMP) to achieve a flat surface across the entire wafer. This is an important quality of the surface in order to insure that the photolithography tools can print the finest features on the wafer surface. The surface of the silicon starts out flat, but topography develops as the dielectric insulating layers are deposited on top of the patterned metal layers. These nonuniformities in the surface due to the successive layers of metal and dielectric can be removed by polishing the surface with equipment that holds the wafers against a rotating polishing pad that is wetted by a suspension of SiO_2 in a high-*p*H liquid. The polishing process removes the topography since higher pressure is applied to the elevated portions of the wafer than to the recessed portions.

3.6 Constraints for VLSI Manufacturing

3.6.1 Process-Control Methodologies

The ability to control individual process parameters to the degree necessary to insure adequate yield is referred to as process control. The ability to quantify process control is very important for the complicated processes required for ULSI silicon manufacturing. It

Table 2. Source gases used for reactive plasma etching of silicides, silicon, and SiO_2.

Silicides	Si	SiO_2
$CFCl_3$	Cl_2	CHF_3
CF_2	F_2	$CF_4 + O_2$
CCl_4	HF	$CF_4 + H_2$
$BCl_3 + Cl_2$	$CFCl_2$	$SiCl_4$
$CF_4 + O_2$	CF_2Cl_2	
SF_6	CCl4	
NF_3	$BCl_3 + CL_2$	
	$CF_4 + O_2$	
	SF_6	
	NF_3	

is particularly important to quantify the contribution individual process steps make to the yield of the total process. One methodology will be described here that is in widespread use throughout the industry. It consists of measuring many parameters and characterizing the statistical distribution of these parameters. The specific characterization employs quantities called process-control indices and denoted by C_p and C_{pk}. The basic definition of C_p and C_{pk} is described by first defining a few terms:

USL, upper specification limit. This is the upper limit of a process-parameter value that will still yield working devices.
LSL, lower specification limit. This is the lower limit of a process-parameter value that will still yield working devices.
USL − LSL = design specification width.

It is assumed that the distribution of the values for the process is Gaussian with a mean value of X. The width of the distribution can be described with the value σ. The definition of C_p is

$$\begin{aligned} C_p &= \text{(design specification width)/(process width)} \\ &= (\text{USL} - \text{LSL})/6\sigma. \end{aligned} \tag{11}$$

This is a unitless quantity that would have a value of 1 when the total specification range is equal to 6σ. This gives no information about whether the distribution is centered or not, and so another parameter, k, is introduced. This is obtained by use of a quantity C_{pk}, which is defined as the smaller of

$$C_{pU} = (\text{USL} - X)/3\sigma \tag{12}$$

and

$$C_{pL} = (X - \text{LSL})/3\sigma; \tag{13}$$

then

$$C_{pk} = (1 - k)C_p \tag{14}$$

where

$$k = \frac{\text{process shift}}{\text{design specification width}}.$$

Figure 18 shows a schematic representation of these parameters for a typical Gaussian distribution of data points. In a typical ULSI process sequence there will be well over a hundred parameters that are measured and evaluated. If one of these parameters has a distribution that yields a $C_p = 1$ and it is centered, then there would be 1350 ppm that would be out of specification due to that process step alone. In practice it is found that in order to manufacture ULSI silicon devices economically, process control must be such that a $C_p = 2$ is achieved with a $C_{pk} = 1.5$ or greater. This requires very tight controls on the process steps.

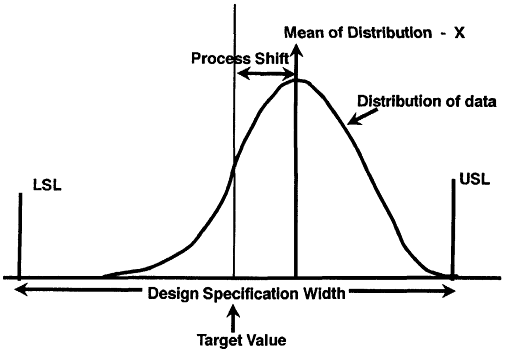

FIG. 18. Graphical representation of the components of the calculation of the process capability index.

A direction that will be common for the factory of the future is to have active control of the processes. This is used to compensate for the variation in the individual steps by adjusting subsequent steps. One example is shown in Fig. 19 in which the effect of active control is shown in one step of the process (Chattergee and Larrabee, 1993). This figure shows the result of having an active feedback for a particular step (polysilicon etching) that will adjust for differences in the material and etch rates. This allows the process-control problems of the polysilicon deposition step to be compensated for during the gate etching.

3.6.2 Defect Control Defect control is becoming the most important parameter in the choices made for the process sequences and the equipment selection. This means that much of the design and development resources go toward making the process as defect resistant as possible. Control of these defects has become one of the controlling

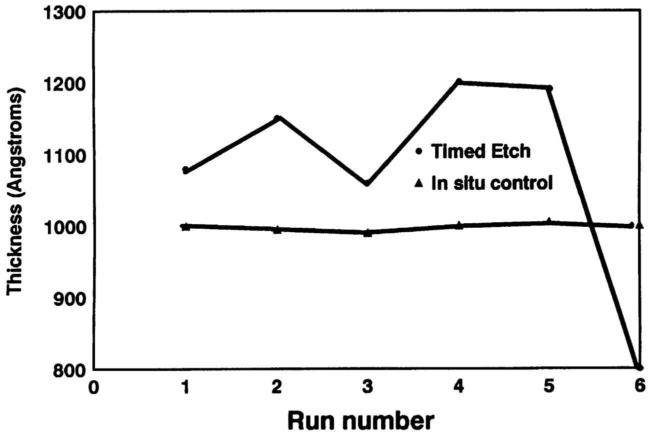

FIG. 19. Etch measurements for polysilicon etch for two different sets of runs without and with *in situ* control of the etch (from Chattergee and Larrabee, 1993).

parameters governing the rate of growth of the silicon device. Figure 20 shows the historical line of learning curves for a variety of memories (Stapper, 1990), which shows a curve of economic necessity that is needed to have a competitive manufacturing capacity. Over the last 10 years the necessity to control defects has required particle densities to be reduced by more than an order of magnitude. The size of the "killer defects" has also scaled with the minimum geometries, which compounds the problem, as shown in Fig. 21. Figure 21 also shows the detection limits that are currently limiting the ability to monitor defects during the processing. The detection limits are above the levels necessary to produce high yielding devices.

A table of defect mechanisms is shown in Table 3 to give an idea of how defects affect the yield of the process (Drum, 1991). This table shows the critical geometry present in a medium-sized VLSI circuit along with defect densities expressed in D_0 = defects/area and N_0 = defects/contact. The D_0 is set to 1/cm^2 or 1 ppm for contacts for this example. This is a technique that is used to model the projected yield of a device. This is done by determining the probability of the defect densities for each level of the process to cause a fatal failure. The yield loss of each individual mechanism may be quite small, but the product of these losses can result in yields close to zero.

This example shows that with one defect per cm^2 or ppm, the yield of a medium-sized

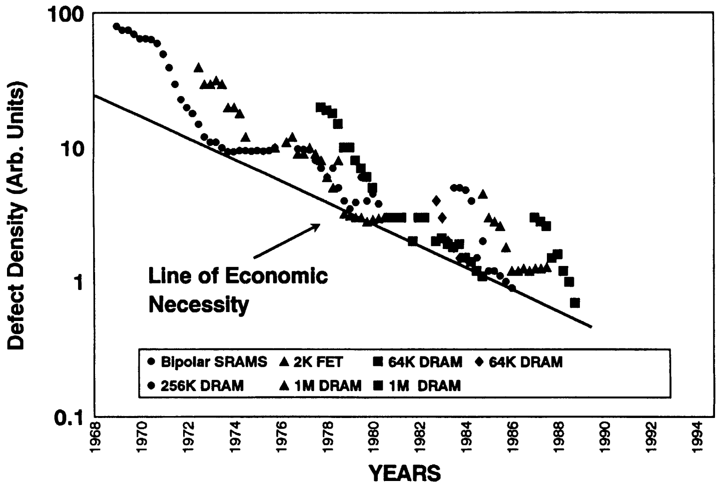

FIG. 20. Defects in memory production showing line of economic necessity for various generations of DRAMS (from Stapper, 1990).

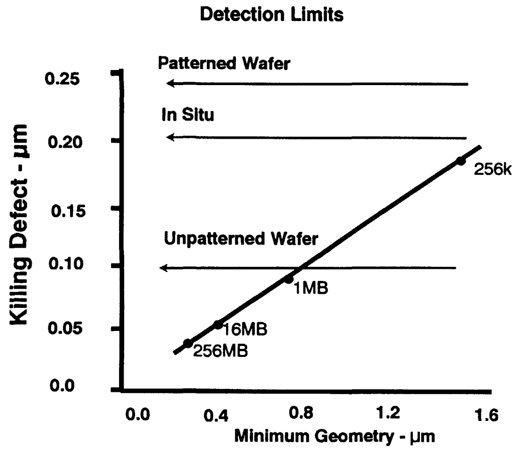

FIG. 21. Chart of the size of killing defects in the memory generations as a function of the minimum geometry. Detection limits are also shown for indicating current capabilities. (From Chattergee and Larrabee, 1993.)

circuit can be about 55%, which would not be acceptable for a modern manufacturing line.

The source of defects is changing as the geometries shrink. The dominant source of defects will be the equipment used to manufacture the devices and the processes chosen. The shift in sources of particles over the last 10 years is shown in Fig. 22 (Chattergee and Larrabee, 1993). The particles used to be coming from the people and the room. The problem is compounded by the fact that these smaller killer defects are more difficult and may be impossible to remove once they are attached to the silicon wafer. This requires the fundamental mechanisms of particle generation to be understood and controlled.

3.7 Reliability and Wearout

A discussion of VLSI devices cannot be complete without some discussion of reliability issues and wearout mechanisms. Although the materials used in making these devices are some of the most stable in the world, the fact that millions of devices are packed into a single area of silicon means that the one part per million failure mechanisms will be fatal for these devices. There are three main device wearout mechanisms that are a concern for silicon devices: hot-carrier charging, dielectric breakdown, and electromigration. These are all quite different in the physics involved but all result in a time-dependent failure mechanism.

3.7.1 Hot-Carrier Aging Hot-carrier aging is a problem for MOS devices where the gate oxide of the MOS device becomes charged by trapped charge at the interface of

Table 3. Yield loss for a medium-sized circuit showing the yield fraction loss for each type of defect. "Win" refers to the contact from the first level of metal (M1) to the silicon or the gate of the transistor. IL refers to interlevel shorts. Via is the connection between the first level of metal and the second level of metal.

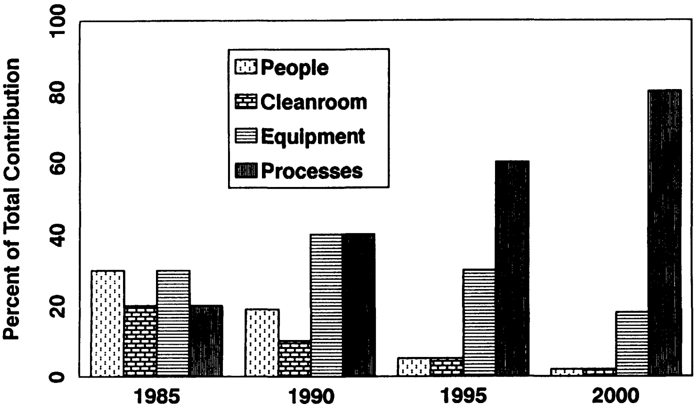

FIG. 22. Chart of the source of contamination over the last 10 years of manufacturing (from Chattergee and Larrabee, 1993).

the silicon and SiO_2. This problem arises as the device dimensions are reduced and the supply voltage is not reduced at the same rate. The lateral electric field generated in MOS devices increases, and if it becomes large enough, it can cause the hot-carrier effects. This has been a major concern in the design of VLSI MOSFETS. The problems associated with this effect are schematically shown in Fig. 23. The charge that is injected into the oxide in this situation can then cause a reduction in the V_t and the transconductance of the transistor. These changes can then cause the circuit to fail when these parameters fall below the values needed for proper operation.

One method that is commonly used to reduce the hot-carrier effects for the MOS devices is to introduce an extension of the drain region of the transistor, which has the effect of reducing the field in the drain region and therefore reducing the hot carriers. This extension is called a lightly doped drain and is schematically shown in Fig. 24.

3.7.2 Dielectric Breakdown Dielectric breakdown of thin oxides is a particularly important concern for the high-density DRAMS. The breakdowns that cause failure in these dielectrics are induced by electric fields. The breakdown can be an intrinsic property of the oxide film or can be due to small weak spots in the oxides caused by contamination, stacking faults, traps, asperities, etc. Any of these defects can cause a local minimum in the dielectric strength of the

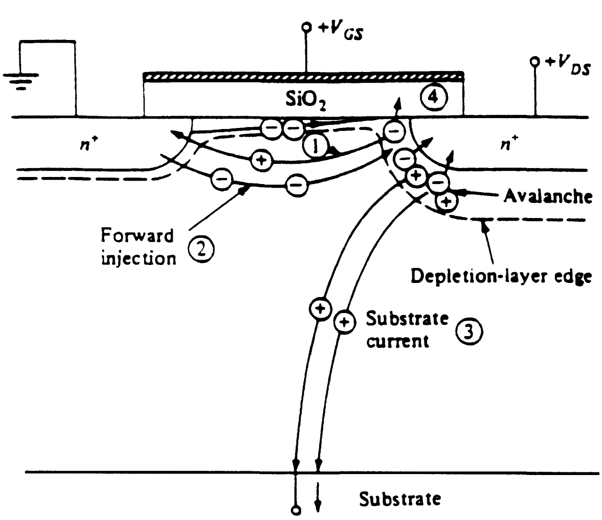

FIG. 23. Illustration of the generation of hot carriers in NMOS devices causing charging of the gate oxide.

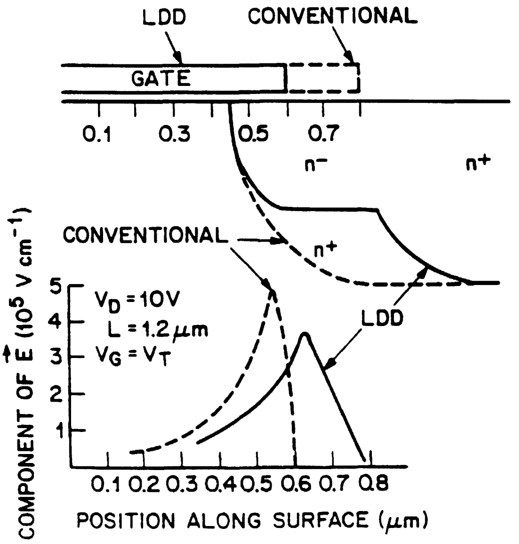

FIG. 24. Cross section of a device having an LDD structure and the electric field in the drain regions (solid lines). The dashed lines show the conventional device cross section and field. The *n*+ region for the conventional drain extends further under the gate than the *n*− region of the LDD structure. The *n*+ region of the LDD structure is formed with a mask (not shown).

oxide. These local minima will then fail in either a field-dependent or a time-dependent stress of the oxide.

3.7.3 Electromigration Electromigration is the phenomenon of movement of atoms caused by the collision of electrons with atoms. The material transport due to this movement of the atoms can cause voids to form in the metal lines used for the interconnect in modern silicon devices. This is particularly important in the modern VLSI devices, in which aluminum lines are used for the interconnect. The aluminum is gathered in the direction of the current flow, leading to a discontinuity in the current-carrying line. The transport mechanism can be much faster in thin-film aluminum lines than in the bulk metal because of the presence of grain boundaries, dislocations, and point defects. This rate of transport is therefore strongly dependent on the method of deposition, the alloying elements, the film thickness, and the temperature of the substrate during deposition.

Several techniques have been used to reduce the risk of failure of an aluminum line due to electromigration. One is simply to limit the current density of the aluminum lines as a design constraint so that it is always below the level to cause significant transport. This works but results in having metal lines that are too big. Another technique involves forming metal grains that have grain boundaries perpendicular to the current flow. This can reduce the electromigration effects but is quite difficult to implement reliably on a circuit. The most common technique is to form thin layers of a refractory material such as TiN on either the top, bottom, or both top and bottom of the aluminum lines. This insures that there is electrical continuity in the metal line even if there is a void formed in the aluminum.

4. APPLICATIONS

4.1 Memory Devices

The most widely used ULSI circuit application is the memory circuit. The memory circuit consists of many cells that store information in the form of individual binary bits. Memory chips come in a variety of forms but can be broadly grouped into three major categories: dynamic random-access memories (DRAM), static random-access memories (SRAM), and nonvolatile read-only memories (ROM). Nonvolatile memories come in programmable versions called PROMs, and electrically programmable versions called EPROMs, and electrically erasable versions called EEPROMs. Each of these types of circuits has specific uses, and in most computers and communication devices you will find all of these varieties used.

4.1.1 Dynamic Random-Access Memory (DRAM) Circuits A DRAM device is the most compact of all of the IC's and is the circuit that will be the first to take advantage of the advances in processing technology. The reason for this is that the basic building block of the DRAM circuit is the memory cell, which consists of a single transistor and a single capacitor. The basic structure is shown in Fig. 25. The cell is called a dynamic memory cell because the memory state is stored by charging the capacitor. The entire memory has to be periodically recharged to compensate for the loss of charge

on the capacitor and maintain the data. The advantage the DRAM has is that the cell can be made extremely small and therefore supply the greatest density of RAM.

4.1.2 Static Random-Access Memory (SRAM) Circuits Static random-access memories consist of a more complicated cell structure consisting of six transistors. The cell is static in that it does not require a refresh cycle to maintain the information. The state of the cell is maintained as long as the power is supplied to the circuit. The cell consists of two inverters, each consisting of an NMOS and a PMOS transistor, and two access transistors. The schematic is shown in Fig. 26(a). The function of the cell is to drive one inverter high and the other low or vice versa to produce the high or low (0 or 1) memory state. The advantage of the SRAM is that reading and writing of the cells can be done faster than can be done with a DRAM. The disadvantage is that the cell takes up more space and therefore allows for less memory per unit area of silicon.

The most significant processing difference between the SRAM technology and other ULSI technologies is the need for the compact six-transistor cell, which for the most modern devices requires the use of thin-film transistors (TFTs). These TFTs allow the six-transistor cell to be folded to allow the cell area to be reduced by stacking transistors on top of one another. The cross section of the cell that results from this arrangement is shown in Fig. 26(b).

4.1.3 Nonvolatile Memories Nonvolatile memories are able to maintain the information stored even after the power supplies are disconnected. This is achieved by particular structures that allow information to be permanently stored by programming the information at the point of manufacture. These devices are called read-only memory (ROM). Other ROM devices can be programmed in the field and these are called programmable ROM or PROM. PROM devices usually require links to be fused for the connectivity, but once the links are fused, the device looks like a ROM. The last category of nonvolatile memory is the erasable PROM or EPROM. These devices have another transistor structure that allows charge to enter into the dielectric of a MOS transistor, which causes the transistor to be permanently on. This information is maintained until the device is exposed to UV or x-ray light. Another version of an EPROM is the electrically erasable EPROM or EEPROM. This device uses a two-transistor cell that allows the cell to be selected and selectively erased.

4.2 Microprocessors and Logic

Other than memories, microprocessors (*q.v.*) and other logic devices such as digital signal processors (DSP), application-specific logic (ASIC's), and other random logic devices represent the largest fraction of silicon VLSI devices. A microprocessor is defined as a computer central processing unit built on one MOS or bipolar chip with a complexity of at least 2000 equivalent gates. The block diagram of a simplified microprocessor architecture is shown in Fig. 27. The specific requirement for a microprocessor that differs from those of the other applications is the need for low-resistance, high-density interconnects. This need results in a large effort devoted to the material and processing issues involved with making multiple levels of metallization that can interconnect the logic and can function with the minimum of signal delay and power dissipation. The basic technology used is almost entirely CMOS, and the building blocks are individual elements such as inverters; NAND, NOR, and shift registers; adders; and dividers. These are assembled in a complicated architecture that requires millions of transistors. The microprocessor is noteworthy only because of the role it currently plays in driving the technology complexity. Figure 28 shows the complexity increase of the Intel microprocessors over the last 25 years.

5. ECONOMIC ASPECTS AND INDUSTRY SCALING TRENDS

5.1 Device Scaling

The historic trends shown in Figs. 2 and 28 are driven by the economies and the demand for including more functionality on a device. The microscopic impact of this trend drives the device design to deal with the fundamental physical limitations of the materials and device function. This trend at the microscopic level is referred to as device scaling. The first treatment of this was described (Denard, 1974), as the scaling rule where the scaling factor S is shown to affect the MOS device parameters such that

Lateral dimensions $X \rightarrow X/S$
Vertical dimensions $Z \rightarrow Z/S$
Supply voltage $V \rightarrow V/S$

This results in the device/circuit parameters:

Gate delay $\rightarrow 1/S$
Capacitance $\rightarrow 1/S$
Power dissipation/device $\rightarrow 1/S^2$
Power density $\rightarrow 1$

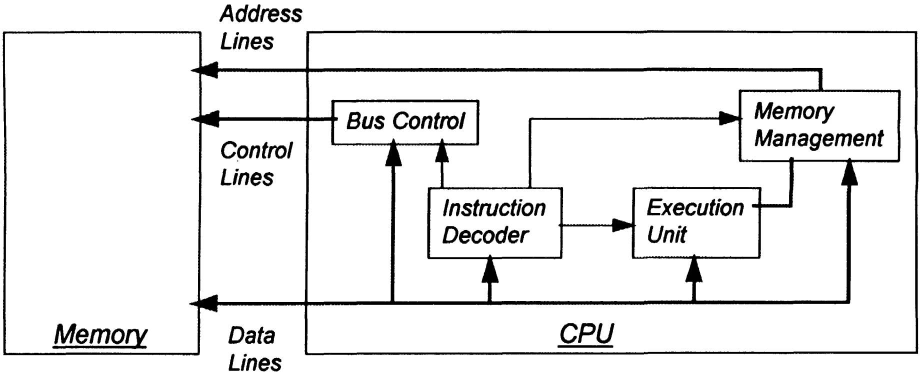

FIG. 27. Simplified block diagram showing the functions performed by a microprocessor.

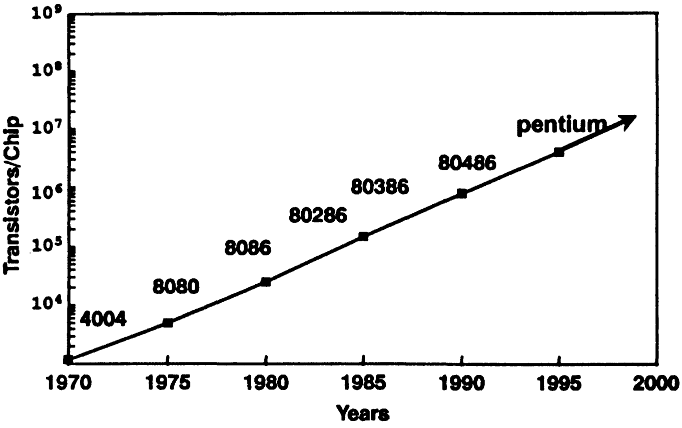

FIG. 28. Projection for transistor density on microprocessors from 1970 to 2000 (from Barrett, 1993).

Packing density → S^2
Speed-power product/device → $1/S^3$

The historic trend has not been toward this monotonic scaling of each part of the device but a scaling of lateral dimensions without a uniform scaling of the supply voltage. This is a result of the needs of the particular applications where the new devices needed to interface with devices from a previous generation and required the same voltages to be used between the chips. The power-supply voltages tended to be changed in steps as seen in Fig. 29. This caused the electric field in the devices (both across the gate oxide and in the drain region) to increase and made the reliability aspects of these high field effects dominate the trend in scaling the devices.

The trend in scaling is now becoming split into two major applications that have different sets of scaling goals. These applications are toward high-speed or toward low-power application. These two conflicting goals have been studied (Hu, 1994), and the studies show that the resulting scaling rules will be different. Projections for the impact that these different scaling rules have on device parameters such as $I_{d,\mathrm{sat}}$ and gate oxide thickness were made. These parameters will be the limiting cases for the ultimate scaling of devices and will determine the ultimate limits for either performance or power. Since these quantities can be individually optimized, the resulting devices will be different depending on the ultimate application.

5.2 Industry Scaling Costs

Although the functionality of the individual chips increases exponentially with successive generations of devices, the cost of

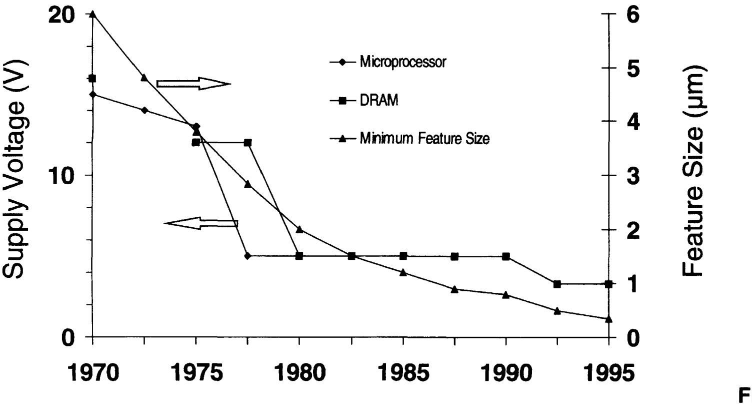

FIG. 29. Power-supply voltage reduction as a function of time.

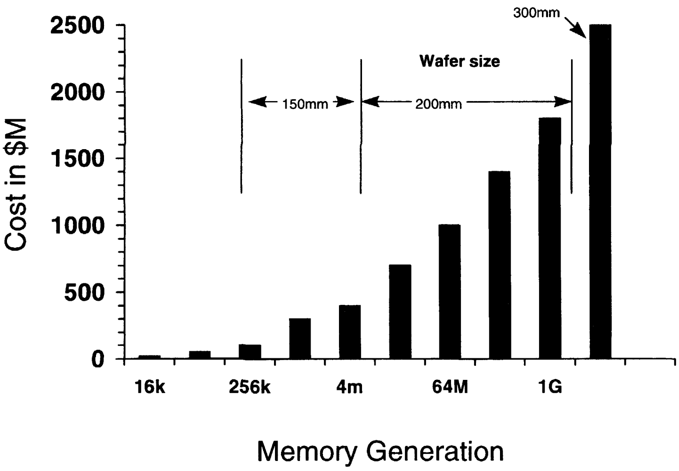

FIG. 30. Wafer fabrication costs as a function of the memory chip generations (from Chattergee and Larrabee, 1993).

manufacturing these devices also increases at an alarming rate. The reason for this is the fact that the individual pieces of equipment become more and more expensive as the technology becomes more complicated and the device dimensions become smaller. This requires the cost of a new manufacturing line to become greater and also requires the lines to be able to produce many more devices to pay for the huge capital investment. Figure 30 (Chattergee and Larrabee, 1993) shows the typical costs of a new line over the years. The cost has gone from about $\$1 \times 10^6$ in 1970 to about $\$1 \times 10^9$ in 1995. The huge costs of these fabrication facilities have driven many smaller companies out of the device fabrication business and create an environment where the device manufacturing for large-volume devices such as DRAM's are done in a few huge factories referred to as "Mega-fabs."

INTRODUCTION

Volcanology is the study of processes involved in ascent of magma to, and eruption onto, a planetary surface. Though waning somewhat from the early days of a planet-wide magma ocean, volcanism is still the dominant force in shaping Earth's surface: some 60% of Earth has been resurfaced by volcanism in the last 5% of the planet's history (Decker and Decker, 1989). As almost all of this new crust is covered by water, the abundance of volcanic activity on Earth is, if anything, underappreciated.

The processes that drive volcanism are fundamentally simple. Molten rock rises buoyantly from its melting source within the Earth because it is less dense than the col-

umn of solid rock it traverses. Volatiles, which become concentrated in magma during its formation, exsolve during ascent and can give rise to fragmentation during final decompression. This explains both the reason for eruption and the cause of its often explosive character (Fig. 1).

Volcanism in operation is complex, however, and produces a tremendous array of phenomena and deposits. The reason is that magmas are themselves complex. Even the chemically simplest magma, rhyolite, cannot be usefully described as less than a six-component system. Most magmas are intimate and dynamically changing mixtures of gas bubbles and multiple crystal phases in silicate melt. Magmas are subjected to a wide range of pressure and temperature conditions during ascent and eruption, to which their response cannot be described in wholly equilibrium terms. Understanding the behavior of magma during ascent, which is at the heart of volcanology, requires the combined insights of laboratory experiments, fluid dynamical modeling, and field observations. A thorough understanding of volcanic systems requires synthesis of results from geophysics, of which seismic, gravity, and magnetic investigations are generally most helpful; geology; petrology; geochemistry; remote sensing; theoretical modeling; laboratory simulation; and direct sampling by drilling.

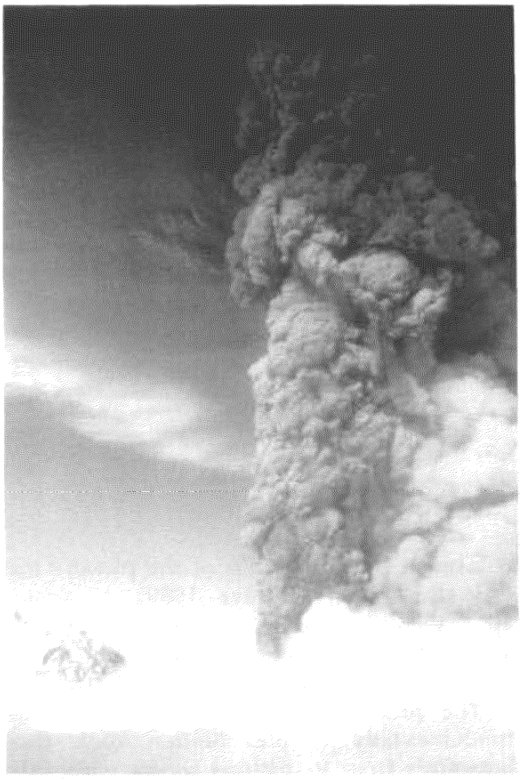

FIG. 1. Oblique aerial view of the 18 August 1992 eruption of Crater Peak, Mount Spurr, Alaska. The ash column is approximately 300 m in width at its base and, in its core, consists of a mixture of magma fragments and magmatic gas at about 1000 °C flowing at 100–300 m/s. Photograph by Robert McGimsey, Alaska Volcano Observatory.

Volcanism is important on a number of levels. From a basic scientific standpoint, it represents the transport of low-temperature–melting components to the planet's surface and must be understood in order to elucidate the development of Earth's crust, hydrosphere, and atmosphere. There are, in addition, several aspects of volcanism of immediate importance to society. Migration of fluids associated with volcanism results in economically important concentration of metals as ore deposits. Energy in the form of volcanic heat, or geothermal energy, is a viable and relatively nonpolluting source of power. Toxic volcanic emissions must be quantified in order to assess the seriousness of anthropogenic introduction of toxic materials into the environment. Volcanism may play a role in both short- and long-term perturbations in climate. Finally, volcanism has caused tens of thousands of deaths in the last few decades. The hazard to human life is increasing as populations living directly on active volcanoes increase and as the skies above even remote explosive volcanoes become crowded with large jet aircraft (Simkin, 1992; Casadevall, 1994). Our species is in fact fortunate that it has not experienced an eruption of the first order in its conscious memory. There was a time, however, when we were in an evolutionary "bottleneck" (e.g., Jones and Rouhani, 1986). How could a species destined to inhabit the Earth almost from pole to pole find itself so endangered? Perhaps it suffered a volcanic calamity in its volcano-rich African homeland. The impact need not have been direct. The relatively nonexplosive 14-km^3 Laki "fires" of Iceland in 1783 resulted in the deaths of over 50% of that island's livestock and 20% of its human population. We may be more shaped by seemingly esoteric natural forces like volcanism than we imagine. Volcanology can probably never mitigate the consequences of such a grand scale of disaster, but it has recently developed a predictive capability that is saving both lives and property during ordinary, "everyday" eruptive crises.

1. PROPERTIES AND PROCESSES OF MOLTEN ROCK

Magma can be defined as rock containing sufficient melt to be mobile. This is to identify it as the primary agent of mass transport in an igneous system and to distinguish it from static deep crust where some melt may be present but where large-scale flow is not occurring. Although melt is the defining phase of magma, it must be emphasized that magma refers to the entire system: entrained crystals and bubbles as well, not just the melt phase.

1.1 Composition of Volcanic Rocks

Because volcanic rocks are deposits observed to form from hot, molten material, they unquestionably form from magma. This material may or may not have changed in important ways since it was inside the Earth. The changes can be assessed by comparing characteristics of volcanic rocks that have experienced different rates of decompression and cooling. Pumice that emerges from the vent at velocities of hundreds of meters per second and is cooled in flight presumably represents magma that has seen the most rapid change to surface conditions of any samples obtainable: decompression in minutes to hours and cooling in seconds to minutes. Lava that emerges at centimeters per second and retains its heat in a slab tens to hundreds of meters thick as a tonguelike flow represents magma that has seen orders of magnitude slower decompression and cooling. Large intrusions that do not reach the surface but are later exposed by erosion may record the results of even slower rates of decompression and/or cooling. Inspection of these various deposits reveals that pumice gives a faithful (perhaps much inflated) view of magma as bubbles and crystals in melt that is now represented by glass (Fig. 2). The entrained crystals are called phenocrysts. Except for a chilled, glassy selvage, thick lava flows and shallow intrusions exhibit similar phenocrysts in a fine crystalline, rather than glassy, matrix. The normal inference is that phenocrysts represent crystals that grew from melt during pre-eruptive storage in a subsurface reservoir and that the fine matrix crystals grew after emplacement in the case of the relatively slowly cooled flow or intrusion interiors (McBirney, 1984).

A similar approach can be applied to bulk composition, in order to assess how closely bulk composition of volcanic rocks may reflect magmatic compositions. Among freshly erupted rocks, there appear to be no variations in major-element and nonvolatile-trace components that are correlative with decompression or cooling rates (e.g., Westrich *et al.*, 1988). Such concentrations apparently represent magmatic values.

The situation is quite different for volatile components. Water contents of fresh (unweathered) volcanic rocks are uniformly low. Exceptions are for magmas quenched to glass while still under high pressure such as in deep ocean or at the walls of conduits. Although low water contents of volcanic rocks could be interpreted as indicating that magmas are uniformly low in water, such a conclusion is at odds with known phase equilibria in silicate melts and with some direct evidence, as is discussed shortly. It is more likely, therefore, that water is lost almost instantaneously upon decompression and that magmas that reach the surface are anhydrous for that reason (Eichelberger, 1995). Chlorine concentration tends to be high in pumice, lower in glassy lava, and lower still in crystalline lava, indicating a relationship of its retention to decompression and cooling rates (Wolf and Eichelberger, 1996). Thus, from examining quickly cooled volcanic rocks, it is possible to determine directly the pre-eruption crystal and melt content and composition of the magma, though not the pre-eruption volatile content of the melt.

Volcanic-rock compositions are neither infinitely variable nor do they form discrete clusters. Rather, rocks associated in time and space—that is, those comprising a volcanic center—define chemical trends. Rocks of most volcanoes fall wholly within the basalt compositional field or within a portion of the "differentiated" basalt-andesite-dacite-rhyolite suite. Within this latter suite, as

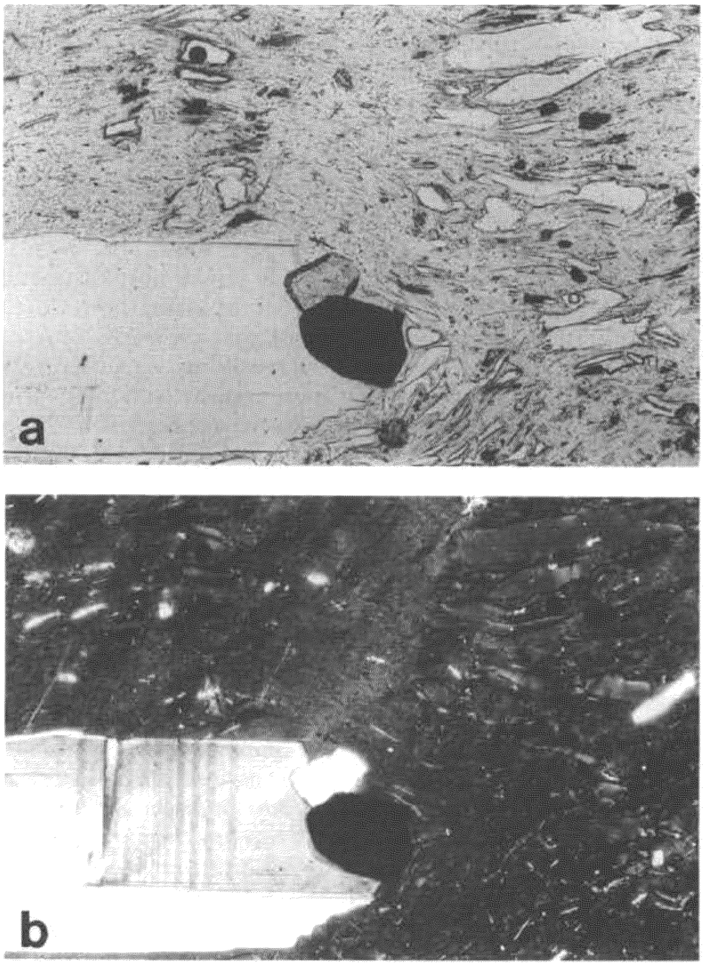

FIG. 2. Photomicrographs of Novarupta Dome rhyolite. The field width is 1.5 mm. The upper view is in normal transmitted light. In the lower view, polaroid filters above and below the same sample are crossed, so that only crystals that rotate polarized light are visible. From these photomicrographs of this quenched material, the three-phase (solid, liquid, and gas) character of magma is apparent. Gas bubbles (e.g., upper right) were inflated by exsolution of steam from silicate liquid during decompression. The matrix is glass (gray, upper view; black, lower view) that formed from melt upon rapid cooling during eruption. The large crystal at lower left is plagioclase feldspar that grew slowly from melt in the magma chamber prior to eruption. Smaller crystals are also of plagioclase and likely grew during ascent to the surface. Photograph by Daniel Wiesneth, Alaska Volcano Observatory.

SiO_2 content increases from about 48 to 77 wt%, the presumed direction of chemical evolution, CaO, MgO, and FeO decrease by an order of magnitude, and Na_2O and K_2O increase several fold. There is a corresponding variation in conditions and properties from hot and fluid to cool and viscous, which in turn have a profound effect on eruptive behavior. The chemical spectrum has classically been interpreted as representing a "liquid line of descent" from mantle-derived basalt by the process of fractional crystallization: growth and removal of crystals from melt. However, special water-fluxed mantle melting conditions, crustal melting, and crustal contamination may play a role in generation of the silicic members of the series (Hess, 1989). Peacefully flowing basalts, such as those of Kilauea Volcano, Hawaii, have long attracted the attention of volcanologists. In this century, disasters such as Mount Pelé in Martinique, the Valley of Ten Thousand Smokes in Alaska, and more recently Mount St. Helens in the United States, Mount Pinatubo in the Philippines, and Mount Unzen in Japan have drawn attention to the often-violently explosive silicic end of the chemical spectrum.

1.2 Melting Behavior

It is instructive to compare the melting of rock to the more familiar melting of ice. Water is a single-component system and consequently, at a given pressure, water and ice can coexist at only one temperature. Rocks are multicomponent chemical systems with more degrees of freedom. At a given pressure, melt and multiple crystalline phases coexist over a range of temperatures [Fig. 3(a)]. The lower temperature limit at which melt is present is the solidus, and the upper limit where crystals are present is the liquidus. Typically, there are hundreds of degrees Celsius between the liquidus and solidus, and most magmas exist in this "mush" state. A magma that is heated above its liquidus will merely dissolve its rock container until it has returned to solid-saturated conditions. Because the crystal and liquid fractions differ both in chemical composition and in physical properties, chemical fractionation can occur by phase segregation during storage or flow.

In contrast to ice, the melting of rocks involves approximately a 10% volume increase rather than a 10% volume decrease. This has two important consequences. First, silicate melts are buoyant within the Earth and tend to rise toward the surface. As mentioned before, this is the basic cause of volcanism and attendant planetary differentiation. Second, because increased pressure favors the solid (denser) phase, in the absence of effects of changing rock composition, temperature of melting increases with depth within the Earth.

Like water, silicate melt dissolves other chemical components and is therefore subject to freezing-point depression, where the solidification temperature is lowered with increased concentration in melt of a solute

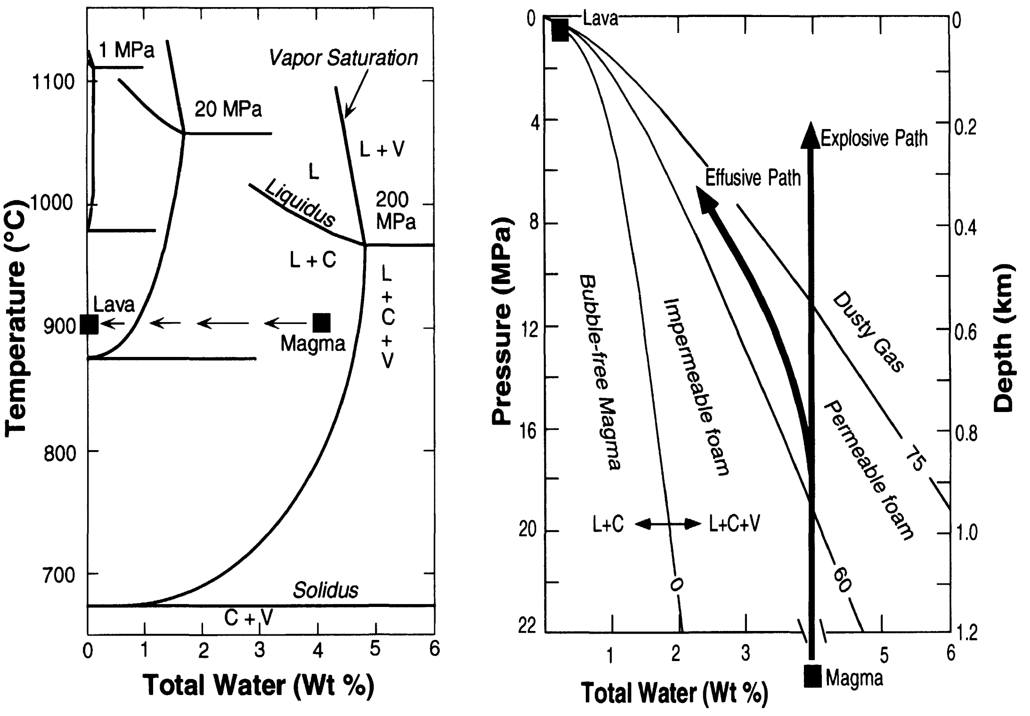

FIG. 3. Effects of water content and pressure on the crystal and bubble content of magma. (a) Phase fields (L = liquid, C = crystals, V = vapor) of silicic magma as a function of temperature and water content at pressures corresponding to depths of 8 km (200 MPa), 800 m (20 MPa), and 40 m (1 MPa) in the Earth. Pressure shifts the vapor saturation curve to higher water content and the solidus to lower temperature. At constant pressure, water lowers the liquidus. Note that loss of water during decompression causes magma to be below its solidus, that is, thermodynamically unstable at the surface. (b) Bubble content of silicic magma as a function of pressure and water content, assuming that the magma is crystal poor and that crystallization does not accompany water loss [violation of equilibrium assumptions of (a) but appropriate to most eruptions]. Curves are lines of constant porosity, as labeled. Solubility of water in melt decreases rapidly at shallow depth. Once exsolved, vapor expands inversely with pressure. 1 wt% water in melt produces approximately a 100-fold expansion of the system upon decompression to 1 atm. Removal of most of the vapor from the system is required for magma to emerge intact as dense lava (effusive path). After Eichelberger (1995).

that does not enter the solid phase. Water itself is highly soluble in silicate melt, and the addition of 1 wt% water to magma lowers the liquidus by tens of degrees Celsius. Because solubility of water in melt increases with pressure, the freezing-point depression effect increases with pressure, and both the solidus and the liquidus of the water-bearing system are shifted downward in temperature [Fig. 3(a)]. This may at first seem inconsistent with the expectation that pressure would favor denser crystals over melt, as was cited previously for dry melting. However, in the hydrous system, water is dissolved in melt when melt is present and free as vapor when melt is absent. The melt-bearing system therefore occupies less volume, and the stability of melt is enhanced by increased pressure as a consequence.

1.3 Volatiles in Melt

The presence of water and other volatiles in magmatic melt has another important effect: volatiles come out of solution and form a free vapor or gas phase during ascent. For most terrestrial magmas, water is the most abundant volatile component, and its solubility in melt decreases by two orders of magnitude from mid-crustal to surface pressures. The shape of the solubility curve, with the saturation value approximately proportional to the square root of pressure and hence of depth, is such that water is held in solution until shallow depth and then rapidly released with further decrease in pressure. 1 wt% dissolved water will produce roughly 100-fold expansion upon eruption. Given that water concentrations of a few to several weight percent water are thought to be common, it is easy to see that where a volcanic conduit constrains expansion to the vertical direction, very high velocities will be achieved. Consequently, exsolution and subsequent behavior of water vapor during ascent are the most important factors in determining the characteristics of an eruption (Sparks, 1978).

The fully expanded erupting material is no longer magma in the sense of having a continuous melt phase. Rather, it is a dusty gas, with a continuous vapor phase. The process by which melt-continuous magma becomes a vapor-continuous eruption plume is called fragmentation and results from a combination of coalescence and breakage of bubbles. Quenched, fragmented melt in the form of glass shards, as well as crystals from the magmatic suspension, constitute the small solid particles of the dusty gas and are known as ash. Larger, incompletely fragmented pieces of magmatic foam are pumice. About 75% porosity seems to be the normal limit of inflation without fragmentation, as represented by pumice [Fig. 3(b)].

At atmospheric pressure, the amount of water vapor required to inflate magma to pumice porosities is trivial, one or two hundredths of a weight percent. Given that this is three orders of magnitude less than the solubility of water in melt at the base of the crust, that water is likely present as hydrous minerals in magma source regions, and that water is strongly partitioned into the melt phase during magma formation (indeed, without the freezing-point depression effect of water, temperatures at depth may not reach the melting point), it might be expected that most magmas would contain significant water content and hence inflate and fragment to ash during ascent. A significant problem, therefore, is how to explain the intact emergence of initially hydrous magma as degassed lava in nonexplosive eruptions. The vapor pressure within entrained bubbles, which controls vapor–melt equilibrium, should be close to the pressure on the magma body, generally referred to as the lithostatic pressure (this may differ from fluid pressure in connected cracks outside the magma body, which will be less, often hydrostatic). If so, magma will not degas at depth to a vapor pressure lower than the lithostatic pressure it is under. But it also cannot emerge without fragmentation if vapor pressure is in excess of ambient pressure. It can therefore be inferred that some process of vapor–melt separation at shallow depth plays an important role in controlling whether eruption of ash or lava occurs.

1.4 Magmatic Properties

A number of important physical and chemical characteristics of magmas influence eruptive behavior.

1.4.1 Density Density of silicate melt is a strong function of composition and a weak function of temperature (Bottinga and Weill, 1970). Bulk density of magma is affected by these factors as well as the quantity of dense crystals and low-density bubbles entrained in the mixture. Although the coefficient of thermal expansion of silicate melt is quite small, it is large enough that even small bodies of viscous magma can be expected to convect (Bartlett, 1969). Because it is much smaller than the equivalent "coefficient of hydration expansion," the volume increase in response to introduction of water rather than heat into melt, heterogeneous distribution of dissolved water will tend to shut off convection (Shaw, 1974). Such magma will tend to stratify and stagnate with the wettest magma on top. Density-controlled stratification of magma in chambers has been suggested to explain chemically zoned eruption products and the most-explosive-first eruptive pattern of some volcanoes (e.g., Hildreth, 1981).

Most, but not all, magmas are less dense than the rocks they traverse during ascent. It may be that low-density continental crust acts as a density filter that discourages the rise of dense mafic, deep-seated magmas to the surface. If so, it is an imperfect one. Basalts do erupt through low-density continental crust, indicating that sufficient overpressure can be sustained within conduits to allow the magma to flow in artesian-well-like fashion.

1.4.2 Viscosity Viscosity of silicate melt is a strong function of temperature, water content, and silica content (Shaw, 1972). Silicate melt contains chains of silicate tetrahedrons. The longer these chains are, the more viscous the liquid. High silica content, low water content, and low temperature all favor polymerization. Thus, silicic magmas are more viscous than their hotter, more mafic associates unless these effects are offset by increased water content. Viscous magmas may be expected to rise more slowly and/or in larger bodies than fluid magmas. The most silicic magmas may sometimes rise as huge balloonlike bodies or diapirs many kilometers across, whereas mafic magmas often flow sheetlike through thin fissures centimeters to meters thick as dikes and sills (Fig. 4). High viscosity retards melt/crystal and melt/bubble segregation processes, reducing the amount of fractionation that can occur during a given storage or ascent time and requiring long times (thousands of years?) for evolution of silicic magmas.

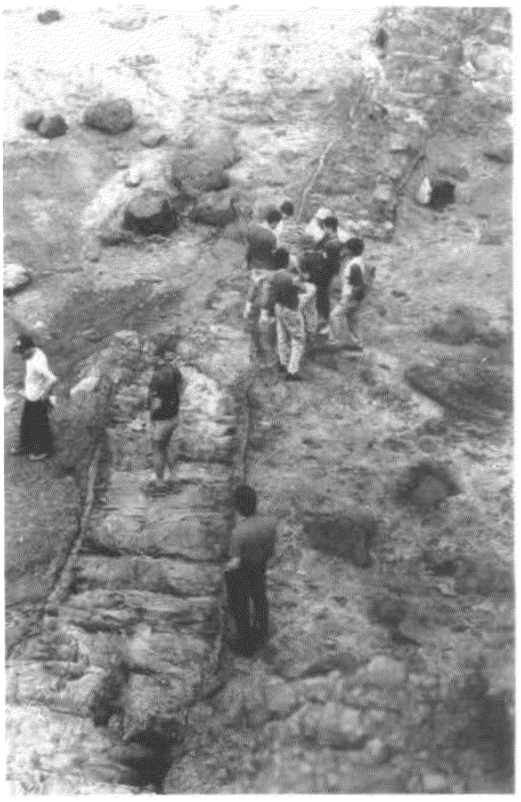

FIG. 4. An andesite dike cuts marine volcaniclastic rocks of similar composition. This exposure is on a wave-cut terrace on the coast of Hokkaido Island, Japan. Photograph by John Eichelberger, Alaska Volcano Observatory.

1.4.3 Bubble and Crystal Content Bubbles increase bulk viscosity of magma (Murase and McBirney, 1984) and represent a reservoir of gas available for instant expansion during decompression. Crystals increase bulk viscosity until they lock the melt in a rigid network of crystals (Marsh, 1981). There appears to be an eruption limit of about 50 vol% crystals in magma that represents onset of this immobility. Because most crystals contain little water compared to melt, crystallization concentrates water in the remaining melt. Where the solubility limit is exceeded, this causes exsolution of water vapor or "second boiling." Thus cooling, as well as decompression, causes vesiculation. This mechanism can produce very high overpressures in the crystallizing body, leading to dike injection, explosion, and/or intense fracturing (Burnham, 1979).

1.4.4 Mass and Thermal Diffusivity Water has the highest diffusivity of any major chemical component in magma, typically 10^{-7} cm^2/s (Shaw, 1974). Thermal diffusivity is about 4×10^{-3} cm^2/s (McBirney, 1984). The diffusivity of heat is therefore more than three orders of magnitude larger than the diffusivity of water. This means that magma bodies will always cool before significant long-distance diffusive chemical transport can occur. This results in the transformation, upon cooling, of melt to glass, and is the reason why chemical diffusion cannot operate over more than micrometer distances during an eruption.

1.5 Magmatic Domains

Although it is difficult to generalize over the entire spectrum of volcanic systems, it is possible to subdivide these systems into domains within which specific processes dominate (Fig. 5).

1.5.1 Source Region This is the domain of melting and melt coalescence. Depending upon whether melt is extracted immediately upon formation or lingers at its source until a critical melt fraction is reached, the chemical process may be described as fractional or equilibrium partial melting, respectively (McBirney, 1984). A melt-rich mass separates from a crystal-rich residue of the same temperature but of more refractory composition and rises diapirically (that is, balloonlike) through its plastic surroundings.

1.5.2 Storage Region(s): Magma Chambers Although magmas may rise directly from source to surface, they more often undergo substantial chemical modification by internal fractionation and external contamination en route. Such processes must be very slow, at least for silicic and therefore viscous magmas, and would seem to require protracted storage in a slow-cooling magma chamber. This ponding within the crust may occur when dense, unevolved magmas rise to their level of neutral buoyancy, or when diapiric ascent is stopped by the thermally controlled mid-crustal transition from ductile to brittle rock behavior. Natural exposures of deep levels beneath eroded volcanic systems

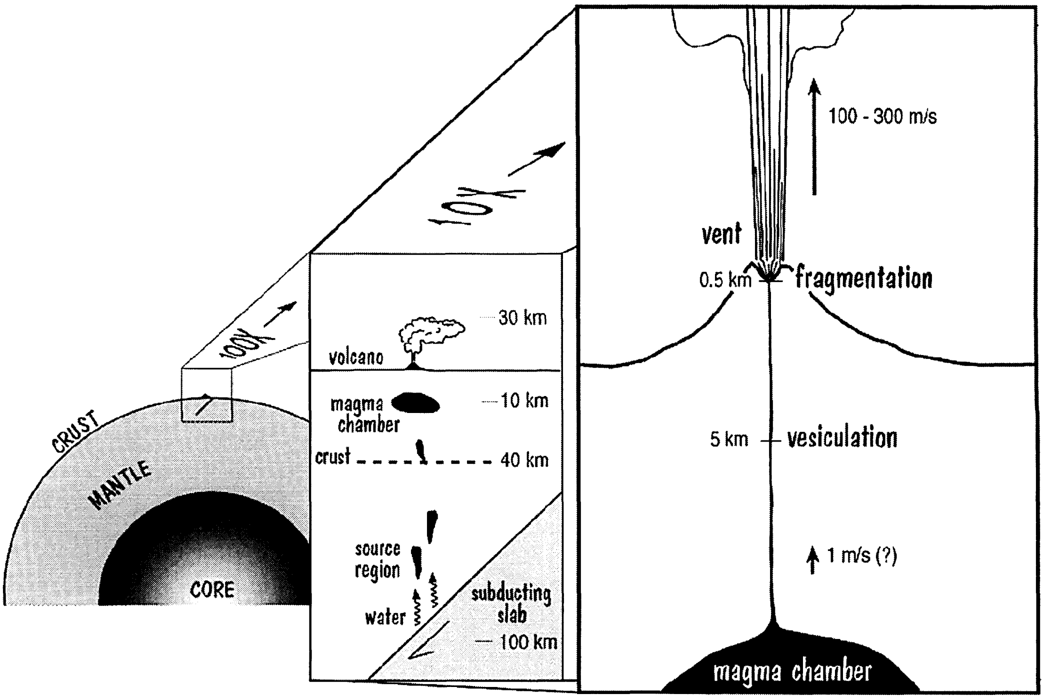

FIG. 5. Diagram illustrating the size relationships of parts of a subduction-zone volcano to the subduction zone and of the subduction zone to Earth. Figure by Deborah Coccia, Geophysical Institute.

provide direct geologic evidence of such features in the form of stocks or plutons—homogeneous or regularly zoned bodies of igneous rock that crop out over many square kilometers and lie in sharp contact with older host formations. Judging from eruption histories of volcanoes, storage times may range upward to hundreds of thousands of years. The chamber itself may last longer than magma within it; that is, it may repeatedly release magma to the surface and be replenished by magma from below. Little is known about the replenishment of such chambers, although petrologic evidence of mixing of primitive and reservoir magma just before eruption (Pallister *et al.*, 1992), together with supporting evidence from deep, magma-induced seismicity (White, 1996), suggests that replenishment may trigger eruptions.

Unlike the situation in the source region, crustal magma chambers will have a strong temperature contrast with the surrounding crust, and will therefore lose heat between replenishment events. This heat loss results in crystallization, which may in turn produce second boiling, overpressurization, and eruption (Tait *et al.*, 1989).

1.5.3 Shallow System: Conduit and Vent Upper-crustal portions of volcanic systems are frequently exposed by erosion and therefore are the portion about which there is the most direct information. This domain is characterized by extreme temperature contrast between magma and environment and by the possibility of direct interaction between magma and groundwater. Although a few volcanoes are open systems in constant eruption, most erupt episodically. They have repose periods of years to millennia interleaved with periods of activity, sometimes consisting of eruptive pulses lasting hours to days between comparable intervals of quiet. In most cases, then, the conduit is simply the preferred pathway for magma from source or holding chamber to surface, occupied by solid rock during repose. Although dikes would seem to be the energetically favored means of transport through cold, brittle crust and are indeed common, the form of shallow feeders ranges from dikes through elongate conduits to circular pipes (Carrigan *et al.*, 1992). Central, pipelike conduits of volcanic mountains are probably meters to tens of meters across.

Vents typically consist of a funnel-like flaring of the conduit toward the surface (Wilson *et al.*, 1980). This upward broadening can develop in three ways:

1. reaming of conduit walls as magma expands and accelerates during decompression,
2. slumping of shallow conduit-wall material into the open conduit during eruption, and
3. subsidence of the area surrounding the eruptive center due to withdrawal of magma from a chamber beneath it.

The first and second effects can be expected in small eruptions, whereas the third usually accompanies eruptions of a cubic kilometer of magma or more. Vents range in diameter from meters for fluid magma eruptions to kilometers for viscous, explosively erupted magmas. The largest structures associated with eruptions are tens of kilometers across, owe their form primarily to subsidence into a subjacent magma chamber, and are more properly termed calderas (Smith and Bailey, 1968). These may contain multiple, central post-collapse vents and/or a marginal circle of vents marking the ring fracture along which the magma chamber roof foundered. Doughnut-shaped "ring-dikes" of granite many kilometers in diameter, for example in the White Mountains of New Hampshire, may be the exposed intrusive roots of such systems.

In rising from a reservoir to the surface, magma rapidly encounters orders-of-magnitude changes in ambient temperature and pressure. Although many of the deep reservoir processes can be described in terms of phase equilibria, this is not the case in the conduit regime. Inspection of Fig. 3(a) shows that decompression will shift the solidus upward. Adiabatic rise of magma is close to isothermal (Rutherford and Hill, 1993), and so the solidus may well shift above temperatures prevailing in the magma during ascent. Thus, what erupts is actually a metastable, super-cooled liquid, and eruption requires that the rate of magma ascent outruns the kinetics of dewatering-induced crystallization.

1.5.4 Eruption Plumes Eruption plumes are an ephemeral portion of the volcanic system that penetrates the atmosphere during an explosive eruption (Fig. 1). The plume consists of magmatic gas, entrained crystals and quenched melt, condensates, vent-wall debris, and admixed atmosphere. A plume will ordinarily rise buoyantly to the tropopause, but convective thrust may carry it as high as 30 km. Plumes rapidly equilibrate thermally with the atmosphere, so that volcanic plumes that penetrate the stratosphere may actually be detected by satellite-borne infrared sensors as anomalously cold, rather than warm, clouds. After cessation of eruption and fallout of coarse material near the vent, the remaining ash cloud may remain as a coherent mass for days, drifting in air currents for tens of thousands of kilometers. Eruption plumes represent a significant contribution of particulate matter and gases to the atmosphere. If they reach flight levels, the resulting ash clouds pose a serious hazard to aviation (Fig. 6). If they are large, they may influence climate.

1.5.5 Surface Deposits Deposits formed when magma erupts can be naturally divided into those formed from magma that has fragmented upon eruption and those formed from magma that remained intact. The latter material is called lava. Depending upon viscosity, flux, total volume, and topography, lava flows may be meters to hundreds of meters thick and travel hundreds of meters or even tens of kilometers from their vents. Magma that does not flow outward appreciably forms a lava dome over the vent (Fig. 7). This often happens in the case of silica-rich magma. Heat is well conserved during extrusion of lava, so that flows and domes may remain hot for many months or years or even decades.

When magma reaches the near surface with external vapor pressure exceeding confining pressure, explosive fragmentation occurs. Some of the ensuing depositional processes are the same as those that form sedimentary rocks (Fisher and Schmincke, 1984). The extreme in energetic fragmental eruption produces a high-velocity eruptive column feeding a "mushroom cloud" of ash (Fig. 1). Fall-out from these cloud deposits comprises air-fall tephra. Such deposits are millimeters to tens of meters thick, blanket topography like snow, are size-sorted and crudely bedded, and may be traced to hun-

dreds, or more rarely to thousands, of kilometers from the vent (Fig. 8). Except near the vent, most such deposits are substantially cooled when formed, because of the descent of constituent particles through cold atmosphere.

Still fragmental but, in a sense, intermediate between lava flows and tephra falls are pyroclastic flows. These behave as a fluid, like lava, but consist of fragmental material (though not size sorted because they are turbulently mixed during flow) like air-fall tephra. Pyroclastic flows form when magma contains sufficient gas to fragment upon eruption, but not enough to thrust it forcefully upward into the atmosphere. They may also be shed from the sides of energetic eruption columns, or issue from collapsing, incompletely degassed domes. The result is a relatively dense (compared to the atmosphere) mixture of magma fragments and magmatic gas that generally follows topographic lows as it flows downhill from the vent (Fig. 9). Heat may or may not be well retained, depending upon distance of travel, thickness of the flow, and amount of mixing

with air. Where heat is retained, the hot glass shards of the deposit will flatten and stick together under self-load in a process called welding. This compaction is revealed clearly by the flattening of included pumice clasts. The resultant cohesive rock is termed tuff (Fig. 10). Where welding has resulted in a complete loss of porosity, tuff is easily mistaken for lava.

An additional important class of deposits in volcanic terranes are mudflows or lahars. These result from the unstable accumulation of volcanic debris around vents. Mixing with surface water from torrential tropical rain as at Pinatubo in the Philippines or with eruption-triggered melt water from alpine glaciers as at Volcano de la Ruiz in Colombia creates a mobile slurry. While cooler (sometimes cold) than lava flows, lahars tend to be more fluid and far-reaching, spreading destruction down valleys as far as hundreds of kilometers from their source.

1.6 Size of Eruptions

Eruption is really only the end-member case for shallow intrusive events, in which magma sometimes stops short of the surface. Thus, the low extreme in volume erupted during magmatic events is zero, but the high extreme is more interesting (Smith, 1979). Typical subaerial eruptions of the Pacific "Ring of Fire," such as Mount Unzen, Japan (1990–1995), Mount Spurr, Alaska, U.S.A. (1992), and Mount St. Helens, Washington, U.S.A. (1980–1986), are 0.01–1 km^3 dense rock equivalent (DRE). The largest such event during this century, described later in this article, occurred on the Alaska Peninsula in 1912 and is 13 km^3 in magma volume. Also noteworthy are the 3-km^3 eruption of Mount Pinatubo, Philippines, in 1991, the 13-km^3 Krakatau, Indonesia, eruption of 1883, and the 14-km^3 Laki "fires" of Iceland of 1783 (Francis, 1993). The largest prehistoric silicic eruptions known, as inferred from mapping of voluminous tuff sheets, are 1000 km^3, such as Pleistocene Long Valley Caldera, California, and Yellowstone Caldera, Wyoming, eruptions, to 5000 km^3, such as the 28-Ma Fish Canyon Tuff in Colorado (Lipman, 1984). Vast Precambrian rhyolite terranes speak of colossal but ill-defined eruptions in the dim past.

Formation of a 1000-km^3 welded tuff sheet requires the sudden emptying of a

Sintering of the glass and compaction or welding of the deposit under its own weight formed the hard, cohesive tuff. Photograph by Pavel Izbekov, Alaska Volcano Observatory.

crustal magma chamber with dimensions of order 10 × 10 × 10 km^3, although probably most are lenslike in form. That this actually happens is supported by syneruptive subsidence of the vent region to form a caldera of a volume comparable to that of the magma erupted. Thus, very large eruptions provide unequivocal proof of the existence of pluton-sized or even batholith-sized magma chambers (Lipman, 1984).

The largest cumulative volumes from multiple eruptions occur in the form of flood basalts, amounting to as much as a million cubic kilometers in less than a million years (Francis, 1993). Such volcanic provinces probably do not represent emptying of individual storage chambers, but rather rapid segregation of fluid melt from a huge mantle source volume.

2. FORMATION AND ASCENT OF MAGMA

2.1 Tectonic Localization of Volcanoes

A map of Earth's active volcanoes reveals that they are not uniformly distributed over the planet but generally occur in lines or arcs, with scattered outliers (Fig. 11). Some areas of the Earth have not experienced volcanism for a billion or more years. These areas correspond to the central regions of continents. By far, the largest class of volcanoes occur as a network of continuous ranges within the ocean basins, most prominently down the center of the Atlantic Ocean. The second most important class consists of a series of arcs that surround the Pacific Ocean and occur in a few other places as well. A third class occurs as chains, most notably the Hawaiian chain, that show a progression in age, so that one end is older and current activity is limited to the opposite end. Occurrence of these classes of volcanoes can be understood in terms of the plate-tectonics paradigm (Decker and Decker, 1989; PLATE TECTONICS).

2.1.1 Mid-Ocean Ridges Mid-ocean ridge volcanoes are almost entirely basaltic, with the exceptions of special locations such as Iceland. The total length of these ridges is 60 000 km or about 1.5 Earth circumferences. Few if any eruptions of these volcanoes perturb the ocean's surface, and so their importance is obscured. Being relatively volatile-poor magmas erupted under

high water pressure, ridge eruptions are effusive, and the lava flows produced are the primary constituent of the upper oceanic crust that floors the ocean basins. Associated shallow intrusive feeders and the crystallized source chamber comprise the crustal substrate. This dense, thin, and therefore topographically low crust covers about 60% of the planet (oceans lap onto the continental edges, and so cover a bit more, 70%, of the planet). Oceanic crust decreases in age from a maximum of about 200 000 000 years near some continental coasts to zero age at active mid-ocean ridges. This is known both from direct age dating and from a ridge-symmetric, mirror-image pattern of magnetic stripes on the ocean floor. Thus, the mid-ocean ridge volcanoes are responsible for generation of oceanic crust. Given that the crust averages about 8 km in thickness, this means an average production of magma of 20 km^3/year or 3×10^5 m^3/(km of ridge length)·year. Associated rates of crustal spreading range up to 10 cm/year. Such large-scale crustal motion is to be expected if the planet's skin rides on convection cells. Earth's upper mantle is apparently able to creep and thereby convect heat from the deeper mantle or core because it is near its melting point. The adiabatic lapse rate for mantle is considerably smaller than the rate of change of the mantle solidus temperature with pressure, and so a rising current of mantle material will undergo melting by decompression. The melt thus produced rises to the surface at crustal tears or rifts to produce mid-ocean ridge basaltic volcanism and generate a new crustal skin.

2.1.2 Subduction Zones If crust is being created from mantle at mid-ocean ridges, an equal area per unit time must be returned to the mantle, or subducted, elsewhere. The magnetic stripes on the ocean floor, which are isochrons of formation age caused by freezing-in of alternating polarities in Earth's magnetic field, are truncated at the deepest structures on the Earth's surface: ocean trenches. Intersecting the surface at these trenches are oblique planes of seismicity that extend to as much as 600 km depth and represent the deepest occurrence of brittle rock behavior in the Earth. The seismogenic zone coincides with the top of an inclined slab that exhibits anomalously fast transmission of seismic waves and hence is probably anomalously cold. From this, it is concluded that oceanic lithosphere (ocean crust and subjacent rigid mantle) is being thrust beneath another rigid plate with which it is converging. Where the collision is between a plate skinned with oceanic crust and one skinned with thicker and less dense continental crust, it is always the oceanic-crust-bearing plate that is subducted beneath continent-bearing crust. Inboard (continent-ward if collision is with a continent) of the trench and parallel to it, an arc of volcanoes is present on the surface. Often this line is quite narrow, as in the Aleutian Arc, and consistently overlies the ~100 km isobath on the subducting slab. Thus, subduction of the slab to some critical depth appears responsible for melt generation and volcanism. An exception is when the angle of descent of the slab is very shallow, as under the Alaska Range and parts of the Andes. Then, mountain building through crustal thickening, but not volcanism, occurs.

Subduction-zone volcanism is quite different from that of the mid-ocean ridges. It involves water-rich magmas, is consequently often explosive, and is on average more silicic in composition, although basalts are still present. Because the andesitic average composition of arc eruptives resembles the average composition of continental crust, it may be that arcs are the site of generation of new continental crust, just as mid-ocean ridges are the site of generation of oceanic crust (Marsh, 1979). Whether this is true depends on whether the silicic component of these arcs is newly derived from the mantle or merely recycled crust. Although the seismic and tectonic picture is quite clear, the petrologic picture is not. Subduction introduces a wealth of possible sources for melt generation: subducting mantle, subducting crust, subducting marine sediment, overlying mantle wedge, and overlying crust.

On the whole, subduction zones represent a cold rather than a hot region of the upper mantle. The planet's interior is being cooled here by introduction of cold crust. This is clear from thermal models and is shown by the anomalously deep earthquakes and high seismic velocities at depth (Marsh, 1979; Zhao *et al.*, 1995). These observations also show that thermal disequilibrium persists between slab and host mantle well past the depth of presumed melting. However, subduction does provide a route for introduction of water into the mantle. That this plays a role in melting is consistent with the water-rich character of subduction-zone magmas. Thus, it is logical to suggest that the profound freezing-point depression effect of subducted water is responsible for arc volcanism.

Direct evidence for rapid introduction of surface-derived volatiles into the mantle is provided by the presence of detectable ^{10}Be in these magmas (Morris *et al.*, 1990). Because ^{10}Be is generated only in the atmosphere and has a short half-life, its presence in subduction-zone magmas and apparent absence in other magmas is consistent with rapid (few million years) transport from surface to magma-source depth by subduction.

If water fluxing is responsible for melting, it likely causes melting in the overlying mantle wedge after release from the slab, rather than in the cold slab itself. Whether this primary melt is andesitic or is of basalt that later fractionates and/or causes additional melting in the crust to produce silicic associates is a matter of debate (Hess, 1989). Certainly, some role of crustal melting in andesite genesis is indicated by the correlation of the abundance of silicic volcanic eruptives with the continental character of the crustal substrate on which the volcanoes rest.

2.1.3 Hot Spots Trains of volcanoes that become regularly younger from one end to the other appear to represent the passage of a tectonic plate over a hot spot within the mantle. Hot spots are thought to reflect Earth-radial plumes arising from as deep as the core-mantle boundary (Sleep, 1992). The outstanding example is the Hawaii/Emperor Seamount chain, which ranges from zero age at the southeastern-most volcanoes of Loihi and Kilauea to 70-Ma Meiji Seamount, where the Emperor chain disappears into the Aleutian trench. The inferred rate of migration of the plate relative to the hot spot is 8 cm/year. Hot-spot volcanism is volatile poor and, in the ocean basins at least, predominantly basaltic. Like mid-ocean ridge volcanism, it most likely arises from decompression melting of ascending mantle. The relationship of such plumes to the large-scale mantle convection inferred from plate tectonics has not been satisfactorily resolved. Iceland appears to be a hot spot coincident with a mid-ocean ridge, and Yellowstone may be a plume impinging on continental crust, consequently causing crustal melting and voluminous silicic as well as basaltic magma production. Although this class of volcanoes is not as important as mid-ocean ridge and arc volcanoes in terms of total volumetric productivity, individual hot-spot volcanoes have the highest eruption rates of any volcanoes on Earth.

2.1.4 Other Occurrences Some volcanism does not fit neatly into the above categories but is usually associated with some sort of crustal deformation. Flood basalts may be the product of the initial arrival at the surface of the fattened head of a new mantle plume. Flood basalt provinces occur both on land in northwest coterminous United States, India, and Siberia, for example, and in the mid-Pacific as lava plateaus. Mafic volcanism behind volcanic arcs, known as back-arc volcanism, may reflect decompression melting in a small-scale mantle-wedge eddy, induced above the descending slab. Widespread, but infrequent and generally small-scale, volcanism in southwestern United States appears to reflect an exceptionally wide zone of crustal extension and shearing associated with the western transform boundary of the North American plate, perhaps inducing mantle diapirism and consequent decompression melting.

2.2 Ascent of Magma and Kinds of Eruptions

Although a few volcanoes, such as Kilauea Volcano in Hawaii, exhibit years-long periods of steady-state flow, most volcanoes are only intermittently active. The typical pattern for subduction-related volcanoes, Earth's dominant subaerial volcanic features, are repose periods of years to centuries interrupted by briefer episodes of multiple eruptive pulses. These magma systems are visualized as a balloon and straw, in which magma stored in a distinct chamber or diffuse mush zone is periodically tapped through a straw extending to the surface at the volcano's vent (Eichelberger, 1995). The straw or conduit is itself a remarkable feature, for it must be repeatedly reused to develop a volcanic mountain at the surface. Yet it is not an open pathway. In repose, it is filled with the solidified magma of the previous episode. Thus, rather than providing a weak route, the conduit may in some cases be stronger than its surroundings. Subsequent magma batches are guided by a common stress field and weak preheated pathway at depth, and perhaps the physical discontinuity represented by the cold conduit near the surface.

The episodic nature of volcanism may arise from the finite resistance of the system to magma flow, and the need to develop storage-region overpressure to overcome it. In detail, the cause of onset of activity is unknown, and may differ for the onset of an episode of activity versus a single eruptive event. One viable triggering mechanism is introduction of fresh primitive magma into the chamber. This suggestion, of course, merely moves the triggering problem deeper. Another possible trigger is second boiling. Crystallization of anhydrous phases, which must be occurring at the margins of a crustal magma reservoir, will necessarily cause exsolution of water vapor and, if chamber volume is held constant, high overpressure (Tait *et al.*, 1989). Triggering of eruptions by large earthquakes has been documented in a few cases.

One of the clearest demonstrations of an eruption trigger, though it does not explain the initial onset of the episode of rise of magma, is the 1980 Mount St. Helens eruption. Catastrophic failure of the volcanic edifice suddenly removed the confining pressure from a foamlike magmatic intrusion growing within the cone, causing it to explode (Eichelberger and Hayes, 1982).

Eruptions will stop when sufficient overpressure has been relieved in the source region or when enough lava has accumulated at the surface to balance the driving force of eruption (Jaupart and Tait, 1990; Stasiuk *et al.*, 1993). Both heat loss and water loss from the conduit, which act to cause crystallization of magma and increase viscosity of residual melt, will tend to stop flow. There may be a threshold flow rate required to offset these losses, below which the system locks up.

Regardless of why ascent to the surface begins, magma undergoes changes in response to the rapidly decreasing confining pressure and temperature of its environment. Release of water generally keeps pace with decompression, since nearly all eruption products are thoroughly dewatered. In contrast, crystallization lags such that dewatered melts may be erupted as supercooled liquids that congeal to glass, without any syneruptive crystallization at all.

Vesiculation of bubbles is an early effect of decompression, and one that can lead to violent explosive eruption. For a silicic, melt-rich magma containing 4 wt% water, bubble growth will begin at about 4 km depth (Sparks, 1978). By the time the confining pressure has declined to 100 bars, the vapor will occupy about 75 vol% of the system [Fig. 3(b)], a porosity typical of pumice. As mentioned previously, it is thought that further expansion then occurs by fragmentation to a dusty gas. This rock particulate/gas mixture is able to expand far more than the gas would by itself, because of the large amount of thermal energy contained in the entrained rock particles and their intimate contact with the expanding gas. If pressure and chemical equilibrium are assumed, with vapor pressure equal to the lithostatic load on the system, the 75% limit of bubble expansion would be reached, and fragmentation would occur when the magma ascends to about 500 m depth. There are, however, a number of untested assumptions in this scenario, and it may be that fragmentation actually occurs deeper or shallower. Laboratory experiments that simulate fragmentation by subjecting synthetic magma or analog fluids to sudden decompression may eventually solve this problem (Alidibirov and Dingwell, 1996).

If magmas often contain several weight percent water and closed-system decompression to one atmosphere pressure produces hundreds-fold expansion, then open-system behavior is required to explain effusive eruptions or lava flows. That is, a large amount of vapor must be separated from the magma prior to extrusion. The alternative is that effusive eruptions are the product of eruption of initially dry magma. In view of the petrologic similarity that coeruptive effusive and explosive eruptions products have in all aspects other than mode of eruption and the drastic effect that water has on phase equilibria, this seems unlikely. Rather, it appears that effusively erupted magmas must have begun with water contents similar to their explosive associates, and lost water such a short time before surface quenching that these losses are not reflected in the phase assemblage. The process must indeed be shallow, efficient, and rapid, because at plausible ascent rates of the order of 1 cm/s, magma with a few weight percent water would traverse the vapor-saturated pressure domain to the surface in hours or, at most, days.

That magmas can behave as open systems during the last few kilometers of ascent is suggested by permeability measurements and isotope-exchange experiments on pumice. It is also suggested by patterns of the variation of hydrogen isotopic composition in explosive to effusive eruption suites that are indicative of melt/vapor fractionation (Eichelberger, 1995). Permeability develops because the crowded bubbles in the magmatic foam begin to interconnect. Thus, there is a transition state between melt-continuous, closed-cell magmatic foam, and gas-continuous magmatic dusty gas in which both the melt and gas phases are continuous. To escape from the system, water need only diffuse micrometers out of melt into the nearest bubble, where it can flow as a vapor over meters to the margin or top of the conduit.

Attempts have been made at modeling this complex process. It seems clear that just as narrowness of conduit and conductivity of wall rock favor cooling, narrowness of conduit and permeability of wallrock favor degassing. Further, the more slowly magma rises, the more likely porous-flow degassing can keep pace with declining confining pressure, so that excess vapor pressure does not develop and fragmentation and explosive ejection do not occur. Other characteristics of lava as opposed to tephra, such as larger reaction rims surrounding hydrous phenocrysts in dewatered melt, higher matrix crystallinity, and lower chlorine content as compared with explosively erupted associates, are most easily explained as a consequence of slower rise of effusive magmas (Rutherford and Hill, 1993).

In accord with these observations, it may be that ascent velocity of magma is a fundamental controlling factor in eruptive behavior. At high ascent rates, neither degassing nor crystallization occurs, and explosive showers of fragmented glass are produced. At moderate ascent rates, degassing occurs but outpaces crystallization, so that glassy lava is extruded. At still slower ascent rates, both degassing and crystallization occur, with the result that partially crystalline domes appear. Ascent rate itself is in turn controlled by conduit size, magma viscosity, and chamber overpressure. Because of these relationships and contrary to common expectation, explosive volcanism is not limited to viscous silicic magmas, nor is effusive eruption to fluid mafic ones.

3. SOCIETAL IMPACT

3.1 Geothermal Energy

Associated with shallow magma chambers are subsurface reservoirs of natural steam or of superheated water (Smith and Shaw, 1975). If the energy content is sufficient, steam from these reservoirs can be used to run turbines and to generate electricity. If not, the steam or hot water can be used directly for space heating. Geothermal energy production offers greatly reduced CO_2 and SO_2 release compared to the burning of fossil fuels and is particularly attractive when fossil fuels are not locally available.

The United States, Philippines, Mexico, Italy, Japan, and New Zealand are the largest producers, in that order. Growth in use of this resource is limited by its rather restricted geographic distribution; the fact that in most cases it is not economically competitive with fossil fuels; and environmental concerns pertaining to noise, release of toxic gases, potential for damage to natural hydrothermal phenomena such as geysers, and aesthetic considerations. In regard to the latter, most active volcanic fields possess scenic and recreational values as well as geothermal potential and are often protected with park status. Indeed, objectives of productivity, preservation, research, and enjoyment are often at odds in volcanic areas (Eichelberger and Sattler, 1994). Nevertheless, geothermal energy is being vigorously pursued where it is a matter of national policy to lessen dependence on other energy sources, as in Japan.

3.2 Climate

The impact of volcanism on climate is one of the most interesting, important, and contentious topics in volcanology. It is interesting because it has likely shaped the past, and may shape the future, of humankind. It is important today because it is the only volcanic hazard that is global in extent and from which, therefore, there is literally no escape. It is contentious because cause and effect in climatic perturbations are very hard to assess, and once assessed they are laden with political implications concerning industrialization, have and have-not nations, and governmental intrusion into the private sector. It would be reassuring to know that all important sources of pollution and "global warming" are natural, beyond our control, and therefore without moral implications. This is not the case. However, neither is it the case that present and future climate anomalies can be attributed solely to humankind fouling its own nest.

Research into volcanic effects on climate has been driven by two factors. One is the anecdotal association of major eruptions with "strange" weather. Among the first to suggest a relationship between volcanism and climate was Benjamin Franklin who, while U.S. Ambassador to France, speculated that the faint sun and poor visibility in Europe in 1784 were caused by a voluminous eruption that was ongoing in Iceland (Francis, 1993). Icelanders were probably more convinced: they lost a quarter of their population and half of their farm animals to the ensuing famine and volcanic fluorine-induced toxicity. Denmark, which then ruled Iceland, considered evacuating the entire island. Suspicions of climatic influence have likewise been entertained following the 1813 eruption of Tambora in Indonesia, the 1883 eruption of Krakatau also in Indonesia, the 1912 eruption of the Valley of Ten Thousand Smokes in Alaska, and the 1991 eruption of Pinatubo in the Philippines. None of these, however, are within even an order of magnitude of the size of the largest eruptions that have occurred since *Homo sapiens* has been extant (Rampino and Self, 1993).

A second driving force in the study of volcanic effects on climate is the evaluation of the role of catastrophe in shaping life on Earth. The fossil record makes it clear that Earth has experienced several mass extinctions of species. The most obvious possible cause is global climate change, for which the source must be either within the planet or without. In particular, a great debate has flourished about the sudden end to the 60-million-year reign of dinosaurs. Present evidence, in the form of global dispersal of meteorite-abundant material at the stratigraphic level of the extinction and identification of a huge crater buried under the Yucatan Peninsula of appropriate age, favor the threat without. But the debate has shown large-scale volcanism to be of potentially serious impact to life worldwide (Rampino *et al.*, 1988).

Establishing a correlation between size of an eruption and perturbation of climate in a rigorous way has only recently become possible. It relies on satellite observations of atmosphere loading from large events and myriad surface and satellite-based observations of surface conditions. Some of the results of these investigations are counterintuitive.

Modest to large volcanic eruptions produce an ash veil that shrouds the Earth. Obviously, such a veil reflects solar energy, and so can cause cooling. However, it also acts as a blanket that rejects heat loss. Those who live at high latitudes can appreciate that there is little to be lost from diminished sunlight in winter, which is already minimal or nonexistent, but much to be gained from a blanket on a dark, several-month night. Thus, an early effect of great eruptions is warm winter temperatures at high latitudes. A longer-term effect is decreased solar input and consequent general cooling.

A number of parameters other than eruption size affect impact. Ash and gases play separate roles. The former affects planetary albedo, while the latter, especially SO_2, which forms H_2SO_4 aerosols, affect atmospheric absorption of incoming and reradiated solar energy. Low latitude of an eruption site facilitates global dispersal, whereas emissions from high-latitude volcanoes spread more slowly. Only those eruption plumes that penetrate the stratosphere, where high-velocity horizontal winds predominate, are likely to have widespread climatic effects. An exception is when emissions at low altitudes are sustained, as in Iceland's Laki "fires" of 1783 to 1784.

The largest eruptions since reliable, well-distributed weather records have been kept are several to ten cubic kilometers in magma volume. The only such "large" eruption that has occurred since satellite observations began is Mt. Pinatubo in the Philippines in June 1991. Various analyses place the long-term cooling effect of this size class of eruption at a few tenths of a degree Celsius and the immediate high-latitude winter warming effect at about a degree (Bluth *et al.*, 1992; Graf *et al.*, 1993). Although these changes seem slight, effects on length of growing season may bring significant consequences to humans.

But what of truly great eruptions of thousands of cubic kilometers of magma? The ash fall alone from such events would be catastrophic on a continent-wide scale, and the atmospheric effects would be comparable to the much-feared "nuclear winter." It is postulated that such eruptions could globally reduce daylight to about the brightness of a full moon, halting photosynthesis (Rampino and Self, 1993). Although the fervor for attributing mass extinctions to such events has subsided, their possible triggering of swings in glaciation remains intriguing. Moreover, severe impact to the populations of geographically restricted species, such as early hominids in East Africa, is possible. Such impacts might explain the "evolutionary bottlenecks" that our ancestors appear to have suffered. At least roughly coincident with the most recent bottleneck and the subsequent explosive expansion of *Homo sapiens* out of Africa was the 3000-km^3 eruption of Toba in Indonesia 74 000 years ago (Stringer and McKie, 1997). Perhaps even more basic to our existence, the very origin of the family *Homo*, the break with the family *Pan*, has been credited to the rise of the volcanic East African Rift, providing a barrier to migration and to climate (Coppens, 1994). *Pan* kept to the trees in the lush forests of the west, but *Homo* developed bipedal talents in its drying preserve to the east.

3.3 Volcanic Hazards

The potential for catastrophe was mild in the days of Pompeii compared to what it is today. Humankind is no more able to control volcanic forces than it was 1900 years ago, but orders of magnitude more people and property are at risk (Decker, 1986). Millions of people live on active volcanoes and millions more fly within range of potentially lethal ash clouds every year. Two rather small eruptions this century each killed almost 30 000 people, and civilization has not yet experienced a large eruption near a major population center. The possibility of small undetected eruptions from remote volcanoes is, for the first time, another cause for concern. An eruption-caused crash of a wide-bodied jet, while not as catastrophic as the destruction of a town or city, is a very serious event and a plausible one, given, for example, the invasion of North Pacific air routes by ash clouds on average four days of the year (Miller and Kirianov, 1995; Fig. 6). Ash clouds cannot be distinguished from weather clouds on aircraft radar and can cause engine failure due to abrasion and/or coating of engine parts.

Concern for volcanic hazards is now the largest driving force in the field of volcanology. Numerous governments and academic institutions have set up observatories for the dual purposes of monitoring volcanic events to mitigate hazards and of studying eruptions to understand magmatic processes. Emphasis has grown on investigating the shallow ascent and eruptive behavior of magma and on interpretation of surface deposits in order properly to assess hazards and identify precursory signals of eruption. As a result of this work, remarkable three-dimensional views of active magma systems have been produced.

4. FORECASTING ERUPTIONS

One of the most important achievements in volcanology in recent years is development of the capability to predict eruptions (Decker, 1986; McNutt, 1996). This capability is a useful but still a somewhat limited one. Although it is often possible to warm of the onset of an episode of activity, later eruptive pulses within an episode sometimes lack recognized precursors. It is seldom possible to determine when an eruptive episode has ended, information that could be as important to local residents as sensing its beginning. Finally, it is generally not possible to predict whether an imminent eruption will be explosive or effusive, or indeed whether the magma may stop just short of the surface as a shallow intrusion. The latter situation leads to troublesome "false-positive" results.

4.1 Characteristics of Useful Predictions

To be useful, a forecast must be accurate and specific. Inaccurate warnings may more than offset any benefits of correct ones. If vague, decisions to suspend or move affected activities cannot be implemented. For example, it does little good, other than for general readiness, to know that there is some possibility of an eruption in the next ten years. Once a warning of imminent eruption is issued, costly measures such as rerouting aircraft, suspending business and agriculture, and caring for evacuees must be undertaken. For minimizing economic losses, it is therefore essential that serious warnings be lifted as soon as the danger has passed.

4.2 Methods of Monitoring and Prediction

Although some observatories predate it, the idea of permanent stations from which to monitor active volcanoes came into its own following the obliteration of the town of St. Pierre by Mount Pelé on Martinique in 1902. The modern era of volcano monitoring began with the explosive eruptions of Mount Usu in Japan in 1977 and of Mount St. Helens in the United States in 1980. By this time, computer systems were able to process large amounts of data rapidly, and governments were willing to commit substantial resources to natural-hazard mitigation. The use of dense seismic networks on suspect volcanoes emerged as the primary tool of prediction, although other kinds of observations remain important.

4.2.1 Eyewitness Reports More than 1900 years after Pliny the Younger's account of the eruption of Mt. Vesuvius, eyewitness records are still the most useful information source for understanding eruptions. Such observations can be used as a predictive tool in the case of large eruptions where precursory ground shaking and cracking may be severe, or when eruptions are preceded by steam emission. Large explosive eruptions and their aftermath are best viewed from space, as lofted ash soon obscures proximal views. Thus, we have only obtained a complete picture of such events in the era of satellites.

Visual observations must be evaluated carefully. Even knowledgeable observers may mistake weather clouds for eruption clouds or old volcanic features for newly formed ones. Remotely placed and telemetered television cameras are very useful where it is impractical or dangerous to station human observers.

4.2.2 Seismology An obvious indicator that an earthquake may be of magmatic origin is that it occurs directly under a volcano (Fig. 12). Swarms of high-frequency earthquakes herald the rise of magma. They are caused by breakage of cold rock just outside the conduit or magma chamber as these structures deform with the movement of magma. Because these events involve brittle rock and therefore low temperature, a surface of seismicity enclosing an aseismic vol-

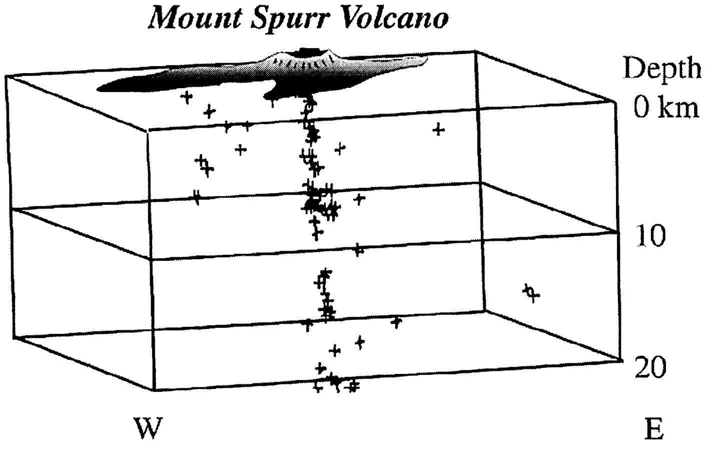

FIG. 12. Seismic events (crosses) beneath Spurr Volcano, Alaska, during its 1992 eruptive episode define the position of a magma conduit that leads from the base of the continental crust (40-km depth) to the surface (Power *et al.*, 1995). Figure by Gail Davidson, Alaska Volcano Observatory.

ume is evidence for a magma chamber. However, some high-frequency, tectonically induced events unrelated to magma movement occur beneath volcanoes. Volcanic earthquake swarms differ from tectonic swarms in that the largest events may occur anywhere in the swarm rather than at the start. In the tectonic case, much of the activity is "aftershock."

The most robust seismic indicators of impending eruption are low-frequency earthquakes and harmonic tremor (Power *et al.*, 1994; McNutt, 1996). Low-frequency events appear to arise from transient pressure pulses due to sudden release of magmatic or hydrothermal fluids (Chouet *et al.*, 1994). They accompany resonance of fluid flowing rapidly in pipes or cracks. During or sometimes just before eruption, these may punctuate or blend into a continuous signal with peak amplitude typically near 2 Hz, the constant humming that is volcanic tremor.

Precursor seismicity may occur over a period of days or even years prior to eruption. It may increase in intensity and decrease in depth. This is not necessarily the result of the slow fitful journey of a single magma body to the surface. Even at the beginning of eruptions following lengthy precursor activity, fresh-appearing magma giving no evidence of shallow storage may emerge. Rather, shallow pre-eruption seismic swarms may reflect repeated damming of intrusive pulses by the cold, water-soaked "lid" of the system (Eichelberger *et al.*, 1995). For reasons not yet understood, seismicity may also begin at shallow depth and progress to include deeper levels, until the entire conduit is seismically illuminated (Fig. 12).

If patterns of seismicity were regularly repeated, then eruption forecasting would be a simple matter and other tools would not be needed. However, this is not the case. Seismic crises occur at volcanoes without accompanying eruptions. Conversely, eruptions occur without recognized precursory seismicity. It is evident that magma can move without generating seismic events, perhaps when using preheated pathways. Sources unrelated to magma, such as hydrothermal systems, tectonic stresses, glaciers, and sea ice cause seismicity at volcanoes. Added to these complications are logistical considerations. Remote volcanoes are difficult to monitor seismically because of access, power, and data transmission requirements. Nevertheless, where seismic monitoring is feasible, it is relied upon as the first warning of unrest.

4.2.3 Geodetic Measurements Early surveying on Kilauea Volcano showed that volcanoes inflate prior to eruption and deflate during eruption (Decker, 1986). Inflation is thus a sign of impending activity, though, like seismicity, not an infallible one. Not all cycles of inflation and deflation are associated with eruption. Alternating pressurization and depressurization of a hydrothermal system are implicated in some cases (Fournier, 1989). However, coincidence of seismicity and inflation in time and space is strongly suggestive of magma migration. In addition, geodetic data constrain the volume of newly emplaced magma and can be inverted to estimate the location of the center of the inflating or deflating volume (e.g., Rundle and Hill, 1988). As a monitoring tool, geodetic measurement is undergoing a revolution because of changes in techniques. The original approach, surveying, was tedious and labor-intensive. The advent of public access to the Global Positioning System (GPS) made rapid measurement at multiple surface points relatively easy, and even real-time, seismic netlike, geodetic monitoring feasible. Still more recently and currently under development, interferometry using images from active synthetic-aperture radar (SAR) satellites has been applied to produce maps of centimeter-scale deformation covering entire volcanic fields (Lu *et al.*, 1997).

4.2.4 Gas Measurements Because gas is released from rising magma and can flow much more rapidly than the magma, it is natural to consider the surface emission of magmatic gases as a precursor to eruption. Unfortunately, there are many reasons why magmatic gas may not reach the surface and why, even if it does, it may not be identifiable. Magmatic gas undergoes a series of chemical reactions when passing from magma to a cooler environment (Symonds *et al.*, 1994), must follow a tortuous path to the surface, and will likely encounter a hydrothermal system during ascent. In many cases, the dominant magmatic volatile component is water that can only be distinguished from groundwater by its isotopic composition. Even then, the introduced magmatic component may be of such small volume relative to near-surface water that any shift in isotopic composition of springs or fumaroles due to rise of magma may not be detectable.

Carbon dioxide is relatively abundant in magmas and insoluble in water. Carbon dioxide emissions from magma, distinguishable in isotopic composition, have been detected with some success (Casadevall *et al.*, 1983). Unfortunately, carbon dioxide is also relatively insoluble in magma at crustal pressures and hence may be released while the magma is still at great depth. Its usefulness as a sign of imminent eruption is therefore limited. At this writing, release of carbon dioxide from a relatively deep intrusion beneath Mammoth Mountain, California, is killing trees and small animals over an area of many acres (Hill, 1996).

For using gas measurements to guide eruption forecasts, most successes to date have come from measuring SO_2 emissions. SO_2 is relatively soluble in magma at crustal pressures, so that close approach to the surface by magma is required for its release. Unfortunately, SO_2 is also highly soluble in water, so that it can be "scrubbed" from the magmatic gas stream by an intervening hydrothermal system (Doukas and Gerlach, 1995). High rates of SO_2 emission can therefore be taken as a sign that magma is approaching the surface, but low rates of emission do not necessarily mean it is not.

Measurement of SO_2 can be done remotely through spectroscopy because SO_2 is a strong absorber of ultraviolet light. Before or after eruptions, real-time estimates of SO_2 flux from a volcano can be obtained by combining wind-velocity data with ground or airborne spectroscopic observations. After an explosive event, an estimate of total erupted SO_2 in ash clouds can be obtained from satellites that were originally intended to measure concentrations of another UV-absorber, ozone. For example, from such data it was determined that the June 1991 eruptions of Mount Pinatubo in the Philippines released 2×10^7 tons of SO_2 (Bluth *et al.*, 1992), an amount that approaches the order of annual global anthropogenic production.

4.2.5 Geology As in the case of weather forecasting, persistence of a trend is a likely scenario. A volcano is likely to erupt in a way that it has been erupting during the most recent portion of its history (Decker, 1986). There are, of course, spectacular examples of failure of this guide, such as the 1912 eruption of the Valley of Ten Thousand Smokes in Alaska and the 1980 eruption of Mount St. Helens in Washington. In the current absence of better understanding, however, it is best to use seismology to sound the alarm and geology to suggest the likely course of events. Two parts of the geologic record must be considered. One is the volcanic edifice itself, which contains the entire history of the volcano, though often concealed by ice or young eruptive deposits. The other is the far-field tephra stratigraphy, which sometimes provides a more accessible record. It may also be a more datable record, if, as is common at lower elevations, the deposits are intercalated with or incorporate organic debris. To be useful, such stratigraphy must be positively tied to a particular volcano, a difficulty in volcanic fields where eruptive centers are closely spaced and of similar composition. This is often accomplished through use of mineralogical or trace-element clues. Even a good tephra sequence, say from sediments in a lake neighboring a volcano, will be incomplete, as it will only contain products of eruptions that had an explosive component, and then only major eruptions under conditions of certain wind directions. Small events, which nevertheless could significantly disrupt modern society, may leave little or no geologic record. In addition to establishing at least a lower limit on the frequency of activity, geologic observations can establish what areas around the volcano are at risk during an eruption from such hazards as pyroclastic flows, lahars (mudflows), debris avalanches, and lava flows. It is clearly wise to prepare maps of hazard zones in advance of eruptive activity, so that they can be used to advantage in the ensuing civil emergency.

4.2.6 Remote Sensing Because of the difficulty of access of many volcanoes, reliance on various satellite-based techniques may be required for monitoring them. It is weather satellites that are most often used for this purpose, as they provide frequent and thorough aerial coverage, though not with high resolution. With pixels of the order of 1×1 km^2, the typical volcano occupies only a small part of the image. Weather-satellite infrared data are useful for two purposes. One is detecting hot spots. Eruption products and erupting vents are hot, though they may be obscured by already cooled ash-cloud tops. Heating may significantly precede eruption, as magma rises within the cone. As with the rise of magmatic gas, however, it is not always a reliable indicator of impending activity. Magma flows much faster than rocks conduct heat, so that pre-eruption surface heating requires fortuitous convective transport of heat by water or gas.

Infrared data have also been found to be useful in distinguishing ash clouds from weather clouds after the cloud has left the vent and become translucent (Wen and Rose, 1994). The presence of ash in a cloud causes changes in the spectrum of infrared radiation that is emitted from the Earth's surface and passes through it. This is important because cloud plumes of purely meteorological origin are common in mountainous terrain. Hot-spot and ash-cloud detection are primary techniques of eruption confirmation, however, not of forecasting. The technology of detecting eruptive events by satellite has much in common with problems of detection of nuclear blasts, missile launches, wild fires, and anthropogenic pollution events.

4.2.7 Other Techniques A variety of other approaches have been applied to volcano monitoring with varying degrees of success. Ash eruptions are often accompanied by lightning, and so lightning-detection systems can be useful in confirming eruptive activity (Paskievitch *et al.*, 1995). Ground-based radar can see eruptive columns, but usually only the coarse, near-vent portion during actual eruption. Eruptions release acoustic energy as well as seismic energy, and this can be detected through the atmosphere by means of pressure transducers (Buckingham and Garcés, 1996). A particularly interesting and innovative suite of physical measurements was obtained in the recent eruption of Unzen Volcano, Japan (Yanagi *et al.*, 1992). This eruption was amenable to close observation because it was long-lasting and highly accessible, occurring in an almost urban setting.

5. CASE HISTORIES

Any theory of volcanism and any response to volcanic hazards must take into account the basic characteristics of volcanic activity. The following chronologies present examples of the events surrounding large (10^3 km^3), medium (10^1 km^3), and small (10^{-1} km^3) eruptions. These chronologies also show contrast in the kind and level of detail they contain. The first case is wholly reconstructed from the geologic record, though the current state of unrest of this volcano is cause for concern. The second is reconstructed from accounts of lay observers and from geological exploration beginning soon after the eruption. The last case is of an eruption of the modern era of instrumented volcanoes.

5.1 Long Valley Caldera, California

Among large continental volcanic systems, the Long Valley Caldera–Mono Craters volcanic complex in eastern California (Fig. 11) is one of the most thoroughly studied (Bailey *et al.*, 1976; Rundle and Hill, 1988). It is also presently the most active silicic system within the contiguous United States. Its most recent major eruption occurred only 550 years ago, and there is a possibility that a minor eruption occurred beneath Mono Lake in 1890. Beginning in October 1978, a sequence of moderate earthquakes occurred northwest of Bishop, California, spreading northward to Long Valley Caldera and southward into the Sierra Nevada mountains. Four of these events had magnitudes larger than 6.0. Recurrent swarms followed. Suspicion that this activity could be linked to the movement of magma arose when it was discovered that the central caldera region was undergoing rapid, blisterlike uplift and extension amounting to several tens of centimeters. A swarm beneath Mammoth Mountain on the southwest caldera rim was accompanied by the dangerously increased and continuing CO_2 emission cited earlier (Hill, 1996).

This volcano has experienced more seismicity, surface deformation, and gas emission than many volcanoes that have progressed from such signs of shallow magmatic intrusion to violent eruption. Even a small eruption would have serious social and economic impacts at the town of Mammoth Lakes, California, located within the caldera. A further reason for interest is that this volcano has produced gigantic eruptions in the past, including an eruption so large that ash beds from it are preserved in the mid-continent. The caldera may mark the site of a large modern magma body in the crust.

Long Valley Caldera lies astride huge, steeply inclined faults of the east front of the Sierra Nevada block. There can be little doubt that it owes its existence to the rise of magmas along this fault zone, though the broader issue of the volcano's relation to plate tectonic forces is problematic. The site became a locus of basaltic to andesitic volcanism 3–4 million years ago. Beginning about 2 million years ago, high-silica rhyolite flows and tephra began erupting from what is now the northeastern margin of the caldera. These products, which accumulated in substantial volume, appear to mark the development of a long-lived, chemically evolved magma chamber in the upper crust and set the stage for what was to follow. That silicic volcanism lagged behind basaltic and andesitic volcanism is a common pattern and suggests that the crust had to be thermally prepared for the establishment of such a reservoir by the rise of hotter, mantle-derived magmas. At 760 000 years ago, a catastrophic eruption of high-silica rhyolite began in plinian (so named because of Pliny the Younger's description of the early eruption column from Vesuvius in 79 A.D.) fashion as a vertically directed high-velocity flow from a central vent, causing widespread tephra fallout. Enough magma was withdrawn that the roof of the magma chamber soon foundered, and a ring fracture around the roof block ripped open (Hildreth and Mahood, 1986). The character of the eruption changed, and pyroclastic flows swept outward from the open ring vent toward the lowlands. In total, some 1000 km^3 of magma erupted, probably within a period of days or weeks. The roof block subsided about 2 km and, with the inward slumping and erosion that followed, left a caldera basin that is 20 $\times$ 30 km^2.

Was this eruption merely the skimming of a volatile-rich top, perhaps the upper 10% (Smith, 1979), of an even larger magma body that continues to evolve to this day, or did it completely exhaust the crustal supply of magma then existing? The answer is not clear. Persistent silicic volcanism associated with the caldera and some geophysical evidence suggests that such a large chamber still exists, but drilling to more than 2 km depth in the center of the caldera has failed to find the heat flow expected above a long-lived shallow heat source.

Following caldera formation, volcanism waned with smaller (though still substantial) rhyolite eruptions of increasing crystallinity. The system was apparently thermally rejuvenated 200 000–100 000 years ago when basaltic to andesitic magmas rose under the caldera and flooded its western floor. With the coming of late Pleistocene to Holocene time, crystal-poor rhyolites are once again being erupted, and the development of a large new crustal chamber whose heat has not yet reached the surface is a plausible, though by no means proven, scenario.

5.2 Valley of Ten Thousand Smokes, Alaska

By far the largest eruption of this century burst from the Mount Katmai region in the Aleutian Arc on 6 June 1912 (Hildreth, 1983). The site was among a cluster of imposing andesitic volcanic cones near where the Alaska Peninsula connects with the Alaska mainland. It may be that focusing of heat in the crust, as represented by this cluster, led to the silicic and voluminous character of the subsequent volcanic activity. But there was no prior hint of the cataclysm to come. A geologist who visited the site in 1898, 14 years before the great eruption, pronounced the volcanoes "inactive." The "persistence of a trend" guide for forecasting would have failed completely in this case, as the size, violence, and composition of the eruption were unprecedented for the district in which it occurred. So large was the eruption that, despite its extreme remoteness at the time, it became famous throughout the world and sparked some of the scientific debates that frame modern volcanology.

Seismicity in the weeks preceding the eruption was of such intensity that residents of the villages of Savinoski and Katmai Bay had evacuated by the time the eruption began. Consequently, there were no known casualties. The first and only reliable direct eyewitness report came from the ship Dora, sailing in the Shelikof Strait about 100 km to the east. At 1 p.m. on 6 June, passengers sighted an "immense" ash column ascending into rare blue sky above the Aleutian Range. This column likely reached 30 km altitude and, within a few hours, engulfed the Dora and then the town of Kodiak, 160 km from the eruption site. Most other eruption accounts are of the ash fall at Kodiak, which was cloaked in choking darkness for the next 60 h. Records from Kodiak and careful field work near the volcano make it possible to reconstruct the main aspects of the eruption (Hildreth, 1983, 1987; Fierstein and Hildreth, 1992).

The eruption site was not Mount Katmai, the prominent peak of the region that lost its summit in the event and that early workers held responsible, but a new vent that opened 10 km away at the base of neighboring Trident Volcano. The initial activity was the extremely powerful, vertically directed eruption seen by the Dora. This early stage was entirely of a crystal-poor, high-silica rhyolite, a magma type almost unknown in the Aleutian Arc and more commonly erupted from volcanoes of continental interiors. The ash column rose into the stratosphere and then spread out as a mushroom cloud that was stretched rapidly by strong northwest winds toward Kodiak, where fallout ultimately reached 30 cm in thickness. Within hours, dense mixtures of ash and gas began surging outward from the margin of the vent and sweeping down a broad glacial valley as pyroclastic flows. A combination of reaming and slumping of the vent formed a funnel-like structure of perhaps a kilometer in depth but at least a kilometer in surface radius. Growth of this hole undermined an adjacent, 700-m-high dacite dome, which partially collapsed into it. The pyroclastic flows lost energy as they flowed down valley and were in part dammed by a glacial moraine about 20 km away. The resulting tuff sheet attains a thickness of some 200 m in the upper valley (Fig. 10).

Sometime around midnight on 6 June, the eruption changed. Rhyolite was joined by crystal-rich dacite and andesite, apparently mixing together both in the conduit and after fragmentation within the eruption column. The source of this new influx of magma is clear, because at about the same time seismicity intensified and debris flows were shed from the towering Katmai cone. Mount Katmai began a fitful collapse, with most of the subsiding summit volume disappearing into the emptying subjacent magma chamber. The eruption became less energetic and soon ceased, but it resumed again at about noon on 7 June, this time with a plinian eruption of dacitic pumice and ash with subordinate andesite and virtually no rhyolite. Another similar pulse followed on the night of 8 June. This ended the explosive activity, but soon thereafter, a small rhyolite dome, Novarupta, emerged at the center of the vent crater (Fig. 7).

Altogether the eruption released about 30 km^3 of pumice and ash, equivalent to about 13 km^3 of bubble-free magma, in less than 60 h. Half this volume is represented by the extensive air-fall tephra deposits and the other half by the tuff flooring of what became known as the Valley of Ten Thousand Smokes. The volume of Mount Katmai lost in collapse, and now partially refilled by a spectacular caldera lake, is equivalent to about half the erupted magma volume. Through this catastrophe, Trident Volcano remained a close but innocent bystander (although it effused a half cubic kilometer of chemically distinct andesite and dacite lava rather placidly during the 1950s). This one huge eruption at Novarupta exhibited almost the entire common range of eruptive behavior and magma chemistry and produced a volume equivalent to that of a moderate-sized volcano in a single very short event. It demonstrated the close spatial, and therefore by implication the close chemical, relationship of contrasting magma types. It showed that even andesitic volcanoes that commonly produce small-volume eruptions sometimes have large-volume crustal magma chambers. Finally, by the 10-km separation of the sites of contemporaneous eruption and collapse, it showed the remarkable subsurface mobility of even silica-rich magmas. The system remains seismically active, and there is geophysical evidence for a large volume of magma remaining at shallow depth beneath the volcanic cluster (Ward, 1991).

5.3 Crater Peak, Mount Spurr Volcano, Alaska, 1992

Short explosive outbursts typify many volcanoes of the Pacific rim. While they leave little by way of geologic record, they can nevertheless be quite disruptive of human activities. One such eruption occurred recently at Mount Spurr, which lies 125 km west of Anchorage near the northeastern end of the Aleutian Volcanic Arc. The volcano is

100 km above the top of the subducting slab and 500 km inboard of the Aleutian Trench (Zhao *et al.,* 1995) on a basement of mainly intrusive rocks (Nye and Turner, 1990). Its large edifice, built of andesite lava and tephra, began to form more than 250 000 years ago. A few tens of thousands of years ago, the volcano collapsed in Mount St. Helens fashion, forming a 25-km-long debris avalanche and leaving the volcano with a horseshoe-shaped caldera rim. A large andesite dome complex, which now forms Mount Spurr's 3374-m summit, grew within the caldera about 5000 years ago. The presently active eruptive center, the 2309-m Crater Peak, is a more mafic satellitic cone that grew in the caldera's breach. This vent has produced about 40 recognizable tephra deposits in the last 5000 years (Riehle, 1985). Eruption products that are apparent mixtures of Crater Peak and summit-dome complex magmas indicate that the two systems are connected at depth despite the 4-km separation of their respective vents.

Prior to 1992, the only witnessed eruption of Mount Spurr had occurred on 9 July 1953. This eruption also issued from the Crater Peak vent and consisted of two explosive pulses, followed by steam and minor ash emission (Wilcox, 1959). In June, August, and September of 1992, short, violent eruptions each produced about 50×10^6 m^3 of tephra, each representing roughly 15×10^6 m^3 of magma. Ejecta ranged from proximal bombs to distal ash comprising narrow bands of fallout extending downwind (Neal *et al.,* 1995). Save for a tens-of-meters westward migration, vent geometry changed remarkably little during the episode.

5.3.1 Eruption Chronology Early indication of unrest at Mount Spurr was a conspicuous swarm of earthquakes during the last half of August 1991 (Eichelberger *et al.,* 1995). Unlike swarms that had occurred in 1982 and 1989, this one was directly under Crater Peak within a volume that had been aseismic for at least a decade, and it was followed by caldera-wide seismicity. By February of 1992, seismic activity had increased to such a level that discussions of Mount Spurr's unrest were included in weekly public updates from the Anchorage- and Fairbanks-based Alaska Volcano Observatory (AVO), which operates a seismic net on the mountain. By early June, AVO seismologists concluded that the seismicity was caused by intrusion of magma into conduits below Crater Peak and the summit-dome complex, and associated readjustments along caldera faults. AVO advised government agencies, communities, and the aviation industry to review plans for coping with an explosive eruption.

The number of earthquakes strong enough to be located peaked at 28 per day on 5 June and then declined to about three to six events per day. Volcanic tremor began on 6 June, and aerial observations on 8 June revealed upwelling in the crater lake, which had turned in color from green to gray. As many as 24 shallow tremor bursts per day, each burst lasting 1 to 10 min, were recorded at stations within 10 km of Crater Peak from 6 to 26 June (McNutt *et al.,* 1995). On 11 June, a field party measured a lake temperature of 50 °C and observed geysers erupting intermittently at the base of the crater wall.

5.3.2. 27 June 1992 Eruption Seismic behavior changed ominously on 24 June with occurrence of hours-long periods of tremor. AVO's weekly update on the morning of 26 June reported "well above normal" seismic activity but still cautioned that an eruption might not be imminent because low-frequency earthquakes, indicative of fluid flow at depth, had not been detected. Aerial observations of the crater revealed that the lake had almost completely drained or evaporated and that several large rocks had been ejected from the vent. That afternoon, a tremor that was continuous and stronger than earlier bursts began. AVO formally issued a warning that an eruption was likely and went on 24-h duty. Early the next morning, a swarm of high-frequency earthquakes, accompanied by the first low-frequency events, struck at 0- to 2-km depths beneath Crater Peak. Their rate soon increased to about one every 2 min. This swarm signaled the final surge of magma toward the surface. 4 h later at 7:04 a.m. on 27 June, tremor amplitude abruptly doubled and the eruption began. 12 min later, telemetry was lost from a seismic station 400 m from the vent and a commercial pilot reported that an eruption plume had risen 5000 m above the cloud cover. Tremor amplitude continued to increase and registered on seismic stations more than 100 km away. Using radar, the National Weather Service (NWS) measured a maximum plume height of 14 500 m. Wet debris flows swept southward off the snow-clad Crater Peak cone. At about 11:30 a.m., seismicity decreased abruptly and the eruption was over.

Clear weather the following day revealed a black, northward-broadening swath of tephra on white snow fields. The eruption cloud dusted Denali National Park, continued northward to the Beaufort Sea, then turned southeast into Canada and the contiguous United States, where it became indistinguishable from weather clouds about 2 July. Because of the initial northward direction of travel of the ash, there were few effects other than curtailment of trips by ski-equipped planes to the ash-covered glaciers near Mt. McKinley.

AVO declared the danger of eruption over on 8 July. This was based on greatly reduced seismicity and SO_2 emission, and on the precedent of a single day of activity in 1953. This conclusion proved to be premature.

5.3.3 18 August 1992 Eruption Recorded seismicity remained low through the first half of August, but this was in part because AVO was deafened by demise of the crater rim seismic station. On the afternoon of 18 August, the hum of weak tremor and low-frequency earthquakes reappeared. Minor ash emission prompted an alert from AVO, and shortly thereafter a violent eruption began at 4:42 p.m. ADT, when strong tremor was recorded by all Mount Spurr seismic stations. Within 16 min the eruption column reached a height of 11 000 m, ultimately reaching nearly 14 000 m. A satellite image 44 min after the onset of eruption shows the plume extending 80 km east from the volcano and covering an area of 2000 km^2. Three hours after onset of eruption, the leading edge of the plume was 300 km southeast of Mount Spurr, and its area had grown to 21 000 km^2.

Close observation from aircraft revealed a dark roiling cloud, periodically surrounded by lenticular shock waves, jetting from the full width of the Crater Peak vent (Fig. 1). Large blocks were being hurled nearly 1000 m above the vent. Small-volume pyroclastic flows descended the east and southeast flanks of Crater Peak. Other flows mixed with snow and ice were to become mudflows on the lower flanks of the cone. A late fusillade of blocks, some as large as 1 m, were thrown obliquely as far as 10 km southeastward. More than 170 lightning strikes were detected during the second half of the eruption. The eruption ended abruptly 3.5 h after it began. Ashfall from the drifting cloud forced the closing of Anchorage International Airport for 20 h, where about 3 mm of ash fell, and caused respiratory and visibility problems within the City of Anchorage.

5.3.4 16–17 September 1992 Eruption Following the August eruption, deep seismicity gradually increased, and by mid-September it had returned to levels comparable to mid-June. Teams visiting the crater on 7 and 16 September noted nothing unusual. However, at about 7:30 p.m. on 16 September, earthquakes and weak tremor were detected by the newly reinstalled crater rim seismic station. Tremor amplitude increased 3 h later, and AVO issued an emergency announcement of impending eruption. A few minutes later, a brief eruption began at 10:36 p.m. Weak tremor through the next hour foreshadowed the main phase of eruption, which began at 12:03 a.m. on 17 September. Intermittent bright incandescence was seen clearly from Anchorage, as a roman-candle-like flame playing hundreds of meters above the vent.

The 17 September eruption lasted 3.6 h. Pyroclastic flows again swept down the south-southeast and southeast flanks of Crater Peak. Tephra fallout on a flanking glacier generated a debris flow that temporarily dammed the Chakachatna River south of the volcano. The eruption closed with a strong swarm of about 50 high-frequency shocks between 5 and 10 km in depth, possibly caused by collapse of the conduit after magma withdrawal. The eruption cloud spread, but again remained as a coherent body that could be tracked for days in its drift across North America.

5.3.5 Post-Eruption Seismic Swarms Following the September eruption, the level of seismicity remained elevated, and several seismic crises caused concern. On 9 November, AVO issued an eruption warning an hour into an intense seismic swarm that lasted 3.5 h and contained 170 detected earthquakes. These earthquakes were localized at 1-km depth beneath the vent and had magnitudes as large as 1.7, but seismicity receded without eruption. Because the duration and energy of this swarm was similar to the three eruptions, the swarm may be viewed as a "failed" eruption, in which magma was rapidly emplaced at shallow depth but did not reach the surface. Soon after the beginning of 1993, Mount Spurr returned to seismic quiet.

5.3.6 Interpretation of Spurr Activity Available data for the Mount Spurr volcanic system suggest the rapid migration of relatively fluid, volatile-rich magma through a narrow conduit rooted at the base of the crust (Fig. 12). Because much of the seismicity defines a near-vertical line from the active vent to 40-km depth, there seems little doubt that the seismicity is associated with flow of magma. Each of the three eruptions was remarkably similar in style, duration, and volume. Quiet periods between events were also of similar duration. This suggests a conduit that gradually filled to the same volume prior to each event, emptied in each event, and was not physically altered during each event. Storage in a conduit extending to the base of the seismogenic zone (Power *et al.*, 1995) would require a conduit radius of 10 m. Chemical characteristics indicate that this was new magma, not a fractionated derivative of that erupted in 1953 (Nye *et al.*, 1995).

There was a mirror symmetry to the pattern of seismicity. Seismicity occurred without eruption at the beginning and end of the episode and aseismic eruption occurred in the middle. This pattern is consistent with thermal waxing and waning of the shallow system. When the system was hottest, less seismogenic brittle fracturing or interaction between magma and hydrothermal fluids occurred. Early and late in the activity, rising magma encountered a cold-wet "lid" and produced seismicity without eruption. This lid was also responsible for masking magmatic gas emission from the system except during eruption (Doukas and Gerlach, 1995).

6. THE FUTURE

Volcanology is concerned with phenomena spanning a tremendous range of time and size scales. Significant events occur over seconds in the case of blasts or over millions of years in the case of evolution of large volcanic fields. Explanations are sought for bubble and crystal growth on the scale of microns, and for volcanic chains on the scale of thousands of kilometers. Many of the recent advances in volcanology have resulted from technological advances in seismic monitoring, geodetic measurements, and geochemical analysis. Laboratory experiments simulating volcanic processes are becoming increasingly sophisticated and realistic. Spacecraft are giving us views and even chemical analyses of volcanism on other planets. Meanwhile, drilling technology, motivated by both geothermal rewards and scientific curiosity, is reaching closer and closer to the magmatic environment itself. Because of the quality and quantity of instrumentation that is now fielded during eruptions—a consequence of the serious hazards that volcanism poses—nearly every major eruption results in a significant gain in understanding of volcanism. Although it would be foolhardy to try to say where these developments will lead, improved eruption forecasts, use of volcano-related resources, and understanding of planetary evolution will almost certainly be forthcoming.

GLOSSARY

Andesite: Intermediate-composition member of the basalt-andesite-dacite-rhyolite family, with 53–63 wt% SiO_2.

Ash: Micron to tens of micron pieces of fragmented and devolatilized magma; individual particles may be of glass, crystals, or both.

Basalt: End member of the basalt-andesite-dacite-rhyolite family; usually defined as containing 45–53 wt% SiO_2.

Bomb: Blocks ejected from a volcano that follow a ballistic trajectory.

Caldera: Zone of kilometer-scale (larger than individual vents) subsidence related to eruption of a large volume of magma.

Conduit: High-aspect-ratio dike or pipe representing the path of magma to the surface.

Dacite: Intermediate-composition member of the basalt-andesite-dacite-rhyolite family, with 63–70 wt% SiO_2.

Dense Rock Equivalent (DRE): Erupted volume corrected by removal of porosity; approximately equal to magmatic volume.

Dike: Sheet of frozen, crack-filling magma that crosscuts the host rock.

Dome: Structure formed by viscous lava piling up at the vent.

Fractionation: Change in composition of a system due to separation of phases of different chemical composition; may occur during melting (fractional melting), crystallization (fractional crystallization), or decompression (degassing).

Fragmentation: Process of explosive disintegration of magma to fine particles called ash.

Gabbro: Intrusive equivalent of basalt.

Geothermal Energy: Extractable energy contained in hot fluids, rocks, or magma.

Hydrostatic Pressure: Ideal pressure condition controlled by loading from overlying water.

Island Arcs: Arcuate arrangement of oceanic, subduction-zone volcanoes—e.g., Aleutian Islands.

Lahar: A slurry of volcanic debris in water that flows at high velocities from volcanic centers, typically forming thick fragmental deposits on the flanks.

Lava: Degassed magma that has emerged without fragmentation at the surface.

Liquidus: Temperature at which a rock system contains an infinitesimal amount of crystalline material (i.e., mostly liquid).

Lithostatic Pressure: Ideal pressure condition within Earth due solely to loading from overlying rock.

Mafic: The magnesium- and iron-rich, silica-poor end portion of the basalt-andesite-dacite-rhyolite family; basalts and basaltic andesites.

Magma: Rock that contains a sufficient proportion of melt to flow.

Magma Chamber: Volume occupied by a stored, spatially continuous body of magma; a magma reservoir.

Mantle: Solid but near-melting, iron- and magnesium-silicate and -oxide-bearing portion of Earth between the crust and core, representing 80 vol.% of the planet.

Peridotite: Olivine-rich rock believed to represent upper mantle material.

Phenocrysts: Crystals in volcanic rocks that are significantly larger than crystals in the rock matrix; thought to represent pre-eruption crystallization.

Plate: Semirigid piece of crust and subjacent upper mantle, generally thousands of kilometers wide and a hundred kilometers thick, that moves as a unit.

Pluton: Kilometers-scale intrusion of magma; a frozen magma chamber.

Pumice: Millimeter- to meter-sized fragments of highly porous volcanic rock.

Pyroclastic Flow: Turbulent mixture of tephra in magmatic gas that moves outward from the vent as a distinct, high-velocity mass flow.

Quench: To cool and/or decompress so rapidly that phases present at equilibrium in the previous thermodynamic state are preserved.

Rhyolite: The most silica-rich volcanic rocks; usually defined as those exceeding 70 wt% SiO_2; the molten equivalent of granite; end member of the basalt-andesite-dacite-rhyolite family.

Second Boiling: Growth of gas bubbles in magma upon cooling because of crystallization of volatile-free minerals from volatile-bearing melt.

Silicic: The silica-rich, magnesium- and iron-poor end of the basalt-andesite-dacite-rhyolite family; rhyolite, dacite, and some andesites.

Sill: Sheet of frozen magma that intruded along horizontal bedding planes or formation contacts.

Solidus: Temperature at which a rock system contains an infinitesimal amount of liquid (i.e., mostly solid).

Subduction: Downward-inclined flow of oceanic crust and underlying mantle beneath an adjacent tectonic plate; the contact between plates is an inclined plane of high seismicity.

Tectonic: Referring to large-scale movements of the Earth's crust and upper mantle.

Tephra: Fragments ejected explosively from a volcano; ash, pumice, and/or bombs.

Tuff: Tephra that has welded to form a cohesive rock.

Vent: Site where magma reaches the surface.

Vesiculation: Growth of bubbles in magma.

Volcano: Land form built by emergence of magma, as lava or tephra or both, at the surface.

Welding: Process of compaction and cohesion of ash-rich tephra, when emplaced at temperature above the softening point of glass.

INTRODUCTION

Waste refers to material deemed undesirable and thus discarded. Just as a rose in a corn field may be called a weed, many waste materials have positive characteristics. For example, sewage contains organic matter that may deplete dissolved oxygen levels when consumed by microorganisms in natural waters. However, sewage also contains nutrients of great value if used properly. In managing wastes, one attempts to maximize the use of the waste constituents, while minimizing adverse impacts on the environment and human health.

Waste materials encompass a tremendously large number of physical and chemical characteristics. Everything from photochemical smog to mine tailings to hospital refuse can be considered waste. The wide range of characteristics requires many management tools. To minimize environmental and human-health impacts, waste managers use an array of control technologies, usually coupled with economic and social incentives. The study and practice of waste management are made more interesting and challenging by the diversity of waste and control approaches.

The field of waste management is in a state of flux. Traditional views on waste characterization and waste-management strategies have been superseded by more holistic approaches. Regarding waste characterization, wastes traditionally have been classified by their discharge locations and labeled air, water, or solid waste pollution. Control technologies were developed for each pollutant type. Currently, intermedia transport considerations are being incorporated into waste-management policy. For example, air pollution at one location can result in water pollution from acid precipitation at another location. Regarding waste-management strategies, emphasis has shifted from pollution treatment to pollution prevention. Rather than constructing treatment works at the end of the pipe, the current approach is to avoid creating the waste. This concept of waste minimization has become a central tenet of modern waste management.

The field of waste management encompasses both a large number and a diverse group of disciplines. Contributors to the field must have strong backgrounds in the natural sciences, engineering, economics, and policy making. A thorough review of each aspect of waste management would require many volumes of text. The scope of this article has been designed to give the reader a broad overview of waste-management technology and practice. Toward this end, many different waste-management approaches are covered briefly here. It is assumed that the reader has a firm understanding of environmental science. Air-pollution technologies are reviewed concisely, with further information available in AIR POLLUTION: COMPONENTS, CAUSES, AND CURES. To give the reader the broadest introduction to waste management, examples and policy implications are generally limited to North America.

1. CLASSIFICATIONS AND ORIGINS OF WASTE

Wastes are characterized in three ways: by source (e.g., industrial, domestic, and institutional), by phase (e.g., solid, liquid, aqueous, and gaseous), or by other characteristics (e.g., hazardous, infectious, and biodegradable). Classification of wastes by source is important since discarded materials are managed according to laws and regulations related to their distinguishing characteristics or source of origin.

1.1 Domestic/Household Wastes

1.1.1 Solid Wastes Domestic solid waste is a part of municipal solid waste (MSW), which includes nonhazardous waste generated in households (residential solid waste), institutions (e.g., schools, jails, hospitals, nursing homes, and public buildings), and commercial and business establishments. The size of the solid-waste stream generated annually in the United States has increased at an average of approximately 2% per year for more than three decades. The United States currently (1995) generates approximately 2×10^8 tons of garbage per year that corresponds to a per capita generation of approximately 2 kg of garbage per day. On a global scale, the MSW generation rate for most European nations is about 0.6 to 1.2 kg/capita·year, while the rates in the United States, Canada, Korea, Australia, New Zealand, and Hungary are about 1.8–2.0 kg/capita·year.

The quantity and composition of the waste stream have a direct bearing on the selection of the most appropriate technologies for management and disposal. The average composition of MSW in the United States changes with season and demographics, but a typical composition is paper and paperboard, 37.6%; yard waste, 15.9%; plastics, 9.3%; metals, 8.3%; food waste, 6.7%; glass, 6.6%; wood, 6.6%; and other, 9.0% (Nebel and Wright, 1996). Significant changes in the composition of the municipal solid-waste stream have occurred because of improved food-processing techniques, the increased use of kitchen food-waste grinders, increased use of plastics for food and other packaging, and the growth in residential recycling and composting programs.

Yard waste refers to leaves, grass clippings, prunings, and other natural organic matter discarded from yards, gardens, and institutional establishments (e.g., golf courses, parks, and cemeteries), as well as material from commercial landscaping and grounds-maintenance activities. Reprocessing of yard waste into compost or mulch is becoming increasingly adopted for reducing the size or volume of the municipal solid-waste stream.

1.1.2 Aqueous Wastes Waste water is generated from a variety of sources including residential sanitary and storm sewers, as well as waste-water discharges from commercial, industrial, government, and other facilities. Aqueous pollutants also can be transported by means of uncontrolled runoff from nonpoint sources following rainfall and storm events. Approximately 3.4×10^{10} gallons of waste water per day are generated by households, commercial establishments, and industrial operations across the United States. This waste water is collected by sewers and transported to a sewage treatment plant commonly known as a publicly owned treatment works (POTW). After treatment in the POTW, the treated waste water typically is discharged to a river, lake, or other water body. There is increasing interest in the direct reuse of treated waste water in areas of scarce water resources.

Untreated or polluted waste water can be harmful to aquatic life and leave water unfit for human use. Potable (i.e., drinkable) water is a vital and indispensable element in an urban environment. In addition, high-quality water is essential to industrial processes and manufacturing operations, since these facilities often possess substantial needs for water as a raw material, cooling or heating medium, or cleaning agent, or for sanitary or other purposes.

1.1.3 Household Hazardous Waste Household hazardous wastes are wastes resulting from products purchased by the general public for household use that, because of their quantity, concentration, or physical, chemical, or infectious characteristics, may pose a substantial known or potential hazard to human health or the environment when improperly treated, disposed of, or otherwise managed (see Sec. 1.3.1). In essence, household hazardous waste refers to materials discarded from residences that meet the legal criteria defining a hazardous waste. Many communities have developed plans and programs to keep household hazardous waste out of the solid-waste stream and to provide options for the proper management of these wastes. The major constituents of household hazardous waste are (percentages in parentheses) oil-based paint (31.9%), solvents (15.4%), latex paint (12.1%), pesticides (9.9%), empty oil cans (8.8%), cleaners (8.3%), waste oil (5.0%), acids/bases (4.0%), petroleum products (1.7%), and other (2.9%) (Tchobanoglous *et al.*, 1993).

1.2 Industrial/Manufacturing Wastes

Different industrial and manufacturing sectors of the economy generate different types of wastes. Standard categories (called the Standard Industrial Classification Code or SIC Code) define manufacturing activity and the resulting waste streams.

1.2.1 Solid Wastes Although the management of MSW has captured public attention, the vast majority of solid waste in the United States (more than 98%) is of industrial and agricultural origin. Of the non-MSW solid waste, 75% is from mining (including oil and gas production), 13% from agriculture, 9.5% from industrial sources, and about 1% from municipal waste-water and drinking-water sludges (Miller, 1994). The characteristics of non-MSW solid waste vary significantly, with about 10–15% of industrial solid waste classified as hazardous.

1.2.2 Aqueous Wastes Aqueous industrial wastes are discharged most commonly to a POTW but also may be discharged to a receiving water body. The characteristics of industrial waste-water discharges can have a profound effect on water quality and on operation of the POTWs to which the industry discharges. Although discharges are permitted through the provisions of the Clean Water Act (see Sec. 2.1), some industrial facilities are frequently in noncompliance with the permitted discharge limits. In addition, industrial sources tend to generate a significant amount of the toxic metals and organic compounds that enter POTWs. Overall, POTWs are not designed to treat these substances effectively.

Pretreatment removes pollutants that may interfere with the treatment process, cause potential damage to the treatment facility, or pass through the treatment system directly into a receiving water body. It is imperative that appropriate pretreatment technologies be employed or developed that will meet site-specific or local water-quality standards and needs. This requires treatability studies and research and development efforts to provide guidance in the selection of the most cost-effective pretreatment alternative for the particular chemical constituents to be managed.

Although industrial waste waters have been treated for more than 50 years, a more desirable approach would be to eliminate or minimize the generation or presence of the contaminant rather than to adopt an end-of-pipe treatment approach. Pollution prevention initiatives would lessen the burden and impact on urban water supplies and treatment facilities. Pollution prevention is best accomplished by means of source reduction activities that effectively reduce or eliminate the generation of a waste or undesirable pollutant at the source (usually within the industrial process). Some typical measures that may be taken to accomplish this objective include modifications to the process (such as changes in design or operating procedures), feedstock substitutions or improvements in feedstock purity, product modification or reformulation, sound housekeeping and management practices, increases in process or machinery efficiency, and in-process recycling, among others. Source reduction refers to any action that results in a reduction in the amount of waste generated by a process that would otherwise require treatment, storage, or disposal.

1.3 Other Special Wastes

1.3.1 Hazardous Wastes The term "hazardous waste" has a very specific meaning as defined in the Resource Conservation and Recovery Act (RCRA) of 1976 (see Sec. 2.1). Under RCRA, a hazardous waste is defined as any waste or combination of wastes that, because of its quantity, concentration, or physical, chemical, or infectious characteristics, may

1. cause (or significantly contribute to) an increase in mortality or an increase in serious irreversible or incapacitating reversible illness, or
2. pose a substantial present (or potential) hazard to human health or the environment when improperly treated, stored, transported, or disposed of, or otherwise managed.

Four characteristics are used to determine if a waste is hazardous: ignitability, corrosivity, reactivity, and toxicity. Listed categories of hazardous wastes include nonspecific source wastes (generic wastes that might commonly be produced by manufacturing and industrial processes), specific source wastes

(wastes of specific industrial origin), and commercial chemical products (specific chemicals, excluding wastes from households, municipal resource recovery operations, agriculture, and mining overburden that is returned to the mine site).

1.3.2 Construction and Demolition Debris Construction and demolition (C&D) waste refers to solid waste, such as building materials and rubble, resulting from construction, remodeling, repair, and demolition operations on pavements, houses, commercial buildings, and other structures. Since the 1980s, C&D waste in the United States has generally been disposed of in separate landfills. C&D waste is primarily concrete (53.8%), wood (22.0%), and brick (21.1%).

1.3.3 Radioactive Wastes Radioactive wastes are generally divided into three distinct categories: high level, transuranic, and low level. High-level radioactive waste consists of spent nuclear fuel from military or commercial nuclear reactors or the wastes resulting from the reprocessing of the spent fuel. A large volume of high-level military waste is currently stored in underground tanks at three major government sites: Hanford, WA, Idaho Falls, ID, and Savannah River, GA. Transuranic wastes consist of isotopes of chemical elements above uranium in the periodic table with half-lives greater than 20 years and having a total activity greater than 100 nanocuries per gram of waste material. These wastes are typically by-products of fuel assembly, weapons fabrication, and reprocessing operations. Transuranic wastes generally have low radioactivity but contain several long-lived isotopes, thereby necessitating separate management of these wastes. Low-level wastes are defined as all radioactive wastes other than high-level and transuranic wastes. Low-level wastes originate from certain reactor operations (both utility- and Department of Energy–operated reactors), industry, and institutions (e.g., hospitals, universities, and research organizations). Mixed wastes refer to low-level wastes that contain both hazardous chemicals and radioactive substances.

1.3.4 Medical Wastes Medical wastes include all infectious waste, hazardous waste (including low-level radioactive waste), and other wastes generated from a variety of health-care institutions including hospitals, clinics, medical laboratories, and medical offices. The composition of this waste is extremely heterogeneous and includes general refuse (such as office paper, food waste, and noninfectious patient waste), infectious waste (such as pathological wastes, human blood and blood products, contaminated and anatomical wastes, etc.), hazardous wastes (such as waste pharmaceuticals, cytotoxic agents used in chemotherapy, mercury, etc.), and small quantities of radioactive wastes.

The major sources of medical waste are hospitals and other large health-care institutions. The quantity of this category of waste generated in the United States is difficult to estimate. In 1987, the U.S. Environmental Protection Agency (EPA) estimated the total generation of hospital wastes at 5900 tons/day, corresponding to a generation rate of 6 kg per bed per day. It is estimated that approximately 10–15% of all hospital wastes are infectious.

1.3.5 Waste Tires Waste tires constitute a ubiquitous component of the waste stream and are becoming an increasing environmental concern. An estimated (2 to 2.5) × 10^8 automobile and truck tires are disposed of annually in the United States. This estimate is consistent with the annual tire production statistics for domestic passenger vehicle and truck tires. Increasingly, landfills will not accept scrap tires because of either voluntary restrictions or legislative mandates. In addition to the annual generation of scrap tires, it is estimated that there may be as many as 2×10^9 waste tires stockpiled with more than 1000 known tire piles or dumps throughout the country. Tire stockpiles pose a variety of aesthetic and environmental problems. Exposed tires collect shallow pools of rainwater, creating warm moist breeding grounds for mosquitoes and rodents. Tire stockpiles also pose a significant fire hazard because of their energy content (approximately 35 000 kJ/kg). The shape of the tire enables it to carry a self-contained supply of oxygen, making it extremely difficult to extinguish a burning pile of tires. Burning tires generate considerable pollution in the form of pungent black smoke and uncontrolled oil runoff.

1.4 Intermedia Transport Considerations

Historically, the legislative framework has focused on regulatory enforcement targeted at a specific medium (e.g., air, water, or soil). This has at times encouraged waste disposal to a preferred medium. Current attention is being given to a broad perspective for waste disposal, instead of the historical fragmented approach to waste management and regulation. The problem of waste disposal encompasses a multifaceted array of challenging technical, social, economic, and political issues.

2. U.S. PUBLIC POLICY CONCERNING WASTE MANAGEMENT

2.1 Federal Legislation

Major federal environmental legislation related to waste management is summarized as follows:

Solid Waste Disposal Act (1965): First federal effort to regulate municipal solid waste.

Resource Recovery Act (1970): Greatly expanded federal authority over the management of municipal solid waste and encouraged waste reduction and resource recovery.

National Environmental Policy Act (1970): Required environmental impact statements for all federally permitted projects.

Clean Air Act (1970): Required EPA to establish national ambient air-quality standards for total suspended particulates, sulfur dioxide (SO_2), carbon monoxide (CO), nitrogen dioxide (NO_2), ozone (O_3), and hydrocarbons (with airborne lead, Pb, added in 1987); new source performance standards; and national emissions standards for hazardous air pollutants (asbestos, benzene, beryllium, mercury, and vinyl chloride).

Marine Protection, Research, and Sanctuaries Act (1972): Designed to prevent or limit ocean dumping of any wastes that might adversely affect human health or welfare or the marine environment by requiring a permit for the transportation of all wastes that are to be dumped at sea.

Federal Water Pollution Control Act (also called the Clean Water Act, 1972, amended in 1977 and 1981): Intended to restore and maintain the chemical, physical, and biological integrity of the nation's waters through the establishment of discharge permits (under the National Pollutant Discharge Elimination System or NPDES), water-quality standards, and use of the best available technology (BAT) to achieve the permitted limits.

Safe Drinking Water Act (1974): Set minimum national drinking-water standards (primary standards to protect human health and secondary standards to control aesthetics) and established mechanisms to protect ground water from potential pollution sources.

Hazardous Materials Transportation Act (1975): Provided a separate management structure for hazardous materials that may pose a threat to health, safety, property, or the environment when transported by air, water, rail, or highway.

Toxic Substances Control Act (TSCA, 1976): Regulated the introduction and use of new hazardous chemical materials, including a ban on the manufacture, processing, and distribution of products containing polychlorinated biphenyls (PCBs).

Resource Conservation and Recovery Act (RCRA, 1976): Enacted to protect the environment from contamination by solid-waste disposal through the listing of hazardous wastes and establishment of a manifest system for tracking the disposition of hazardous wastes from generators to treatment, storage, or disposal (TSD) facilities.

Hazardous and Solid Waste Amendments of 1984: Expanded RCRA by establishing new technological standards for land-disposal facilities, promulgating new requirements for underground storage tanks (USTs), placing restrictions on the future land disposal of some 400 chemicals and untreated hazardous wastes, and emphasizing "waste minimization" as the preferential strategy for enhancing environmental quality.

Comprehensive Environmental Response, Compensation and Liabilities Act (CERCLA, also called Superfund, 1980): Provided the framework for the liability, compensation, cleanup, and emergency response actions associated with contaminated sites resulting from accidental or nonpermitted releases or disposal (prioritized on the National Priority List, or NPL), and established a revolving fund from a tax on petroleum and 42 listed chemicals to ensure adequate financial coverage for the ultimate closure of present and future hazardous-waste–management operations.

Superfund Amendments and Reauthorization Act (SARA, 1986): Provided additional funding for the continued cleanup of contaminated waste sites from the following sources: taxes on petroleum and chemicals, a corporate environmental tax, general appropriations, Superfund penalties, and parties responsible for site cleanup (including historic owners or operators of the site, generators of the hazardous substances that have polluted the site, or transporters that have brought the hazardous wastes to the site).

Ocean Dumping Ban Act (1988): Extended the ban on ocean dumping to include sewage sludge and industrial waste.

Clean Air Act Amendments of 1990: Designed to reduce air emissions and improve ambient air quality through the establishment of nonattainment areas, with emphasis on alternative clean fuels for automobiles, hazardous air pollutants, SO_2-emissions reduction for acid-rain mitigation, and chlorofluorocarbons-emission restrictions (for protection of the atmospheric ozone layer). A phaseout of ozone-depleting substances was established by the Montréal Protocol, with an accelerated phaseout schedule agreed upon by 187 nations in December 1992 in Copenhagen.

2.2 Regulatory Issues

A broad combination of state and federal regulations has set quantitative standards for emissions and disposal of wastes in various forms. Most of these regulations are addressed to readily identified generators or point sources of pollution. The present political environment has shifted in the direction of deregulation and reform. Cost-benefit analyses, risk-based considerations, and economic incentives for voluntary action are being more widely adopted in formulating environmental policy. Some important regulatory issues include

1. the establishment of cleanup standards,
2. greater attention to nonpoint (i.e., diffuse) sources of environmental pollution, and
3. emphasis on pollution prevention.

The regulation of special wastes (such as tires, medical waste, batteries, etc.) must be formulated carefully to avoid improper disposal of these wastes if the regulations are perceived as excessively burdensome.

3. WASTE TREATMENT

3.1 Treatment and Disposal to a Receiving Water Body

3.1.1 Treatment Technologies Treatment technologies can be categorized in two ways: by treatment type and treatment objective. Treatment types include physical, chemical, and biological processes. The two primary treatment objectives are pollutant destruction and phase transfer (where, e.g., pollutants are removed from water and concentrated in a gas stream or on an adsorptive media). Typical processes for drinking-water, municipal waste-water, and industrial waste-water treatment are listed in Table 1.

3.1.1.1 Physical Processes. Physical processes generally are phase-transfer processes. (Incineration, a physical process re-

Table 1. Typical engineered treatment processes (less common processes in italics).

Process type	Type of water treated: Drinking water	Waste water	Industrial waste water
Physical	Pretreatment, sedimentation, filtration, *adsorption, disinfection, membranes*	Sedimentation, *filtration*	Sedimentation, filtration, adsorption, ion exchange, membranes
Chemical	Disinfection, *precipitation, oxidation*	Disinfection, *oxidation*	Oxidation, *disinfection*
Biological	Not used commonly in engineered systems	Suspended growth, attached growth	Suspended growth, attached growth

sulting in pollutant destruction, is discussed in Sec. 3.2.1). The major types of physical-treatment techniques include particle removal, sorption, transfer to the gas phase, disinfection, and membrane processes.

Particle-removal processes include pretreatment, sedimentation, and filtration. Pretreatment typically is a two-step process. In the first step, called coagulation, water containing particles is mixed rapidly with a coagulant (commonly alum or ferric chloride) to neutralize the negative charge on the particles. In the second step, called flocculation, coagulated water is mixed slowly to enhance particle growth. Larger particles will settle faster according to Stokes's law. Particle settling usually occurs by gravity sedimentation (although enhanced particle removal by centrifugation is employed in specialized applications). Sedimentation basins (also called settling tanks or clarifiers) have large surface areas and very low horizontal water velocities. In an analogous process called dissolved air flotation (DAF), small air bubbles are used to float pretreated particles to the surface of a tank where they are skimmed off. Filtration is often a polishing step. The most common filter type is a gravity-fed filter using sand or anthracite/sand layers. Pressure filters employing diatomaceous earth or wound fiber media can be used with small flows. During operation, the filter will clog, and the rate of filtration will decrease or particles will break through. When performance is unacceptable, filters are backwashed by passing clean water through the filter in the upflow (or reverse flow) mode.

Adsorption processes are used to remove adsorbable compounds from water (or air). The most common adsorbent is activated carbon, formed by heating natural materials (e.g., wood or coal products) to temperatures in excess of 900 °C. In a typical installation (called a fixed-bed absorber), granular activated carbon (GAC) is packed into a tower, and water is treated continuously. The bed life ends when the pollutant concentrations in the effluent exceed the regulatory limit. At this point, called breakthrough, the carbon must be removed and regenerated by heating it again to high temperatures. Another form of adsorption is ion exchange. In this process, ions are removed from water by passing the water through a fixed-bed adsorber packed with ion-exchange resin. Ions are exchanged for innocuous species (typically, cations are exchanged for H^+ or Na^+ and anions for OH^- or Cl^-). Ion exchange is common for the production of high-purity water and desalination.

Two types of gas-transfer processes are used to treat water and industrial wastes. Air-stripping reactors typically are designed with countercurrent flow of clean air and contaminated water (often sprayed from the top of the reactor). The interfacial area for mass transfer is increased by filling the reactor with small plastic shapes called packing. Distillation has limited use in environmental applications because of its high energy costs. Distillation is used primarily for desalination and purification of used solvents.

Disinfection refers to the inactivation (or death) of pathogens (i.e., harmful microorganisms) to levels consistent with maintaining public health. Some disinfection processes are purely physical and include ultraviolet (UV) irradiation, heat treatment, and gamma radiation. UV treatment is being used in North America with increasing frequency as an alternative to chlorine for the disinfection of municipal waste waters.

Membrane processes are gaining in popularity for the treatment of drinking water and some industrial waste streams. In a typical application, water diffuses across the membrane to produce a clean water stream (called the permeate), while pollutants are concentrated in the retentate. Most membrane processes are pressure driven, leading to high energy costs in some cases. Common membrane processes (in order of decreasing molecular-weight cutoff, MWCO) are microfiltration, ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO).

3.1.1.2 Chemical Processes. Chemical processes are used for neutralization, precipitation, oxidation, and disinfection. Neutralization involves the addition of acids or bases to bring the *p*H of the water or waste to near neutral (*p*H 7). Chemical precipitation is used to remove metals from water. In industrial- and hazardous-waste treatment, metals commonly are precipitated as their hydroxide or sulfide solids by the addition of lime (CaO) and sulfide salts. In drinking-water treatment, high levels of calcium and magnesium (called the hardness cations) produce hard water, which prevents the lathering of soap and encourages scale [i.e., $CaCO_3(s)$] formation. Hardness is removed through the addition of lime and soda ash (Na_2CO_3), with calcium and magnesium precipitated as $CaCO_3(s)$ and $Mg(OH)_2(s)$, respectively. This process is called precipitative (or lime-soda ash) softening.

In chemical oxidation, strong chemical oxidants are added to oxidize many types of pollutants. Common chemical oxidants are air (or oxygen), chlorine, ozone, potassium permanganate, and hydrogen peroxide. In some cases, oxidants are used to oxidize inorganic pollutants. Examples include the oxidation of sulfide (for odor control in municipal waste-water treatment and some ground waters) and iron and manganese (which can cause discoloration of drinking water, pipes, and laundry). Chemical oxidants also are used to oxidize organics, including cyanide, dyes, and phenols in industrial waste streams and taste- and odor-causing compounds and naturally occurring organics in drinking-water treatment. The goal of chemical oxidation is to convert pollutants to less harmful forms, but complete oxidation to carbon dioxide is rare. Thus, the production of intermediates must be monitored closely. Chemical oxidation methods are being developed in which radical species (primarily the hydroxyl radical) are formed continuously. These methods are called advanced oxidation processes (or AOPs) and include UV/ozone, ozone/hydrogen peroxide (Peroxone process), UV/hydrogen peroxide, and other oxidant combinations.

Chemical oxidants are used for disinfection as well. The primary oxidants in drinking-water and waste-water treatment are chlorine and ozone. Chlorine reacts with ammonia in many municipal waste waters to form chloramines (primarily monochloramine, NH_2Cl), which are the main disinfectant. Chlorine reacts with naturally occurring organics during the disinfection of drinking water to produce many by-products, including trihalomethanes (THMs, primarily chloroform) and haloacetic acids. These by-products currently are regulated in drinking water. In waste-water treatment, residual chlorine discharged to receiving streams can result in fish kills. Thus, chlorination is being minimized in both drinking-water and waste-water treatment. Alternative disinfectants are being explored, including UV for waste water and ozone for drinking water.

3.1.1.3 Biological Processes. Microorganisms have been used to treat waste streams since the inception of engineered treatment systems. The most common microorganisms employed in engineered systems are bacteria. Bacteria can be classified by the energy and carbon sources they use. Heterotrophic bacteria use organic carbon as both the energy and carbon sources and are the most used for the removal of organic compounds from waste water.

Biological processes are characterized by the physical system and the availability of electron acceptors. The two main types of physical configurations are suspended-growth systems (where bacteria are free-floating in a reactor) and attached-growth systems (where organisms grow on a solid support). Biological processes are used primarily to oxidize pollutants, and thus an electron acceptor is required. The main categories of electron acceptor systems are

1. aerobic processes (where the electron acceptor is oxygen),
2. anoxic processes (where oxygen does not exist and the electron acceptors are other oxidized species such as nitrate and sulfate), and
3. anaerobic processes.

Biological processes can be used for the removal of specific pollutants or for the removal of general organic material in waste waters. Organic matter is of concern, because aerobic heterotrophs consume oxygen when the organic carbon is used as an energy source. Thus, where waste water is discharged without treatment, dissolved oxygen levels may decrease and fish kills may occur. Organic matter that results in the reduction of dissolved oxygen when consumed by microorganisms is called biochemical oxygen demand or BOD.

Nitrogen and phosphorus commonly limit the growth of algae. Thus, when nitrogen or phosphorus is supplied to a receiving water body from a waste-water discharge, algae blooms may occur. To prevent algal blooms, biological nutrient removal (BNR) processes are used to control the release of reduced nitrogen (ammonia), oxidized nitrogen (nitrite and nitrate), and phosphorus. Common biological processes are shown in Table 2.

Table 2. Common engineered biological processes and their uses.

Electron acceptor type	Physical configuration			
	Suspended growth		Attached growth	
	Process	Use	Processes	Use
Aerobic	Activated sludge	BOD removal	Biotowers	BOD removal
	Aerated lagoons	BOD removal	Rotating biological contactors	BOD removal
	Nitrification	Nitrification		
	Aerobic digestion	Stabilization		
Anoxic	Denitrification	Nitrogen removal	Denitrification	Nitrogen removal
Anaerobic	Anaerobic digestion	Stabilization	Anaerobic filter	BOD removal

The two most common biological processes for BOD removal are activated sludge and biotowers. The treatment train in the activated-sludge process consists of a primary clarifier, activated-sludge basin (also called an aeration basin), and final (or secondary) clarifier. Bacteria are allowed to grow in the activated-sludge basin to a set mass concentration. Oxygen is provided to the bacteria through air blowers or, less commonly, pure oxygen. Bacterial solids leaving the activated-sludge basin are recovered in the secondary clarifier and recycled. In this sense, the "sludge" (biological solids) is "activated" (i.e., previously exposed to the influent contaminants). Activated-sludge systems (a form of secondary treatment) are extremely common in the treatment of municipal waste water. Variations of the activated-sludge process also are used to treat industrial wastes. For example, sequencing batch reactors (batch versions of the activated-sludge process) are ideal for the biodegradation of some industrial and hazardous wastes.

The biotower (also called a trickling or roughing filter) is a vertical tank containing media (often rocks) onto which bacteria grow. Waste water passes through the packed bed and organics are consumed by the bacteria. Air is introduced, often by drafting, to provide an electron acceptor. Another attached-growth process in use is the rotating biological contractor (or RBC). In an RBC system, bacteria grow on large disks that are slowly rotated through the flowing waste water. Oxygen is provided by air as the disks rotate out of the waste water.

3.1.2 Management of Residuals

Waste streams (called residuals) are generated by nearly all of the processes discussed previously. In particular, sedimentation generates a settled sludge, filtration generates a backwash stream, and most biological processes generate a biological sludge from the clarifier(s). The quantity of sludge to be disposed of is significant. In the United States, rates of sludge production are 6.4×10^8 kg/year for municipal waste water and 1.8×10^9 kg/year for drinking-water treatment. The type of residuals management scheme depends on the nature of the solids.

Inorganic solids generally are thickened, dewatered, and disposed of. Thickening processes are used to increase the percentage of solids in the sludge to the 1–10% range. Common thickening processes are gravity, flotation, and centrifugation thickening. The purpose of dewatering is to increase the percentage of solids to the 20–40% range. Common dewatering devices are centrifuges, filter presses (where the water is squeezed out through a fabric), and vacuum filters (where the water is aspirated through fabric). The dewatered sludge may be disposed of by land spreading, lagooning, composting, and landfilling. Because of pressures on landfill space, recycling of sludges is becoming more economical. Ocean dumping of many sludges is no longer allowed.

Biological sludges require additional processing. The typical sludge-handling protocol for municipal waste-water sludges includes thickening, stabilization, dewatering, and final disposal. The goal of stabilization processes is to reduce pathogens and odors and decrease the potential for putrification. The most common stabilization process is digestion. In digestion, thickened sludge is placed in a closed tank for 10–30 days. Solids are converted to gases (methane and carbon dioxide) and volatile acids (short-chained organic acids). Digesters can be aerobic or anaerobic. The methane produced can be burned to recover heat or generate small amounts of electricity.

3.2 Treatment and Disposal to the Atmosphere

3.2.1 Thermal Oxidation (Incineration) and Pyrolysis An alternative disposal option for municipal solid waste is incineration. Incineration may be more properly regarded as a waste-processing technology for reducing the volume of waste requiring disposal. However, incinerators require a substantial capital investment and are unable to incinerate everything in the waste stream. Depending on the composition of the incinerated waste stream, approximately 10–30% by volume of the input waste will remain as ash. There are environmental concerns regarding air emissions and ash disposal. Consequently, the siting and permitting of new incinerators have received considerable public outcry and have become extremely controversial issues.

The most widely used incinerators for municipal solid waste are mass-burn facilities that are designed to incinerate the waste stream with virtually no preprocessing. Modular incinerators are typically smaller-scale facilities that are intended to incinerate unprocessed waste. Refuse-derived fuel (RDF) incinerators typically utilize a shredded-waste stream from which heavier, noncombustible items such as glass and metal have been removed. Most incinerators employ an energy-recovery system that captures the heat released during combustion and converts it to steam or electricity.

3.2.2 Air-Pollution Control Technologies This review focuses on technologies for the control of air pollutants from industrial sources. Three types of particulate control technologies are in use: force-field settlers, baghouse filters, and scrubbers. Force-field settlers use different forces to remove particles from air: gravitational settlers employ gravity, cyclones use centrifugal forces, and electrostatic precipitators (ESPs) use electrical forces. ESPs are the most efficient force-field settlers. In ESPs, particulates acquire a negative charge as they pass through a corona discharge and are removed on a positively charged electrode. Baghouse filters remove particulates by passing contaminated air through filter bags. A baghouse may contain hundreds of filter bags. Baghouse filters are among the most efficient technologies of particulate removal. Scrubbers transfer particulates to a water stream. Scrubber types (countercurrent spray, cross-flow spray, venturi, and cyclone spray) differ in the manner in which air and water are introduced to the chamber. Venturi scrubbers are the most efficient scrubber type.

Gaseous pollutants are removed by absorption, adsorption, or incineration. In absorption, the pollutant is dissolved in water. For example, SO_2 can be absorbed as sulfate (SO_4^{-2}) in a lime solution. Adsorption processes were described in Sec. 3.1.1.1. Adsorption on activated carbon is used to remove organics from air. Incineration can be used for the oxidation of certain air pollutants. For example, CO can be incinerated to form CO_2.

3.2.3 Management of Residuals Each air-pollution control technology creates a waste stream. For force-field settlers, baghouses, and adsorbers, a solid waste is generated. For scrubbers and absorbers, an aqueous waste is generated. Care must be taken to dispose of or reuse the waste streams to avoid resuspension of the air pollutants.

3.3 Treatment and Disposal on Land

In North America, early environmental legislation was focused on air- and water-pollution control that indirectly encouraged land disposal as the preferred waste disposal option. In addition, open land was plentiful and landfilling operations were simple and inexpensive. During the 1980s, concerns over the environmental impact of landfills began to emerge. As a result, more stringent regulations were enacted, land-disposal costs (called tipping fees) escalated dramatically, and the siting of new landfills became a controversial political issue. The opposition to landfills relates to the use of land that could be used for other purposes, the attraction of rodents and scavengers, odors, traffic, aesthetic and property value issues, and the potential for ground-water contamination. Communities began to experience limitations in existing landfill capacity, particularly in more densely populated areas.

3.3.1 Septic Systems Septic tanks are small physical systems for the treatment of waste water from individual homes or institutions. Septic tanks may have one or more chambers. In the two-chamber configuration, the first compartment is used for the settling, digestion, and storage of sludge, while the second compartment provides backup settling and storage capacity. In a typical system, the residence time for liquid is about 24 hours, and the sludge (called septage) is removed every two to three years. Septic tanks produce two waste streams: septage and a liquid effluent. The septage is pumped from the septic tank and discharged to a municipal waste-water treatment plant. Effluent flows to a leaching field for percolation into the ground. Septic tanks require sufficient percolation rates and are not recommended where drinking-water sources are nearby.

3.3.2 Composting Composting refers to the controlled biological decomposition of organic solid waste under aerobic conditions. Approximately 3×10^7 tons of yard waste (leaves, tree trimmings, grass) are disposed of in the United States annually. Yard waste accounts for approximately 20% of the municipal solid-waste stream. Composting transforms the organic waste materials into useful soil amendments such as humus or mulch.

Composting of municipal waste-water sludges is growing in popularity. Sludge composting is almost always performed under aerobic conditions. The compost temperature must reach 50–70 °C to kill pathogenic organisms. Co-composting of waste-water sludge and MSW can be accomplished, but a market for the final product has not yet developed in the United States.

3.3.3 Subsurface Disposal Many wastes are disposed of in landfills or through deep-well injection.

3.3.3.1 Secure Landfills/Burial. Historically, landfill disposal of municipal solid waste and industrial hazardous waste was economically attractive. The more restrictive regulations concerning the construction and operation of a secure landfill facility have resulted in increased costs being associated with this disposal option. A typical landfill consists of an excavation, frequently lined with clay or a synthetic geomembrane, and a water-collection and -treatment system. The solid waste is deposited in layers over a cell within the landfill. The waste layer is often compacted to reduce volume and covered daily with soil to minimize risk to human health and the environment. Drums or containers of industrial waste are disposed of in a similar fashion by placing them within a cell and covering them with soil. Once a cell is full, an impermeable cap is placed over the waste to prevent precipitation from percolating through the landfill.

3.3.3.2 Deep-Well Disposal. Historically, hazardous liquid wastes were commonly disposed of by pumping these materials through injection wells into well-confined geological formations (such as limestone or sandstone formations). Injection wells typically extend 2000 feet below the Earth's surface. The injected waste material remains in place unless disturbed. The primary concerns with injection-well disposal relate to the leaking potential (with subsequent drinking-water contamination) and the possibility of subsurface destabilization. To minimize these concerns, it is imperative that the geology of the site selected be compatible with the waste stream.

4. OTHER WASTE-MANAGEMENT STRATEGIES

4.1 Introduction

Recently, much activity has centered on the prevention of pollution before it is generated (rather than the treatment of pollution after it is generated). This approach, called pollution prevention or waste minimization, emphasizes the efficient use of materials and energy. (Pollution prevention with industrial aqueous wastes was discussed briefly in Sec. 1.2.2.) A hierarchy of waste-minimization strategies has been developed based on their effectiveness for reducing costs and environmental impacts. The four main approaches to pollution prevention are, in order, source reduction, recycling/recovery, reuse, and substitution. Each approach is discussed in more detail.

4.2 Source Reduction

The desired ideal with respect to waste management is to reduce or eliminate the generation of the waste material at the source. This process is called source reduction. Elimination of a waste obviates the need for the transportation, treatment, and disposal of the waste material. Source reduction is the most desirable pollution-prevention option, because it minimizes the amount (or toxicity) of material entering the waste stream.

4.3 Recycling/Resource Recovery

4.3.1 Introduction Recycling refers to the collection and reprocessing of resources into new products. The concepts of recycling and resource recovery are being championed as the preferred options for alleviating the problem of municipal solid-waste disposal. Apart from the avoided disposal costs, many communities and entrepreneurs believed that recycling technologies would be economically profitable. To date, this has often not been the case, and many recycling programs have been plagued by high implementation costs and a lack of stable and economically viable markets for recycled materials.

4.3.2 Collection and Sorting of Recyclable Materials A variety of collection strategies for recyclable materials have been implemented successfully, including drop-off centers, buyback and processing centers, commercial recycling programs (for office paper, corrugated boxes, construction and demolition debris, bulk waste, and additional materials), residential curbside collection, apartment-building collection, rural recycling programs, material recovery facilities, composting (including backyard composting, large-scale community composting in windows, and in-vessel composting and anaerobic digestion), and mixed-waste processing.

Municipal recycling facilities typically employ a variety of sortation techniques including manual, magnetic, and air classification in conjunction with crushers, grinders, and balers to produce clean, segregated recyclable materials in large quantities.

4.3.3 Paper and Paperboard Recycling Two common examples of recycling are paper (and paperboard) and glass. Business centers in large cities generate a large volume of high-grade office paper. Many enterprises also generate substantial quantities of bulky corrugated boxes. Many paper mills have been retrofitting their facilities for recycled paper feedstock and recycled paper, corrugated board, and paperboard and will most likely sustain a stable future demand.

4.3.4 Glass Recycling Only container glass used to make bottles and jars is being recycled in large quantities currently. Approximately 7×10^9 glass containers are being recovered annually in the United States. The special consideration in the recycling of glass is the need for color separation. Permanent dyes are used to make colored glass with the most common colors being clear (flint), brown (amber), and green (emerald).

4.3.5 Aluminum Recycling Of the various types of aluminum products, aluminum cans are the most feasible to recover for recycling. The packaging industry constitutes the largest market for raw aluminum, consuming 27% of total aluminum production. Aluminum cans are intended for short-term consumer usage and are discarded quickly (typically after a few days or weeks).

Many aluminum cans are returned to the point of purchase because of beverage container deposit laws in many states. In addition, aluminum cans are nearly always included in municipal and commercial recycling programs because of their relatively high market value and ease of identification. In 1989, recycling operations recovered 60.8% of all used aluminum beverage containers. The market for used aluminum beverage containers arises from the fact that the manufacture of new aluminum cans from used containers requires 95% less energy than production from virgin raw materials.

Household aluminum scrap can be collected as a source-separated material in conjunction with a curbside recycling program or included in a commingled recyclables program. Approximately 9×10^8 kg of aluminum are used annually to fabricate household products other than beverage containers. An additional 3.6×10^8 kg of aluminum are used annually to make wire and cable, including bare wire (4.5×10^7 kg), aluminum-conductor steel-reinforced and bare cable (1.4×10^8 kg), and insulated and covered wire and cable (1.8×10^8 kg). Some of this wire and cable also becomes household scrap.

Approximately 90% of scrap aluminum in municipal solid waste is in the form of wrought alloy products such as those mentioned above. However, most postconsumer aluminum scrap is used to produce casting alloys on account of their less-demanding product specifications. Thousands of aluminum scrap processors are currently operating in the United States and process a variety of grades of household scrap. Foreign end users also play an important role in the recycling market. Nearly 5 × 10^8 kg of aluminum scrap (not including used beverage containers) and remelt secondary ingot are shipped to foreign buyers annually.

4.3.6 Recycling of Other Scrap Metal Scrap metal typically refers to ferrous metal, including discarded automobiles and steel cans. Recycling of ferrous scrap dates back to antiquity. Producing steel from scrap metal is economically desirable from the perspective of energy conservation. Approximately four times as much energy is required to produce steel directly from iron ore as is required to produce steel from scrap. In addition, there are advantages in terms of reduced air pollution and reduction in landfill burden. Steel cans are extensively used as containers for food, beverages, paints, and other products. Steel cans may typically have a thin lining or coating of tin for corrosion protection.

"White goods" (i.e., large appliances such as refrigerators, freezers, washers, dryers, stoves, furnaces, and water heaters) also can be recycled. These items contain significant amounts of sheet steel and are typically replaced after approximately 15 years of use. An estimated 2.9 × 10^7 units were replaced in the United States in 1991. Because of their physical volume and their high content of recyclable material, it is highly advantageous to collect and recycle these items.

4.3.7 Recycling of Other Materials The generation and composting of yard wastes are discussed in Secs. 1.1.1 and 3.3.2, respectively. Plastics recycling is discussed in Sec. 4.6.2.3.

4.3.8 Energy Recovery from Waste Oils The heat value of waste oils can be recovered through the process of fuel blending. Waste oils typically must be treated to remove sediments, water, and bottom fractions. The treated waste oils can be mixed with coal or fuel oils to produce a waste-derived fuel.

4.4 Reuse

Reuse refers to the continued use of a resource in the same form. A glass bottle that is reprocessed into paving material is said to be recycled. However, a glass bottle that is refilled is said to be reused. Common reused materials include ferrous metals, aluminum (and other nonferrous metals), and glass bottles. Resource reuse often has the added benefit of energy savings because of the high energy requirements of mining and glass processing.

4.5 Substitution

Substitution refers to the replacement of a resource with a more renewable or less toxic substance. It is used as a form of pollution prevention in some specialized manufacturing processes.

4.6 Integrated Waste Management

4.6.1 Background Management of a particular resource often requires a combination of disposal, pollution prevention, and treatment approaches. These activities should be integrated to maximize resource utilization, while minimizing environmental harm. To illustrate the many management options, plastics disposal and recycling are discussed in more detail.

4.6.2 Management of Plastics At the present time, about 3 × 10^{10} kg of plastic resin are produced, sold, and consumed in the United States each year. Approximately 1.4 × 10^{10} kg of plastic are currently disposed of as municipal solid waste. This represents 7–8% by weight and 20% by volume of the roughly 2 × 10^8 tons of municipal solid waste generated annually in the country. The percentage of the solid waste stream consisting of plastics by weight in most European nations is virtually identical to that in the United States at 7.1–9.0%.

4.6.2.1 Disposal Options. Plastics are well suited to a variety of disposal options. For example, plastics are suitable for landfilling because they are so inert. They contribute to the stability of the landfill and the integrity of the cap and do not migrate or contaminate soil or water. In addition, plastics are attractive for incineration and energy recovery (quaternary recycling) because they possess a high calorific content since their constituents are generally hydrocarbons derived from petroleum or natural gas. They may be incinerated to recover some of their energy content to produce high-temperature steam and/or electrical power. They can also be used as a fuel supplement. The advantage of incineration is that no sorting, separation, or cleaning is required. However, because of the chemical composition of certain polymers (e.g., halogen-containing polymers such as polyvinyl chloride) and the pigments, stabilizers, and other additives used in plastics products, there are concerns regarding the possible emissions of heavy metals (lead, chromium, cadmium, zinc, mercury), acid gases (HCl, HF), and other pollutants such as SO_2, NO_x, dioxins, etc. It is therefore critical to operate the incinerator at the appropriate conditions and to employ proper emission-control systems. The ash generated (approximately 20% by volume) may contain heavy metals and require disposal in a secure landfill.

Plastics are also suitable for pyrolysis. Pyrolysis involves the liquefaction and/or gasification of the plastics waste stream at elevated temperatures (1000 °F) in the absence of oxygen to prevent the formation of oxygenated compounds. The process yields a variety of products, principally low–molecular-weight aliphatic hydrocarbons that are rich in hydrogen. The products generated depend on the specific process conditions such as temperature, residence time, and feedstock composition. Increasing temperature results in an increased gas fraction and a decrease in the solid and liquid oil fractions. The thermal cracking process associated with pyrolysis is endothermic and is carried out in one of three types of reactors, namely rotary kiln, fluidized bed, and tubular shaft. Like incineration, the advantage of pyrolysis is that no sorting, separation, cleaning, or feedstock preparation is required. The disadvantages are the substantial capital investment required and the fact that the generated hydrocarbons must compete economically with similar petroleum products manufactured from crude oil or natural gas.

4.6.2.2 Plastics Biodegradation. Consideration has been given to synthesizing polymeric structures that are inherently biodegradable or incorporating additives that would accelerate the biodegradation or photodegradation of the plastic. Unquestionably, this approach is most appropriate in certain niche markets (e.g., mulch film, compost bags, six-pack rings, baby diapers, medical disposables, etc.) but has serious limitations for long-life durable goods and may pose a barrier in terms of contamination of plastics waste streams targeted for recycling. The use of accelerant additives has been shown to be effective, but the ultimate fate of the actual polymeric matrix remains an issue. Biodegradable resins are generally more expensive than their nondegradable counterparts.

4.6.2.3 Plastics Recycling. Most plastics are inherently recyclable (thermoplastics) and the majority of plastics processors (including many thermoset processors) typically recycle regrind from unacceptable parts to be economically competitive. However, the recycling of postconsumer scrap plastics poses a more serious technological and economic challenge. The plastics materials must be collected and transported to a handling and sorting facility. This may involve a residential curbside collection program, a materials recovery facility (MRF), or some other entity. Some technologies have been developed to process a commingled plastics waste stream directly. The extrusion of plastics lumber for garden furniture, decks, parking barriers, park benches, etc., is an example of this approach. The variability in bulk density, moisture content, contaminant level, and processing characteristics associated with differences in the feedstock initially posed a technical challenge to the industry. However, this problem has been largely overcome by the adoption of appropriate process-control methodology. The technology has been successfully demonstrated and commercialized, but the product must compete economically with wood.

4.6.2.4 Plastics Segregation and Sorting. A wider range of technological and market options exist if the polymeric materials can be segregated by type. Because of the bottle deposit laws in many states and the fact that most plastic soft-drink containers consist of polyethylene terephthalate (PET), the recycling of PET beverage bottles has been highly successful. Table 3 provides current statistics on postconsumer recycling (PCR) of plastics.

The sorting of plastics by type can be achieved by various means. Plastics can be sorted manually. Many recyclable plastics containers are coded using the Society of the Plastics Industry, Inc. (SPI) labeling system (1 = PET, 2 = HDPE, 3 = PVC, 4 = LDPE, 5 = PP, 6 = PS, and 7 = other) to assist in identification of the plastic. This is particularly useful for source-separation programs involving the consumer. Trained personnel at a sorting facility are very efficient and adept at identifying the major commodity resins, but some remain difficult to distinguish (e.g., PET and PVC). Manual sorting at a centralized facility is expensive and has the potential for exposing workers to residual household and industrial chemicals from the collected containers.

4.6.2.5 Chemical Recycling. The depolymerization of a plastic back to its monomeric precursors can be achieved for certain polymers by chemical and/or thermal processes called chemical recycling. The monomers can then be repolymerized or transformed into other polymers. Condensation polymers, such as polyesters, polyamides, polyurethanes, and polyethers are produced by a reversible step-growth condensation polymerization. These materials are particularly amenable to chemical depolymerization via an alcoholysis-hydrolysis reaction mechanism. Alcoholysis includes methanolysis and glycolysis in which the polymerization reaction is reversed to yield monomers or oligomers. Goodyear has commercially demonstrated the recycling of PET by means of glycolysis. Complete depolymerization by methanolysis requires an excess of methanol and heat. For PET the resulting products are dimethylterephthalate (DMT) and ethylene glycol. The DMT can be purified by distillation and repolymerized. Hoechst Celanese, Eastman Chemical, and DuPont have commercially demonstrated the viability of this process. Complete depolymerization of PET can also be achieved by hydrolysis, which yields terephthalic acid and ethylene glycol. This process has been patented by Amoco.

The hydrolysis of polyurethanes results in the production of polyols, carbon dioxide, and diisocyanate. The reaction rate can be increased by increasing temperature and pressure. The glycolysis of polyurethanes is generally preferred because of economic considerations and technological convenience. Typically, ground polyurethane is fed into a continuously mixed reactor containing glycol at 200 °C. The reactor also contains an organometallic catalyst and is maintained under an inert nitrogen atmosphere.

The chemical depolymerization of polyamides generally takes place at high temperature in the presence of water and inorganic acids. Some polymers, such as polymethyl methacrylate, polystyrene, and

Table 3. Post-consumer plastics recycling (Powell, 1991). Abbreviations: PET = polyethylene terephthalate, HDPE = high density polyethylene, PVC = polyvinyl chloride, (L)LDPE = (linear) low-density polyethylene, PP = polypropylene, PS = polystyrene, N/A = not available.

Material	Product	Total sales (10^6 kg)	Postconsumer recycling (10^6 kg)	Postconsumer recycling (% of sales)
PET	Soft-drink Bottles	367	128.9	35.1
	Custom bottles	175	4.2	2.4
HDPE	Bottles	432	60.3	14.0
	Pigmented bottles	620	42	6.8
	Base cups	48	19.6	41.1
	Other packaging	500	3.0	0.6
PVC	Bottles	92	0.7	0.8
	Nonpackaging	N/A	2.7	N/A
LDPE and LLDPE	Bottles	28	0.05	0.2
	Other packaging	2099	21.3	1.0
PP	Custom bottles	61	0.6	1.0
	Other packaging	300	1.0	0.3
PS	All packaging	923	11.0	1.2

various acetal homopolymers, may be depolymerized to give high yields of their constituent monomers by heating in the absence of oxygen. The monomers may be isolated, purified, and synthesized into new polymers.

4.6.2.6 Practical Aspects of Plastics Reclamation. Myriads of potential applications exist for reclaimed plastics. Besides the direct reprocessing into finished products, reclaimed plastics can be employed in conjunction with virgin plastic materials. For example, multilayer extrudates and blow-molded containers can be fabricated with an interior layer consisting of recycled material.

The major barrier to more widespread recycling of plastics is essentially one of economics. With the relatively low cost of crude oil, the price of polymeric feedstocks and commodity virgin polymers is also relatively low. In a free market, recycled polymers must compete with virgin resin. The collection, transportation, separation, cleaning, and pelletizing results in a significant cost with very little or no margin compared with virgin material. Fluctuating market demand and limitations of supply have also posed difficulties. However, as the recycling infrastructure becomes established, markets will become more stabilized. In addition, technological developments will result in more efficient and economical operations.

There are currently several large-volume nuisance plastics waste streams besides rigid container packaging. These include flexible film, wire and cable coatings, medical disposables, and automotive shredder residue and represent substantial volumes of potentially recoverable materials. Further research efforts need to be directed at developing efficient and economical technologies for reprocessing these materials.

5. ENVIRONMENTAL REMEDIATION AND RESTORATION

5.1 Emergency Spills and Releases

Requirements for emergency planning were codified in the Superfund Amendments and Reauthorization Act (SARA) of 1986 (see Sec. 2.1). Specifically, emergency planning needs and procedures were included in the Emergency Planning and Community Right-to-Know Act (also called EPCRA or SARA Title III). Contingency planning was required in SARA Title II through emergency planning, emergency notification, community right-to-know reporting requirements, and toxic-chemical release reporting requirements. Certain Occupational Safety and Health (OSHA) regulations also cover emergency procedures.

5.2 Inactive Municipal/Hazardous-Waste Disposal Sites

5.2.1 Risk Assessment Risk assessment is the quantification of the probability of adverse effects from a pollutant. Risk assessment involves four steps: hazard identification, toxicity assessment, exposure assessment, and risk characterization. Hazard identification is the process of listing the potential harmful pollutants. Toxicity assessment involves the use of dose-response data to relate intake to adverse effects. In exposure assessment, the population at risk, exposure times, and exposure doses are quantified. The final step in risk assessment is the integration of the first three steps to characterize the risk fully. All data required to assess fully the risk from inactive municipal/hazardous-waste disposal sites rarely are available, and risk assessments must frequently embrace and quantify the uncertainty in the analysis.

5.2.2 Remediation Strategies

5.2.2.1 Containment. Containment refers to the restriction of movement of a contaminant in the environment by the construction of a low-permeability barrier. There are two general approaches to containment: passive control and active control. In passive control systems, ground-water migration into and/or out of the contaminated zone is reduced with vertical barriers, and surface-water infiltration is minimized with a cap. Vertical barriers typically extend to a confining layer of relatively impervious material (called an aquitard).

Vertical barriers are characterized by their placement and construction technique. Barriers can be circumferential (surrounding the contaminated zone and extraction wells), upgradient (blocking ground-water intrusion and allowing for extraction of the contaminated plume downgradient), or downgradient (preventing plume migration and allowing for extraction wells to remove contaminated ground water). In terms of construction, vertical barriers include slurry trench cutoff walls, grout curtains, and steel sheet pilings. Slurry trench cutoff walls can be made of soil-bentonite, cement-bentonite, or plastic concrete, while cement- or chemical-based grouts are used in grout curtains.

The primary active system for the containment of contaminated ground waters is pump-and-treat. In this approach, contaminated ground water is extracted from the contaminated zone. It is treated at the surface, usually by air stripping, activated carbon adsorption, chemical oxidation, or biological methods (see Sec. 3.1.1). The treated ground water is discharged or recharged to the subsurface. Extraction of contaminated ground water typically is accomplished by the use of recovery wells or drain-tile collection systems. In the drain-tile collection system (also called a french drain), contaminated ground water flows into a trench excavated around the site. The trench is filled with filter media and collection piping. The drain-tile collection approach is being used to collect ground waters in the vicinity of Love Canal in Niagara Falls, New York.

The primary advantage of pump-and-treat systems is that annual operation and maintenance costs are fairly low. However, the pump-and-treat approach has been criticized for the long times (typically years to decades) required for treatment. After an initial period of rapid decontamination, the rate of pollutant removal often slows dramatically during pump-and-treat.

An alternative to pump-and-treat is the use of permeable or reactive barriers. In this approach, barrier walls are constructed of materials that allow for treatment of the ground water as it passes through the wall. Examples include the use of activated carbon, ion-exchange resins, or zero-valent iron (which is capable of dechlorinating some chlorinated organics).

5.2.2.2* In Situ *Treatment Technologies. *In situ* treatment technologies treat contaminated soil in place without excavation. Treatment processes may be physical, chemical, or biological in nature. Physical *in situ* processes include soil flushing, soil vapor extraction, low-temperature desorption, electrokinetic treatment, and stabilization/solidification. Soil flushing is a modification of the pump-and-treat process whereby contaminant mobility is increased by the nature of the flushing solution. The flushing solution can be water, acids (for recovering metals and organic bases), bases (for phenol), complexation agents (for metals recovery), or surfactants (for organics). The flushing solution is introduced by injection wells, infiltration galleries, spray irrigation, or flooding. In soil vapor extraction (or SVE), air is passed through the soil to remove volatile organics. Air is introduced by drawing a vacuum on vapor extraction wells or perforated pipes located in the unsaturated (or vadose) zone. In a modification of SVE called air sparging, air is blown into the ground water, and volatilized contaminants pass into the unsaturated zone where they are collected by an SVE system. In low-temperature soil treatment, air is passed through soil that has been heated to 300–400 °F. Volatile organics are stripped into the air stream and subsequently treated. In electrokinetic (or electroosmotic) soil treatment, a direct current is applied to the soil to generate a voltage field. Pore water containing the contaminants moves in response to the field and can be captured and treated. Electrokinetic methods are used mainly for the removal of metals from soil.

Other physical processes that can be employed *in situ* or *ex situ* include stabilization and solidification. In stabilization (also called fixation), the mobility of contaminants is decreased significantly by the addition of binders. In solidification, the larger amounts of added materials are used to solidify the waste as well as bind contaminants. Stabilization and solidification are used for the treatment of sludges, soils, sediments, and oily wastes. Typical binding agents include lime, portland cement, pozzolanic materials (such as cement-kiln dust and fly ash), silicates, organically modified clays, and organic polymers. One form of solidification is vitrification. In vitrification, the soil is heated to 1600–2000 °C in a glassmaking furnace or *in situ* and cooled rapidly. The resulting amorphous mass can be crushed and used as a road aggregate.

Bioremediation refers to the treatment of contaminated sites with biological processes. The contaminated soil system replaces the biological reactors described in Sec. 3.1.1.

The primary concern of bioremediation systems is the proper introduction of electron acceptors (usually oxygen) or other nutrient. Oxygen and nutrients can be introduced into the ground water through injection wells or recharge trenches. Oxygen may be added in the form of air or hydrogen peroxide. Careful balance of extraction and reinjection wells is critical in maintaining adequate dissolved oxygen levels in the subsurface.

Modifications of the basic bioremediation scheme described earlier have been employed. For example, exogenous (non-native) bacteria may be added to the site. In addition, anaerobic biodegradation of some contaminants in the subsurface is possible. In some cases, addition of cometabolites can increase rates of biodegradation. Cometabolites induce enzyme systems that allow for the serendipitous degradation of the pollutant. For example, introduction of methane gas may enhance cometabolism of trichloroethylene (TCE).

5.2.2.3* Ex Situ *Treatment Technologies. *Ex situ* treatment technologies are used with excavated soils. Several of the *in situ* processes described in Sec. 5.2.2.2 (especially low-temperature desorption, electrokinetic treatment, stabilization/solidification, and bioremediation) also can be used with excavated soils. *Ex situ* bioremediation processes typically involve slurry treatment, land treatment, or composting. Other *ex situ* processes include disposal and soil washing. Excavation and disposal may be feasible if land disposal costs are low. Safety considerations during the transport of contaminated soils are critical. In soil washing, fluids (typically water, acids, chelating agents, surfactants, or solvents) are passed through the soil to solubilize the contaminants. For example, acids may be used to remove metals bound to the soil. Soil washing typically is performed on excavated soils or soil fractions.

6. FUTURE TRENDS IN WASTE MANAGEMENT AND RECYCLING

6.1 Multi-Life-Cycle Products

An important tool developed recently for environmental professionals is life-cycle analysis. In life-cycle analysis, the environmental impact of a product from "cradle to grave" is determined. This includes the impact of the procurement of the raw materials as well as the product design, manufacture, use, maintenance, repair, and final disposal. If used properly, life-cycle analysis can be a valuable tool in quantifying the overall impact of a product and can be used to determine real product costs.

As recovery, recycling, and reuse programs grow, it becomes necessary to think of products as having multiple lives. Product design may need to incorporate the future use of all material in the product. For example, car manufacturers are incorporating the final disposal and reuse of materials in the design of automobiles. This trend is likely to become more important in the future.

6.2 Treatment and Recycling at Point of Generation

Environmental technology is at a crossroads. Traditional "end-of-pipe" treatment technologies are being complemented with or supplanted by pollution-prevention concepts. However, treatment and pollution prevention are not mutually exclusive. Treatment of waste streams to allow for material recycling will have an increasingly important role in waste management.

On-site recycling or reuse is particularly attractive, because it avoids problems with transportation and storage of recycled materials. In addition, on-site recycling can eliminate concerns regarding inconsistencies in the markets for recycled materials. Especially where economies of scale are not important for treatment and recycling processes, on-site treatment and recycling may be very efficient.

7. SUMMARY

This review has provided a brief introduction to a large number of topics in waste management and recycling. Treatment processes will continue to play a major role in the management of solid wastes, municipal waste waters, hazardous wastes, and air pollutants. The complementary tools of pollution prevention (recovery, recycling, reuse, and substitution) will grow in importance as economic pressures increase. The need for efficient waste-management practices has never been more acute as we enter the twenty-first century.

GLOSSARY

Aerobic: Biochemical process or condition associated with the presence of oxygen.

Compost: Humuslike material resulting from the biological decomposition or breakdown of organic materials.

Effluent: A waste liquid from a manufacturing or treatment process that is discharged to the environment.

Fly Ash: Solids, including ash and other matter, that rise with the hot gases from combustion and are removed by emission-control devices.

Hazardous Waste: A waste material that, because of its quantity, concentration, or physical, chemical, or infectious characteristics, may pose a substantial potential hazard to human health or the environment when improperly treated, stored, transported, disposed of, or otherwise managed.

Postconsumer Material: Those products generated by a business or consumer that have served their intended end uses and that have been separated or diverted from solid waste for the purposes of collection, recycling, and disposition.

Recycling: The process of separating materials from the waste stream and using them for another purpose.

Refuse-Derived Fuel (RDF): A solid fuel obtained from municipal solid waste.

Resource Recovery: The extraction and utilization of materials and energy from the waste stream.

Reuse: The use of a product more than once in its same form and for the same purpose.

Sanitary Landfill: An engineered repository for the disposal of solid waste on land.

Secure Landfill: A landfill designed to prevent the entry of water and the escape of leachate through the use of impermeable barriers.

Yard Waste: Leaves, grass clippings, and other organic manner from yards and gardens.

INTRODUCTION

Water serves many purposes in society, some of which have been recognized for eons. Other uses are the result of relatively recent industrial influences on our way of life. Some uses are compatible with all recognized uses of water in our society while others change the quality and quantity of the water, impairing other uses. Water pollution can be considered to result when contaminants are added or the physical quality, e.g., temperature, is changed to a degree sufficient to affect other uses adversely. Natural processes can in time ameliorate most water-pollution problems, but when limited time is a critical element in the intended reuse of a body of water, man-made adaptations of the natural processes can be employed to restore water quality.

Water quantity and quality are linked in determining when a given water use and subsequent reuses are compatible, simply because many water-pollution conditions are concentration dependent. That realization gave rise to an often maligned adage, "dilution is the solution to pollution." Although true to this day in the case of many contaminants, there is more than dilution alone that must be considered with regard to persistent organic compounds, for example, in preventing or resolving water-pollution problems. Through the last two centuries the demand for water has generated a hierarchy of uses, with human consumption at the top, considerable jockeying for intermediate positions, and relegation of waste disposal to the bottom of the list.

Legal doctrines on water use vary with geography and culture. In the eastern United States, riparian rights imply equal and unabridged right to water flowing along a property line, whereas in the western regions of the country, prior appropriation entitles a person first in time to claim all the water he needs, preventing others upstream from taking any at a later time. In the East, both quantity and quality issues were involved in adjudications, but in the West, quantity was (and is) the main issue. Emerging water quality concerns, even in the West, beginning in the 1950s and extending well into the 1990s have promoted new federal legislation and regulatory practices that will dominate municipal, industrial, and some agricultural uses of water into the 21st century, based on a wide range of quality issues. The major ef-

fort in water-pollution regulation is administered by the U.S. Environmental Protection Agency (EPA), which in its 1994 inventory of water quality found that about 40% of the water bodies in the United States that were assessed by individual states were not suitable for such activities as fishing or swimming (Browner, 1994). While these uses of water are desirable amenities in more developed countries, it is clear that they are not the highest and best uses in the hierarchy of uses, and it is also clear that the effort to achieve the fishable/swimmable objective will impose significant additional requirements on other uses. The U.S. EPA employs strategies of technology-based controls and water-quality standards within an effluent-discharge permit system to achieve this objective.

In less-developed countries direct recreational uses may not be considered at all. Generally, drinking water and agriculture demand highest priority, transportation of goods (shipping) and industrial use a lower priority, and waste disposal the lowest priority. Local and regional interests can influence the priority rankings in any given society, however, and controversies may arise as water flows from one area to another within a watershed.

The problems and approaches to control of water pollution are similar in many industrialized nations, with control strategies frequently following the lead of the U.S. EPA. The major pollution problem in nonindustrialized nations is the lack of infrastructure for treatment of domestic sewage. This results in a serious impact on human health because of the lack of facilities for storage and treatment of drinking water.

1. WATER SOURCES AND THEIR SUSCEPTIBILITY TO POLLUTION

1.1 Fresh Water

The amount of fresh water in rivers and lakes, 125 000 km^3, is only 1/10 000 of the total water available on the planet (van der Leeden *et al.*, 1990). Another (10 to 20) × 10^6 km^3 are thought to exist in ground water. The total quantity, which is fairly constant decade to decade around the globe, is not nearly as important in considering water use and pollution as is its nonuniform distribution over terrestrial space scales of 10^4 to 10^5 km^2 and time scales of 10 to 1000 d. More than two-thirds of the water that falls on the earth as precipitation returns to the atmosphere as evaporation, and half of the remaining precipitation runs off in flood events and is not available for use. Most of the fresh surface water is in lakes, having a turnover time of about 100 a, while streams, with turnover times of 11 d on average, contain only 1% of the surface water. By comparison, the replenishment time of ground water is on the order of 1000 a.

The water stored in reservoirs and lakes, together with the water that flows perennially in streams, is subject to heavy stress due to use and reuse for water supplies, agriculture, industry, and recreation, frequently resulting in misuse. Most cities and industries in the United States discharge waste water to streams and rivers, rather than to lakes and reservoirs. Even though the waste waters are treated, large quantities of contaminants are carried by river systems. Within the last decade or so, most communities have installed treatment plants removing 80–90% of particulate and dissolved organic contaminants. The remaining 10–20% of these contaminants could still result in substantial pollution. For example, a community of a million people could add 9 to 18 metric tons of organics per day to the river running through their town, even with 80–90% sewage treatment efficiency. In addition, inorganic salts and metals are added, which are not as effectively removed in treatment. Similarly, ground water used for municipal and agricultural purposes is normally returned to streams. Whether downstream uses are impaired or not, i.e., whether pollution occurs, depends on the type and amount of contaminants added by incremental uses and on the physical, chemical, and biochemical processes that influence the fate of contaminants.

1.2 Marine Waters

Marine waters constitute most of the water on the planet. Even the tremendous volume of ocean water in which contaminants may be dispersed does not necessarily confer immunity from pollution for marine-water resources. Estuaries and near-shore coastal waters are most susceptible to pollution because of the load of contaminants brought to the coastal zone by rivers, local concentration of municipal and industrial activity, and the belief, sometimes correct, sometimes wrong, that less treatment is required for marine disposal of wastes.

Almost all of the water-carried wastes of a continent enter the coastal zone through an estuary. Estuaries take many physical forms, including fjords, broad deltas, and drowned river valleys, all of which have salinities modified from ocean concentrations as a result of evaporation and dilution by fresh-water inflows. Mixing of river flows and waste discharges with the ocean water in an estuary is influenced by the winds and tides, and by the density distribution in the water associated with both salinity and temperature differences. Depending on the degree of mixing and circulation of water masses within the estuary, contaminants may have a long residence time in the system, which can lead to pollution problems.

Although good circulation and short residence times tend to suppress the onset of pollution, there are still situations where pollution can result in well-mixed estuaries. In many of these cases the pollution is the result of seabed accumulation of organic or metal-laden particles. Two physical-chemical factors contribute to this phenomenon in addition to the amount and type of contaminants carried into the estuary by rivers and waste discharges. The first is that current speeds in the estuary are generally lower than in the rivers so that gravitational sedimentation is facilitated. Also, the mixing of oceanic salts with the essentially fresh-water character of rivers and waste water enhances precipitation and coagulation of dissolved and fine particulate matter, which adds to the sediment load. In some estuaries, especially in fjords where a strong density gradient restricts vertical mixing, particles that once settle into the bottom layer of the water column may be retained permanently. Sediment-quality criteria have been the subject of research within the EPA since the early 1980s. This research has focused mainly on toxicity to benthic invertebrates and on sediments as a food route for bioaccumulation of harmful organic chemicals. Science advisors to the EPA have suggested that additional research may lead to regulatory criteria within the next decade.

Offshore from the estuarine environment, the near-shore coastal zone has been the subject of pollution concern related primarily to the disposal of sediment removed by dredging of harbors, and to discharge of waste water from large municipalities and industries, e.g., the pulp and paper industry. The coastal zone extends from the low-tide line to the 200-m depth contour, coinciding with the geophysical demarcation of the continental shelf. The coastal zone can be as wide as 1400 km along some coasts and less than a kilometer along others. Dilution and off-shore transport of contaminants is generally more favorable in this physical environment than in rivers and estuaries. Consequently, there are advantages to disposal of waste-water effluents in the coastal zone over estuaries. A large outfall pipeline or tunnel, terminating in a multiple array of relatively small-diameter diffuser ports, is commonly used in the United States to transport the effluent several kilometers off shore. The practice is becoming more common for major municipalities around the world, although there are still coastal cities that discharge untreated waste water close to the beach through outfalls without multiple-port diffusers, thus failing to take advantage of the high degree of dilution that could be achieved.

Physical features of the coastal zone can interfere with effective waste disposal in the coastal zone. For example, continental headlands that protrude seaward from the beach can impede both circulation of water and exchange of near-shore water with open-ocean water. Outfalls are therefore best located farther off shore rather than inside the region of headland influence. Similarly, outfalls should not be located close to the entrance to estuaries or bays because tidal incursions can carry diluted wastes into the estuary, thereby diminishing one of the advantages offered by off-shore disposal (Baumgartner *et al.,* 1994). This problem also occurs sometimes with barge disposal of dredged materials off the mouth of estuaries, from the movement of deep off-shore coastal waters into an estuary. During parts of the tidal cycle, the deep, landward currents can be strong enough to carry the dumped particulates back into the estuary, where they again might settle in the channels that were just dredged.

Waste disposal has caused definite pollution problems in a few highly developed coastal areas in the United States, notably off of Los Angeles, New York, and Boston. In all cases the predominant manifestation has been the sediment accumulation on the seabed of particulate material discharged with partially treated waste water and digested sludge. Nutrients and persistent organic chemicals in and on the particulates have contributed to fish diseases and the disruption of indigenous biological communities in the region of the discharges. Billions of dollars have been expended to abate the pollution and prevent recurrence; however, many scientists and regulators disagree on the effectiveness of the technologies employed in these efforts. Furthermore, a report of the National Research Council (1990a) concludes that although over \$130 $\times 10^6$ is spent annually on coastal monitoring of water quality, most programs fail to provide the information necessary to assess the condition of the environment, anthropogenic effects on it, and the effectiveness of remediation and control measures. Two major difficulties with improving the state of affairs are the vast complexity of marine environmental processes and the limited knowledge possessed by the scientific community to describe and predict causal relationships.

Open-ocean waters beyond the coastal zone can become contaminated by atmospheric fallout, oil spills, and dumping of hazardous wastes and sewage sludge as practiced by some countries of the world. Barge dumping of treated municipal sludge into coastal and off-shore waters is prohibited by the United States, although discharge of treated waste-water effluent is allowed. Floatable and soluble materials tend to stay in the upper mixed layer of the ocean, the most active photosynthetic zone. The depth of this layer, which varies between 100 and 1000 m, changes with season and geographic location. Although mixing between the upper and deeper layers of the ocean is impeded by strong density gradients, particles formed in the upper mixed layer, or discharged there, may eventually settle so far that they can no longer be resuspended by surface-generated turbulence, and thus become incorporated with the natural detrital sediment load of the deep ocean waters.

Atmospheric fallout and washout of chemicals, primarily volatile organics, has resulted in the accumulation of chlorinated hydrocarbons in the fatty tissues of marine animals far from terrestrial industrial sources, highlighting a case where the large potential dilution capacity of the ocean is not necessarily an effective barrier to pollution. A large portion of petroleum hydrocarbons found in the ocean evidently derive from atmospheric transport of fugitive gases from terrestrial sources, although it is estimated that a third or more of the oil spilled at sea is evaporated and becomes part of the atmospheric burden. Major oil spills from vessels such as the *Exxon Valdez* represent only about 1% of the annual input of hydrocarbons to the world's oceans. Lead and mercury also have been found in sea-surface sampling off shore from municipal–industrial coastal developments. However, the direct connection to adverse impacts on marine resources from atmospheric inputs has not been documented.

Typical municipal and industrial waste-disposal operations have not represented a direct threat to global open-ocean water quality, contrary to the situation in many near-shore coastal waters. Indirectly, contaminants in low concentrations carried into the open ocean by currents flushing the coastal zone could conceivably contribute to diminished water quality. Unfortunately, through the decade of the 1990s this has been a matter of research interest only, and only cursory observation by regulatory authorities. To call it surveillance would overstate the magnitude of the attention dedicated to this effort.

When ocean disposal of certain materials is justified, technologies can be employed to avoid contamination of the upper mixed layer and facilitate transport to and long-term retention of the material in the deep waters of the open ocean. For example, containers have been proposed for disposal of such materials as hazardous chemicals or radioactive wastes. Although not an existing technology, proposals have been made to use pipelines to transport liquid carbon dioxide to the seabed, where it can be retained for a long time—conceivably long enough to help reduce the rate of carbon dioxide buildup in the atmosphere (Marchetti, 1977).

2. SOURCES OF SURFACE-WATER POLLUTION

Pollution in surface waters can result from many kinds and amounts of contamination. It may take just a small amount of contaminant to pollute a water body intended for a drinking-water supply. But the same water might not be considered polluted if the water were to be used, for example, for agriculture. Nor is pollution restricted to biological and chemical contaminants. Physical factors of the environment can also contribute to pollution. For example, heated water discharged from a power plant can change the temperature of an aquatic environment. It might not be a problem in a lake or a river during the winter, but it can certainly be a problem in the summertime. For example, young salmon in the Columbia River are especially vulnerable to a microbial infection when summer temperatures are raised only slightly above the normal midsummer temperatures. There are also many kinds of contaminants that can usually be accommodated by the natural environment without resulting pollution.

The major sources of surface-water contamination are construction, municipalities, agriculture, and industry. However, the water delivered to earth in the form of precipitation is not necessarily pure to begin with. Near the coast, it may contain particulate and dissolved sea salts, and further inland, it may contain organic compounds and acids scrubbed from contaminants added to the atmosphere both by natural processes and by anthropogenic activities. Gases from plant growth and decay and gases from geological activity are examples of naturally derived atmospheric contaminants that can be returned to earth via precipitation. The acid-rain problem of the New England states is a classic example of anthropogenically derived atmospheric contaminants that contribute to surface-water pollution.

2.1 Construction and Land Use

Because construction involves land clearing and grading, this activity is a major source of sediment contamination of streams. Agriculture and forestry are also operations traditionally responsible for pollution of streams with particulate matter. In addition, other land-use activities such as recreational off-road vehicle use can destabilize soil formations, thus increasing erosion. The runoff of fine-grained soil particles, especially in hilly terrain with high rainfall, can smother gravel beds that serve as a spawning habitat for fish. In addition, suspended particulates and colloidal material can harbor microorganisms, necessitating increased treatment for municipal water-supply facilities. Nor is the damage associated with construction limited to aquatic resources; erosion also decreases the topsoil resource needed for sustainable plant growth.

Erosion, both anthropogenic and natural, is a continuous process. All things considered, tens of thousands of hectares of riparian area are lost to erosion each year in the United States, and hundreds of millions of tons of topsoil are carried by rivers to the sea per year. Natural erosion of river banks in some areas masks the pollution caused by human activities. For example, such rivers as the Mississippi carry about 500 mg L^{-1} of suspended solids, so that even many tons of solids added over a section of the river by a construction event might not adversely affect the use of the water. In other areas, the amount of river-bank erosion can be exacerbated by poor land-use practices. Some streams are naturally very sediment free, so that the addition of as little as a ton of soil in a year can cause pollution of a major portion of the stream.

Beginning in the 1970s, U.S. pollution-control agencies began to restrict road construction and timber harvesting operations in forest areas to reduce soil erosion. Although these restrictions were primarily intended to reduce impacts on fish habitats, their serendipitous result was to enhance retention of topsoil. The 1980s saw a great deal of attention devoted to reducing soil runoff from individual home-site construction projects, as well as large home and shopping-center developments. Then, in the 1990s, the promotion of "no-till" planting in the agriculture industry helped to reduce wind- and water-carried loss of topsoil, and this in turn helped to reduce potential water-pollution problems in rivers and reservoirs. Measures designed to control soil loss to rivers may have reduced the concentrations of other contaminants, such as pesticides and metals, that can also pollute surface waters. However, the main sources of many of these contaminants are municipalities and industries as well as agriculture.

2.2 Domestic and Municipal Sewage

Domestic sewage includes human wastes and a variety of waste materials that arise from household products such as foods, soaps, paints, oil, and grease. These wastes contain microorganisms, metals, plastics, decomposable organic chemicals, and toxic chemicals. Municipal sewage comprises a matrix that includes everything in domestic sewage plus water-carried wastes from industries, schools, hospitals, and airports connected to the municipality's sewer system. In many cities, street washings and other wastes poured into streets contribute to the contaminant load in municipal sewage.

Pollution may result when these wastes are poorly treated or when even highly treated sewage is discharged into a watercourse that is physically or biologically incapable of accommodating the waste load. Human wastes make up a considerable portion of the contaminants in sewage. Many of the stream-water pollution problems that have occurred—and pollution-control technologies that have been developed—are related to human wastes. The components of human wastes that characteristically cause stream pollution problems worldwide are intestinal microorganisms and organic matter.

2.3 Intestinal Microorganisms

Many intestinal microorganisms can remain viable in surface waters for a long time and can cause illness, disease, or even death if they come in contact with humans. The primary method of defense for downstream water users against water-borne outbreaks of disease (such as typhoid and cholera) has traditionally been high-quality physical treatment (chemical precipitation and filtration) and disinfection of river water with chemicals such as chlorine prior to distribution to consumers. However, disease and illness can also be a problem for other uses of the stream resource, such as recreational bathing and harvesting of shellfish. For example, bacteria, viruses, and other microorganisms can cause upper respiratory and ear infections in bathers, while fairly large disease episodes have been attributed to the ingestion of improperly cooked shellfish harvested from polluted coastal waters. Also, some recreational users, misled by the clarity and coolness of streams in remote areas, become ill following ingestion of raw or poorly disinfected water. Visibly clear and ostensibly unpolluted mountain stream water can easily be polluted by wastes from one or two humans upstream, or even by the native warm-blooded animal population. For example, the gastrointestinal disorder known as giardiasis can be caused by the protozoan *Giardia lamblia* found in water and snow contaminated with animal feces. It is prudent—if not entirely necessary—to assume, without qualification, that all surface waters are contaminated with microorganisms of human health significance.

To some degree, the quality of surface water for recreation is protected by the treatment of domestic and municipal sewage at the point of discharge into the watercourse and by the natural purification processes in the water. High-quality sewage treatment processes can remove more than 99.99% of the microorganisms in sewage, although this level of treatment is not always provided. Even if it were provided, waste-water treatment alone is never sufficient to result in river water of suitable quality for direct human consumption. Major storm events can greatly increase the volume of water flowing through older sewage systems (combined sanitary and storm sewers), thus increasing the likelihood that untreated and poorly treated sewage will reach the watercourse. Such events frequently result in the closing of nearby bathing beaches because of the temporarily high concentrations of bacterial counts indicative of fecal pollution.

2.4 Organic Matter

Of the many organic chemicals in municipal sewage, two broad categories are important on the basis of the type of surface-water pollution problems they cause. One group, xenobiotics, contains the persistent synthetic chlorinated organic compounds that were produced by the petrochemical industry in ever-increasing amounts after World War II; these include insecticides and chlorinated hydrocarbons such as polychlorinated biphenyls (PCBs) and trichloroethylene (TCE). Such chemicals degrade very slowly in the environment and can cause long-lasting toxicity, either acutely or chronically as a result of bioaccumulation in tissues.

Other organics are grouped in a class labeled biodegradable organic matter, which includes natural organic compounds found in wastes, such as carbohydrates and proteins. Many industrial chemicals also fit in this category. The problem with these organics is the depression of the dissolved-oxygen content of stream waters caused by their microbial decomposition. The main feature of this pollutional effect in the stream is that the loss of dissolved oxygen is detrimental to aquatic organisms. A secondary effect is that if all the dissolved oxygen is consumed by aerobic microbial oxidation of the wastes, anaerobic decomposition becomes prominent, releasing noxious septic gases from the stream. Waste-water treatment methods, including trickling filters and activated sludge aeration, were developed in the first 50 years of the 20th century to deal with this problem.

Quantitative methods have been developed to assess the impact on surface waters and to calculate the degree of treatment needed before municipal wastes are discharged as effluents. Such methods are based on an understanding of the physical and biochemical processes controlling the decay of microbes and chemicals over time.

2.5 Die-off of Indicator Organisms

Early in the development of quantitative assessment methods, scientists realized that many different microorganisms that exist in human wastes could not be effectively cultured and counted. Consequently, they settled on the coliform group of organisms to serve as an indicator of fecal pollution because they could be cultured and counted easily. Known to exist in large numbers in the gut of all warm-blooded animals, the coliform group provides a good indication of fecal pollution; however, it was not very specific, and so other indicators such as fecal coliforms and streptococci may now also serve as indicators of the sanitary quality of water.

Tests have shown that 99.99% of the indicator bacteria can be removed by waste-water treatment. But the residual 0.01% remains a problem, raising concerns about the quality of water for recreational use, for example. The fact is that the number of bacteria in sewage is tremendous (500×10^6 to 2×10^9 per 100 mL), so that the percentage of removal is not as useful as is the actual remaining concentration in assessing quality. The microorganism concentrations allowed for various uses of water are relatively small. For drinking purposes, the concentration of fecal coliforms should, of course, be zero, but a concentration of less than 1 per 100 mL may be allowed; and for bathing, a concentration of 1000 per 100 mL is frequently accepted. If, for example, raw sewage has a population of 10^9 per 100 mL, a removal efficiency of 99.99% would still leave 100 000 per 100 mL. Simple models are used to determine if the concentration will decrease to acceptable levels through die-off and dilution before the sewage reaches a bathing beach.

Indicator-organism concentrations generally decrease with time of exposure in the aquatic environment, although under some conditions there appear to be brief periods of positive growth. The concentration as a function of distance downstream of the discharge point can be calculated by knowing the current speed and direction or by measuring the travel time from place to place with dyes or other tracers. Both physical and biological processes contribute to the die-off, and physical properties of the flow regime are used to compute the dilution factor. Depending on the location and proximity of uses, the degree of treatment, the point of discharge, and the method of discharge can be designed to optimize the rate of natural purification, further reducing downstream pollution problems.

The concentration C of bacterial indicators of fecal contamination has been observed to decrease with time t according to a first-order reaction, the same way in which radionuclides decay with time, where K is the die-off rate constant. Whereas radionuclide decay is characterized by the half-life of an isotope, a parameter frequently employed in water-pollution analyses obtained by solution of the first-order reaction equation is t_{90}, which is the time required for 90% die-off of the bacteria. Thus, given the value of K, we have

$$t_{90} = 2.3/K. \qquad (1)$$

The general solution used to find the concentration at any time C_t, after the initial concentration C_i is determined, is

$$C_t = C_i e^{-Kt}. \qquad (2)$$

To find the concentration of bacteria after effluent has traveled in the river for, say, 8 h, it is necessary to determine the value of K for the specific situation being studied. Results of many studies in lakes and streams have shown that K varies widely, depending on the temperature of the water, the amount of sunlight, and the depth at which the effluent plume travels with the current. Using an average value for fresh water of about $K = 0.038/\text{h}$, the initial concentration $C_i = 100\,000$ per 100 mL would be reduced to about 74 000 per 100 mL in $t = 8$ h through die-off alone. Dilution with ambient and tributary flows would additionally reduce the concentration.

In many cases, it is preferable to predict the concentration at a given distance downstream, rather than at time increments. Most U.S. rivers have a remarkably uniform, low-flow current of 1.5 to 2 km/h, which can be used to convert low-flow travel time to distance. In our example, this travel distance would be between 12 and 16 km. Travel time for other flow conditions vary from river to river, and so field measurements may be needed to relate bacterial concentrations to specific locations downstream.

In analyzing coliform die-off cases in the marine environment, an average value of 1.2/h can be used for K, nearly 30 times greater than that of fresh water. This rapid die-off rate is usually attributed to the salinity of the marine environment, although it may also be related to a greater concentration of predatory animals. In addition, the natural flocculation and sedimentation of particles that occur in estuaries could account for removal of bacteria from the water column. If the sewage data for the above example were instead considered in the marine environment, the concentration after 8 h of exposure would be reduced to 7 per 100 mL. There are, however, disposal practices in the marine environment that can reduce the die-off rate. For example, when an effluent is discharged at a great depth, the die-off can slow down considerably because sunlight cannot penetrate deeply enough for ultraviolet radiation to be an effective biocide.

Noncoliform pathogenic microorganisms may decay at rates different from those of coliform indicators. As methods of diagnosing water-borne illnesses become more sophisticated and specific in relation to identifying the causative organisms, it will be necessary to establish values that can be used to predict die-off rates for specific pathogens rather than the broad coliform indicator group.

In addition to the decrease of bacterial concentrations due to die-off in either fresh or marine surface waters, bacterial concentrations are decreased as the water is diluted with upstream ambient water at the point of effluent discharge and further diluted as it flows downstream. The effect of dilution may or may not be important in meeting water-quality criteria, depending on the initial mixing, the nature of the subsequent flow patterns, and the distance to water use areas.

2.6 Dilution of Effluents

Dilution can be—but is not necessarily—an effective way to prevent pollution of surface waters. Because many people apparently believe that dilution is always the only thing that needs to be done with wastes, while others believe that dilution only distributes and masks the ultimate adverse effect of wastes on the environment, it is necessary to use objective methods of analysis in evaluating aquatic waste-disposal practices. Through the analytical process of risk assessment, it is clear that certain principles underlie the utility of dilution in managing waste discharges. The first principle concerns the concentration dependence of the pollutant response mechanism. That is, if the concentration is reduced sufficiently, will the degree of effect be directly reduced? Further, once the contaminant concentration is reduced, can it subsequently become more concentrated? Reconcentration is a phenomenon often associated with sediments and persistent organic chemicals such as PCBs. Dilution of waste streams containing high concentrations of suspended solids may prevent significant pollution near the discharge site, but such sediments may eventually settle out of the water column and concentrate in depressions in the stream bed. There they can cause a variety of problems. With persistent organic chemicals, whose solubility in water is low and whose affinity for sorption to animal tissues is high, harmful levels can bioaccumulate even from highly diluted mixtures. Thus, dilution may or may not solve a potential concentration-related problem.

Aside from concentration–toxicity considerations, social and economic considerations enter into the decision to use dilution. In addition, its use is also dependent on the availability of a sufficient quantity of dilution water. In the arid southwestern United States, for example, many streams are ephemeral; that is, they contain water only after major rainfall events. In other streams in arid climates, the effluent from municipal treatment plants is the predominant flow for more than 50% of the year; that is, they are effluent-dependent streams. In such situations, dilution is somewhere between small and nil, except during storm runoff. For example, if the stream flow is 10 million liters per day (ML/d) and the effluent flow is 30 ML/d, the contaminants dissolved in the effluent will be reduced in concentration by just 25%, on the assumption that the concentration of each contaminant upstream is zero. (Generally, the effective dilution will be even less than that because there is almost always some measurable concentration of contaminants upstream.) The general equation used in determining the concentration after dilution is

$$c_f = \frac{c_e v_e + c_a v_a}{v_e + v_a}, \tag{3}$$

where c_f = cross-sectional–average final concentration in the stream, c_e = concentration in the effluent, v_e = volume flux of the effluent, c_a = concentration in the ambient dilution water upstream, and v_a = volume flux of the ambient dilution water.

In large rivers, the amount of dilution initially achieved depends on the method used to discharge the effluent into the river. To maximize the initial dilution, it is necessary to employ a diffuser. For example, if the river flow is 120 ML/d, and a diffuser is used to distribute the effluent across the whole width, a discharge of 30 ML/d could result in an 80% reduction in concentration of contaminants if the ambient concentration is zero. The final concentration would be one-fifth the effluent concentration. Of course, the ambient concentration is almost always greater than zero, so that Eq. (5) must be used to estimate the final concentration accurately.

In many streams construction of diffusers may be either inappropriate or prohibited. Consequently, the rate at which the concentration of a contaminant decreases through turbulent mixing (dispersion as distinguished from molecular diffusion) depends on natural processes that occur during stream flow. A rough guide to expected dilutions can be provided, based on assumptions of steady flow of the sewage and the river, using an empirical equation expressing the distance X to achieve complete mixing of the contaminant across the width and depth of the stream as a function of the average current speed U, the width W, and a measured transverse mixing coefficient ϵ (Fischer *et al.*, 1979):

$$X = 0.4UW^2/\epsilon. \tag{4}$$

But effluent flows are not steady, and there is a wide variation in widths and transfer coefficients, and so it is not possible to estimate a range of values for the dilution rate in cases like this. Without specific case-by-case data to generate reliable estimates, regulatory agencies often resort to "worst-case" scenarios to predict the impact of a discharge on downstream water uses. The rationale is that it is prudent to assume that without a physical structure, like a diffuser, to mix the effluent into the river, only the natural die-off processes can be considered in predicting downstream concentrations. This may result in overestimating downstream concentrations of many toxic pollutants that have very slow degradation rates, but, as will be shown subsequently, it is by far a necessary approach for predicting downstream bacterial concentrations.

Large bodies of water, particularly open coastal waters, offer much greater opportunity for effective initial dilution and long-term dispersion of waste streams. The dilution achieved with a multiple-port diffuser depends on the depth of water, along with other physical parameters. For most cases solutions can be estimated satisfactorily with normalized graphical results (Fischer *et al.*,

1979) or digital output from computer programs (Baumgartner *et al.*, 1994). The rate of dilution that can be achieved with a multiple-port ocean outfall is quite commonly well over 100 to 1 within a minute of discharge in waters 20 m deep or more, using a diffuser section less than a kilometer in length. An initial dilution of 100 to 1, commonly sought in design of outfalls, is sufficient to reduce toxicity of many chemical contaminants to an acceptable level.

In the effective placement of ocean outfalls, depth is not the only determining factor. If, for example, a location chosen for its great depth has poor circulation, the net result may be less effective dilution of wastes than that offered by placement in shallower but more open water. Such considerations are a major concern in the placement of outfalls in fjords, bays, and sometimes estuaries. When bacterial die-off is an important consideration, the *distance* from a designated use area is usually a more important factor than initial dilution *per se*. In this case, the time it takes microbes to travel a long distance increases the likelihood that they will be inactivated. Most modern coastal cities employ multiple-port ocean outfalls far off shore to protect beaches and near-shore recreational areas from the effects of bacterial contamination.

Following this initial dilution, waste streams undergo additional dilution, or dispersion, as they are transported by ambient currents and mixed with the surrounding water by turbulence. The process is analogous to the dispersion that takes place when smoke plumes dissipate in the atmosphere after the smoke has risen to an equilibrium level. In some aquatic systems, however, the effluent plume is not as easily observed.

One simplified equation that has been used successfully over the past 30 years for large bodies of water (Brooks, 1960) provides the maximum concentration at a distance X downcurrent from the point where horizontal transport begins:

$$c_{\max} = c_{pi} \operatorname{erf}\sqrt{\frac{Ub^2}{16\epsilon_0 X}}, \qquad (5)$$

where $c_{\max}$ = centerline (maximum) concentration at distance X, c_{pi} = plume concentration at the end of initial dilution, $\operatorname{erf}(x)$ = standard error function of (x), U = current speed in the X direction, b = width in the Y direction (orthogonal to X) at the end of initial dilution, ϵ_0 = constant horizontal (Y direction) eddy diffusivity, and X = travel distance [note that U/X can be replaced by $1/t$ (time)].

A typical problem is to estimate the highest concentration that would occur near a recreational shellfish area from an outfall 8 km away when the current speed (U) is 15 cm s^{-1}. The width of the plume after initial dilution, which would be obtained from local observations, would likely be about 1000 m. A commonly cited value for near-shore eddy diffusivity is $\epsilon_0 = 10^4$ cm^2 s^{-1}. The result is typically surprising: it shows that even with a travel distance of 8 km in a large, open body of water, the concentration is diluted to only 87%, that is, by a factor of about 1.2. Contrast this factor of 1.2 after traveling 8 km to an initial dilution factor of 100 achieved during a rise of 20 m.

The example shows that initial dilution is often more important in reducing harmful levels than is dilution due to dispersion associated with ambient currents. This is true for most contaminants, including heavy metals, ammonia, biodegradable organics, and toxic organics that are found in partially treated effluents. But in the case of indicator bacteria, the transport distance is more important than initial dilution because a long time is needed for die-off of bacteria to allowable levels. Assessments of the type shown in this example have demonstrated to the satisfaction of regulatory authorities that chlorination or other bacterial disinfection methods may not be required when treated municipal effluents are discharged to appropriate marine waters. Use of chlorine has been discouraged because of the fear of creating chlorinated organics in the effluent stream that could bioaccumulate in aquatic organisms to detrimental levels, or in human consumers.

2.7 Organic Matter and Dissolved Oxygen

Biodegradable organic compounds are decomposed by bacteria and other organisms that live in surface waters. While some organics are mineralized to carbon dioxide and oxides of nitrogen, others are synthesized into more microbial biomass, most of which is subsequently decomposed as well. All this decomposition consumes dissolved oxygen (DO), upon which many desirable species of fish, other aquatic organisms, and wildlife depend. Depressed dissolved-oxygen concentrations are inimical to these life forms. For example, some fish can survive at concentrations near 1 mg L^{-1}, but most are adversely affected at DO concentrations below 4 mg L^{-1}. Dissolved oxygen is a precious resource in surface waters because there is not very much to begin with. The maximum amount of oxygen a pure surface water can hold is a function of salinity and temperature; but, compared to the maxima of many other substances, it is remarkably low. Fresh water contains from 8 to 15 mg L^{-1} DO over the temperature range 30–0 °C, respectively, and sea water contains 6–11 mg L^{-1} over the same range.

Domestic sewage can contain about 300–400 mg L^{-1} of organic compounds, 60% of which is readily degradable by bacteria commonly found in nature. *Readily degradable* implies that most of the material will be decomposed within about a week in a suitable aquatic environment. The change in the concentration of the organic matter with time is conveniently described by the first-order decay equation used to describe bacterial die-off. However, the value of this K depends on the specific organic compounds in the sewage. For domestic sewage, an average value is about $K = 0.4/\mathrm{d}$, ranging from 0.1 to 0.7/d. As more industrial wastes are contributed to the sewer system, the rate constant may increase or decrease. The amount of organic material discharged to a surface water depends on the population served by the municipal sewer system.

2.8 Impact of Organics on Dissolved Oxygen of Receiving Waters

The biochemical oxygen demand (BOD) is the most commonly used parameter in the analysis of the effects of organics on oxygen resources in water. The BOD is the amount of oxygen used over the course of time, usually 5–20 d, as the organic matter is oxidized both microbially and chemically. A laboratory method is used to determine BOD from samples of treated sewage obtained over various time periods. The data obtained in the laboratory are used with the first-order BOD equation,

$$\mathrm{BOD}_t = \mathrm{BOD}_L(1 - e^{-Kt}), \tag{6}$$

to provide estimates of the reaction rate coefficient K and the ultimate value, called the limiting value of BOD, or BOD_L. (This K is not related to the K used in computing bacterial die-off.)

Typically, in more developed countries of the world, municipal sewage is treated to remove organics, and hence to reduce BOD, before discharge to surface waters. The amount of BOD remaining after treatment can range from 10% to 70% of the amount originally in the sewage. The impact on the DO resource of receiving waters depends on the amount of BOD added, the rate constant, the amount of DO in the water body before the sewage is added, and the rate at which additional oxygen is transferred from the atmosphere to the receiving water. Many rivers and streams have depressed initial DO concentrations, that is, a DO deficit, at the point where an effluent is discharged because of BOD added by cities upstream.

Most DO problem situations require that we determine the oxygen deficit resulting from the simultaneous effects of the oxygen demand of a waste and the competing restoration of oxygen from atmospheric reaeration. The combined result is termed the self-purification capacity of the water body. The deficit shown graphically as a function of time (or distance) is known as the oxygen sag curve because of its characteristic shape (Fig. 1). From this curve the lowest DO value likely to occur in the water course can be predicted, the location where minimum DO occurs, the amount of deficit caused by the discharge of the effluent, and the time required to return to the natural saturation level of DO. In this example, a BOD of 30 mg L^{-1} results from a continuous discharge of an industrial effluent mixed into a small stream saturated with DO at 10 mg L^{-1}, causing the DO to drop to 4.2 mg L^{-1} by the fifth day, i.e., causing a deficit of 5.8 mg L^{-1}. By this time the effect of reaeration surpasses the rate of oxygen demand and the deficit decreases with time as more and more DO is restored. By 40 d the DO level is nearly back to the saturation concentration. In many cases an effluent is only mixed with part of the stream flow and continuing downstream dilution with uncontaminated water would restore the DO more quickly.

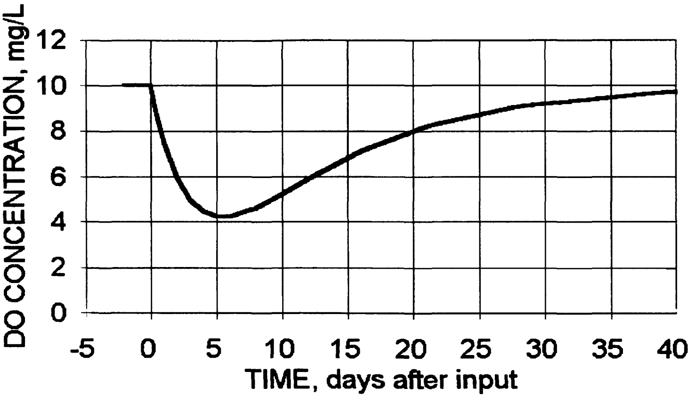

FIG. 1. Oxygen sag curve, for BOD of 30 mg/L, K = 0.1/d, and R = 0.3/d.

Stream-flow rates for near worst-case low-flow conditions are used to convert time to distance in order to identify stream locations where critical conditions might occur. Steady-state solutions of this type are useful for many regulatory purposes, although time-varying analyses can be performed with computer programs for more precise estimates.

Sometimes, water-quality regulators impose limits both on the amount of deficit per se and on the resulting DO value itself. For example, a regulation could require that a waste discharge must neither increase the deficit by more than 10% nor depress resulting DO concentration below 5 mg L^{-1}. Additional regulations may require more rapid return to saturated DO conditions to protect resources farther downstream. If the results of this evaluation are unfavorable, a lesser environmental impact can be achieved by use of one or more alternatives, including more treatment, moving the point of discharge, and reducing the amount of organic material entering the sewer system.

When water systems are heavily used, or highly valued water uses are threatened, additional factors require consideration in the DO analysis:

1. the diurnal demands and supplies of oxygen resulting from photosynthesis;
2. the oxygen demand of organic materials deposited in the sediment layer;
3. the oxygen demand of nitrogen compounds discharged in the effluent;
4. variations in the reaeration coefficient R with travel time due to flow conditions in the water body; and
5. the wide temporal range of sewage flows.

Comprehensive computer programs are available to describe the concentration of oxygen in large watersheds consisting of dozens of interconnecting streams and dozens of waste-water inputs; however, data on plume travel, K values, and R values still have to be obtained with time-consuming laboratory studies and physically demanding field studies. Dilution of wastes is one of the most important factors to consider in assessing impacts. The methods used to assess effects on bacterial concentrations are applicable to assessment of BOD effects on the dissolved-oxygen resource of a water body. If the dilution capacity of the water body is not exploited, only the decomposition of organics and reaeration can be considered in the restoration and maintenance of DO.

3. TOXIC SUBSTANCES

In addition to water-pollution problems caused by bacteria and BOD, referred to in some regulations as "conventional pollutants," chemicals added to a municipal sewer system can escape complete removal in standard waste-water treatment units and cause harm to organisms in the receiving water. In the United States the Toxic Substances Control Act gives EPA the authority to regulate certain types of chemicals that may present an unreasonable risk to health and the environment. Of the tens of thousands of chemicals that might be covered under this rubric, EPA has listed several dozen organic and inorganic compounds and a handful of pesticides, labeled as "priority pollutants" for regulation in waste waters discharged to water courses. Individual states may add others. The list includes benzene, dioxin, methyl chloride, phenol, and vinyl chloride. Many are from industrial discharges to the system, but the source of some is household and municipal use of pesticides and cleaners. Even though toxic chemicals occur in relatively small concentrations in waste waters compared to conventional pollutants, frequently in the range of micrograms to milligrams per liter, the annual mass emissions are impressive amounts because of the large volumes of treated effluents returned to the aquatic environment. A sense of the scale involved is provided by data from the seven large municipalities in southern California that discharge treated effluents into coastal waters of the Pacific Ocean (National Research Council, 1990b). In 1985 the amounts of DDT and PCB carried in 440×10^9 gallons of effluents totaled about one metric ton apiece for the year. Chromium, copper, and zinc emissions were approximately 100, 250, and 400 t, respectively, while BOD and suspended particulate matter emissions were each on the order of 2×10^5 t. Nearly 15×10^6 people are served by these treatment facilities, and although not all population centers have the same mix and substantial contribution of industrial wastes as does this region, the relative proportions could be applied to other areas to acquire a first approximation of the mass of contaminants involved in treated waste-water discharges. While the population and the waste-water volume have grown considerably in the area in the last two decades, the mass of contaminated material has decreased significantly for many industrial chemicals as a result of control at the source, and for domestic contributions as a result of greater use of secondary treatment processes. The greater removal of particulate material (in Los Angeles as well as in every city employing secondary treatment) has resulted in a materials handling problem from the resulting digested and dried municipal sludge. To encourage recycling, EPA has developed stringent criteria for acceptable use of this resource under the term "Biosolids." The use of this material is growing in agricultural areas, although public acceptance is still problematic.

Agriculture is also a source of pesticide contamination of surface waters. The major concern with pesticides is the effect they have on aquatic organisms and riparian wildlife, although human exposure is also considered in establishing maximum allowable concentrations in receiving waters. Allowable concentrations for aquatic species are generally determined from laboratory dose-response studies of organisms selected from several taxa, exposed for several time periods to pure chemicals diluted in a small container of clean water. The shortcomings of this methodology are abundant. In short, it does a poor job of representing the exposure conditions seen in the natural environment. Attempts are continuously being made to incorporate more realistic exposure conditions in laboratory assays. For several years research has been conducted in simulated stream segments (Zischke and Arthur, 1987), and observations in natural settings are being incorporated into the process of promulgating water-quality criteria (U.S. EPA, 1991).

The majority of published work on water-quality criteria is based on 96-h acute toxicity studies in which the concentrations are chosen to produce lethal effects on a portion of the test organisms. A great deal of the pioneering work of this type involved metal ions such as chromium, cadmium, silver, lead, nickel, mercury, and zinc. The form of the metal as introduced into the test water is a factor in the degree of toxicity expressed, as is the ion balance in the water, conveniently represented in a crude way by the carbonate hardness concentration. In the mid 1960s, possibly related to the publication of *Silent Spring* (Carson, 1962), a new wave of research was focused on pesticides, detergents, and other organic materials. The test results are used to calculate a concentration expected to result in lethality for 50% of the test organisms. The 96-h LC_{50}, as it is called, is analogous to medical studies where median effective doses (ED_{50}) and median lethal doses (LD_{50}) are developed. The allowable stream concentration is established as a fraction (e.g., 0.01) of the LC_{50} to account for uncertainties and to attempt to avoid even sublethal adverse impacts. A more direct approach currently being used is to conduct chronic exposure studies to assess one or more of a variety of impacts on growth, fecundity, behavior, disease, and tissue accumulation of contaminants. Attempts are also being made in the use of data for regulatory practice to take into account the sensitivity of aquatic organisms to the frequency of exposures and the duration of each exposure.

For many years criteria were available only for fresh-water systems, but these were applied to marine waters as well. Now criteria are being developed using marine species, and attempts are being made to develop criteria for specific watershed units such as the Laurentian Great Lakes and the ephemeral and effluent-dependent water courses of the U.S. arid West. Regulatory agencies have recognized that an overwhelming resource requirement would be needed to develop criteria for a variety of biogeochemical environments, and an increasing number of specific chemicals, to say nothing about the question of the synergistic and antagonistic effect of a mixture of chemicals in a waste stream. Currently (1996) the U.S. EPA is proposing to require the use of whole-effluent toxicity testing (WET or WETT) as a way to focus available resources on this approach that cuts directly to the question of local standards, realistic exposure scenarios, and composite wastes.

WET testing is a new element in the repertoire of water-pollution regulatory practice (discussed subsequently) that targets point sources as the highest-priority input class for control. That is not to say that responsible regulators view publicly owned sewage treatment plants as villains, necessarily, but rather that they present a convenient point for removing a large amount of contamination from a large volume of water about to enter a water course. Some large industries would also be viewed the same way. Just how effective conventional treatment plants are in removing toxics is somewhat uncertain. Almost all plants have been designed from theory and practice to remove settleable particulate matter and BOD. That bacterial indicators and toxics are removed is due in large part to their fortuitous association with particulate matter. With conventional primary and secondary treatment followed by a modest amount of initial dilution, most toxic standards can be met by conventional plant effluents.

When effluents are subject to a WET test standard, the options for response are more limited for a municipal treatment works than an industry. The municipal plant may have received a slug dose of an unknown chemical from an illegal or accidental one-time discharge to the sewer system. If it is a routine occurrence, technicians might be able to find the input source and prohibit its recurrence. If the causal agent is properly a constituent of the municipal sewage coming into the plant, the plant operators may be able to improve the efficiency of solids and BOD removal, or add supplemental units such as air strippers, carbon filters, or chemical precipitation, all of which would be expensive for treating the whole flow of the plant. Industrial dischargers have only their plant processes to contend with and may be able to sort out the causative agent and control it with process changes, substitution of chemicals, or pretreatment of individual small process streams. The major concern with employment of WET testing is that test results could force the removal of constituents that while toxic to organisms exposed in laboratory bioassays would not be a problem once discharged to a flowing stream environment where there would be a decay of the toxic agents in addition to dilution (Parkhurst and Mount, 1991). One example is the case of ammonia in municipal effluents, which could be lethal in sufficient concentration to some fish species used in the test but which are not present in the water course, as for example in many arid West washes. Furthermore, the ammonia is oxidized to nitrate that is of a substantial nutritional value to trees and other foliage along these washes (Baumgartner *et al.*, 1993).

4. NONPOINT (DIFFUSE) SOURCES OF POLLUTION

Agriculture is the largest persistent diffuse source of contaminants to surface waters. The primary contaminants are pesticides, fertilizers, salts, and particulate matter. The components of this industry include traditional grain and table-crop farming, dry-land farming dependent on irrigation, production of fiber (e.g., cotton), forestry, cattle grazing and pasture, animal feed lots, and aquaculture. Depending on size, feed lots and aquaculture operations may be subject to point-source discharge regulations and require individual permits. Cattle operations can be a significant source of fecal coliforms to receiving waters.

Overland runoff and channelized irrigation return flows contribute turbidity and nutrients to water courses, causing photosynthetic growths that diminish the aesthetic quality of the water. In some cases, especially during warm, low-flow times of the year, the growth of aquatic plants and animals depletes oxygen to dangerously low levels. In the arid sections of the nation, irrigation return flows are high in dissolved salts as a result of high evapotranspiration rates and the initially high solids concentration of ground water used for irrigation.

Control efforts directed at agricultural runoff include development of Best Management Practices (BMPs) and education to help practitioners conserve water and chemicals, retard and capture water tending to run off too quickly, and treat and reuse water contaminated with animal waste on site. BMPs provide economic incentives as well as environmental payoffs. In some states farmers can be fined if they are not able to demonstrate compliance with BMPs.

In addition to diffuse agricultural contaminant inputs, regulators have discovered that significant input occurs from runoff from urbanized areas. This discovery was enhanced by the discovery that water-quality deterioration persisted even after vigorous control of point-source discharges was achieved. The search for additional inputs led to the conclusion that there were large pollution loads distributed over many diffuse sources. These inputs can occur at a rather uniform rate in regions such as around Puget Sound in the state of Washington where winter rains provide a steady runoff, or more sporadically as in areas prone to thunderstorms of short duration but high intensity. Technological advances have been made in dealing with the latter, consisting of devices and reservoirs to divert and capture the first flush of stormwater systems.

Rural areas, irrespective of agriculture, are also a source of domestic-sewage pollution of water supplies. A large percentage of rural residences are not connected to sewerage systems, relying instead on individual septic tanks for waste disposal. Even when septic tanks are operated properly, and many are not, the effluent can contribute large quantities of nutrients, BOD, and intestinal microorganisms to surface waters and ground-water aquifers. In particular, the nitrogen content of the effluent, in the form of either ammonia or organic compounds, is oxidized by soil bacteria to nitrates, which can be a health hazard for infants consuming water containing greater than 10 mg/L nitrate nitrogen (U.S. DHEW, 1962). The natural organisms in the infant's gut reduce the nitrate to nitrite, and nitrite interferes with hemoglobin uptake of oxygen, causing methemoglobinemia, also known as blue-baby syndrome.

5. GROUND-WATER POLLUTION

Pollution of ground-water aquifers has become a matter for scientific and regulatory interest because of high-visibility pollution cases involving inadequate disposal of industrial materials, primarily chlorinated organic solvents used in cleaning electronic components such as circuit boards. Another category of organic compounds frequently identified as contaminants is "BETX" (benzene, ethylbenzene, toluene, and xylene) associated with the petroleum industry and leaking underground storage tanks (LUST). There is evidence that these chemicals may be of human health concern, primarily as cancer-causing agents. An additional concern is that chlorination of ground water in water-purification plants can create chlorinated organics that may be hazardous. Municipal landfills of household and industrial wastes can contribute some of the above chemicals and are frequently a major contributor of metals.

Previously, the major concern with ground-water quality was the incursion of sea water into the aquifer due to reduction of the water table by excessive withdrawal in coastal municipalities. This resulted in reduced quality in domestic and agricultural well water from the increase in dissolved solids but was not a direct health concern. In some areas the rate of intrusion was controlled by the injection of treated municipal sewage effluent into the aquifer at the intrusion front, which in itself was an action that caused health concerns due to the unknown fate of viruses and other contaminants in the effluent. In arid regions, effluents and surface waters (stream flows and storm-water flows) are being used to replenish aquifers, either by injection wells or infiltration basins, again raising questions about contamination (Kanarek and Michail, 1994).

A number of treatment techniques have been developed, many still in the exploratory stage, to deal with the problem of pollutants in ground water. In some cases it may be possible to remove the soil layer that contains the pollutants and either treat the soil or dispose of it in an acceptable location. In other cases the water in the soil layer can be extracted and treated, to be either returned to the soil or used directly for some aboveground purpose. For volatile organics, an acceptable treatment method is air-stripping, caution being required to assure compliance with air-quality standards. Depending on the soil type, organics may be adsorbed to the clays so that the concentration in the water is established by a partition coefficient. As the water is removed from the affected area by pumping, the concentration decreases because a contact time is needed for a new equilibrium to be established. There is a trade-off between pumping too rapidly, resulting in lower concentrations, and pumping too slowly, increasing the time required to remove the pollutant. Some organic chemicals are more readily transported with the water (e.g., polar compounds), while others (nonpolar organics) have high retardation coefficients with respect to the transport of water.

In situ methods have been used to treat pollutants in the soil–aquifer matrix using a variety of methods. Sparging (injection of air) is one way to effect volatilization of organic compounds and to add oxygen to aid in aerobic biodegradation of contaminants. Also, chemicals have been added to aid in the destruction of pollutants, a good example being nitrates that can be reduced to nitrogen gas if sufficient carbonaceous organics are added as an energy source for soil microbes. Ethanol, methanol, or other easily biodegradable organics have been used. One method that has lost favor is the injection of (presumably) special strains of bacteria purported to have specific ability to attack certain chemical forms. More recently the emphasis has been on supplying nutrients, such as nitrogen and phosphorus, and relying on naturally occurring microbial communities to grow and complete the job of biodegradation. Details of these and other methods are being published regularly, as, for example, by Zoller (1994).

Phytoremediation is a method being researched using plants to sequester metals from polluted soil or ground water. This is an extension of the methods using plants such as water hyacinths in constructed or natural wetlands as one step in the treatment of municipal sewage. One application in the treatment of ground water is to use the plants solely as a concentrator, intending to dispose of the plants along with the contaminants in an acceptable manner. A variation is to extract the concentrated contaminants for reuse (e.g., uranium) or to treat the plant tissues in some way before disposal. Ground water contaminated with nitrates can be used to irrigate certain crops that not only tolerate nitrates but grow luxuriantly exposed to high nitrates. Selenium, a contaminant of many western soils and ground waters, can present a hazard to animals if they are fed crops that accumulate selenium. However, if the crops are harvested and used as feed supplements in areas where cattle experience selenium deficiency, two favorable objectives are achieved: water reuse and improved crop quality. In arid climates, however, the quality of ground water may deteriorate over all, in spite of loss of certain contaminants to irrigated plants, as a result of high water loss to evapotranspiration through the plants. Overall, the evaporative loss of water will cause the concentration of total dissolved solids to increase to the level that interferes with subsequent reuse of the irrigation return flows.

6. REGULATORY PRACTICE

Water-pollution regulatory practice in the United States is founded on a system of discharge permits—known as the National Pollution Discharge Elimination System (NPDES). Holders of these permits, e.g., municipal sewage treatment authorities and industries, must comply with the restrictions and requirements of their particular permit, such as limits on concentrations and mass emission rates of specific constituents. They also have to meet water-quality standards established for the water body into which they discharge their effluents. Some permits, especially for coastal-water discharges, require elaborate environmental monitoring projects. The permit holder is required to conduct monitoring activities and report the results to demonstrate compliance with permit conditions specifically, and generally to demonstrate the preservation of environmental quality. On occasion, regulatory agencies conduct special studies to verify and revise monitoring programs. Monitoring data reflect the wide variations of conditions found in the natural environment, and dischargers and regulators are often challenged to rationalize monitoring results with predictions used in setting permit conditions.

Permit conditions of regulatory agencies usually allow exceptions to one or more of the water-quality criteria within a mixing zone adjacent to the point of discharge. A mixing zone might be established by purely arbitrary considerations or by use of data and simulations with mathematical models. Many mixing-zone determinations are made on the basis of the expected dilution rate that will be provided by efficient diffuser designs intended to optimize initial dilution. For large bodies of water, a common approach is to describe the width of the zone as the depth of water at the disposal site, and the length as the length of the diffuser. For large rivers, it is common to restrict a mixing zone so it does not extend completely across the river, thereby leaving a "safe passage" for aquatic species to avoid high concentrations of waste-water constituents. But sometimes the shape of a mixing zone is entirely arbitrary, say a rectangular zone downstream from a discharge pipe equal to one-fourth the width of the stream and extending downstream for 1 km. Frequently, there are two or three mixing zones for different groups of contaminants and degrees of toxicity.

Regulatory interest may be appropriately directed toward both discrete and average values of contaminants. For example, the state of California and the U.S. EPA specify maximum allowable instantaneous values for some parameters as well as several temporal average values (e.g., 30-day and 6-month arithmetic means). In some cases, these regulations are based on knowledge of the effects on aquatic organisms. In other cases, these values are specified to acquire statistics on the performance of the waste-water treatment plant.

Beyond the mixing zone, there may be regions where current streams of diluted effluent, each leaving the zone at a different time in different direction, would converge over a reef, a kelp forest, or a swimming area. In this case, the frequency and duration of exposure may be more important than the highest observed concentration in assessing the overall impact on these resources.

6.1 Risk Assessment

Except for certain special considerations, NPDES permits require a degree of treatment that is standardized throughout the country. That is, there is a "technology" standard that is applied irrespective of the impact of the effluent on the environment. Generally, the standard technology is identified as "secondary treatment," which involves a biological treatment method following plain sedimentation to remove 90% of BOD and 90% of the suspended solids. A temporary modification of the secondary treatment requirement has been granted to several coastal communities that have demonstrated that this level of treatment is not necessary to meet water-quality requirements and to protect the marine environment. In other cases where the receiving water is termed "water-quality limited," additional treatment requirements have been imposed.

Critics of the technology-standard approach have argued that a rational approach should be applied to all discharges, e.g., a water-quality–based approach. They argue that valuable resources are wasted if a technology is required for technology's sake unless it can be demonstrated that a problem would arise if the technology were not employed. They also point to places where in spite of the employed technology there is no improvement in environmental quality. The scientific arguments persist on both sides and frequently are resolved in court. The modification desired by coastal communities was incorporated into federal law in 1972 and was in effect for about a dozen years. It was the subject of federal legislation introduced in 1994 to grant a second opportunity for San Diego, California, to apply for an exemption from conventional biological secondary treatment, following improvements made in the treatment methods and extension of the outfall. San Diego's attempt to acquire a permit modification under the 1972 provision was not successful.

There is a possibility that a new paradigm can be developed to regulate water quality using the methods of risk assessment applied in a variety of health programs. The promise posed by risk-assessment techniques is not guaranteed to be entirely applicable in water-quality science, because there are social considerations, including economic and political implications, in addition to the physical and biological science questions that are addressed (Freudenburg, 1988). Nevertheless, in 1992 the U.S. EPA published a framework for ecological risk assessment as a basis for making environmental decisions, hoping to provide a means "... of targeting environmental protection resources at the problems and the geographic areas posing the greatest risks" (Norton *et al.*, 1992). Risk assessment is a scientific process that interfaces with a regulatory role of risk management (Fig. 2). On the science side are distinct tasks to characterize the resource (or site) at risk in terms of the biological communities and the physical parameters that represent the natural environment of the resident and transitory species. The site needs to be characterized also in terms of the values assigned by societal interests, such as recreation, and preservation of certain species. An important technical task is to characterize the nature of the stress on the site, such as the magnitude or intensity of the contaminant, the variability of its input function, and its temporal and spatial fate within the environment at risk. Results of site and source characterizations are integrated to produce a quantitative exposure assessment, i.e., a determination of what the concentration (or other measure of intensity) will be for the resource components at the site. Next, a quantitative description of the response expected is generated, based on laboratory dose-response studies, etc. The information and data resulting from exposure and response assessments are used to calculate a measure of risk, sometimes as simply as the quotient of response over exposure (Norton *et al.*, 1992), or in other cases a qualitative expression of risk.

The output of the risk assessment, according to at least one model (Baumgartner and Duedall, 1990), is then used by a regulatory program to make risk-management decisions on the content of permits, to monitor recovery and preservation of the resource and to pursue legal remedies as needed. From the beginning of the regulatory process and at various times during the permit period, there will be a need for evaluation of alternative strategies, providing a continuing interface for the scientific and regulatory roles. Many

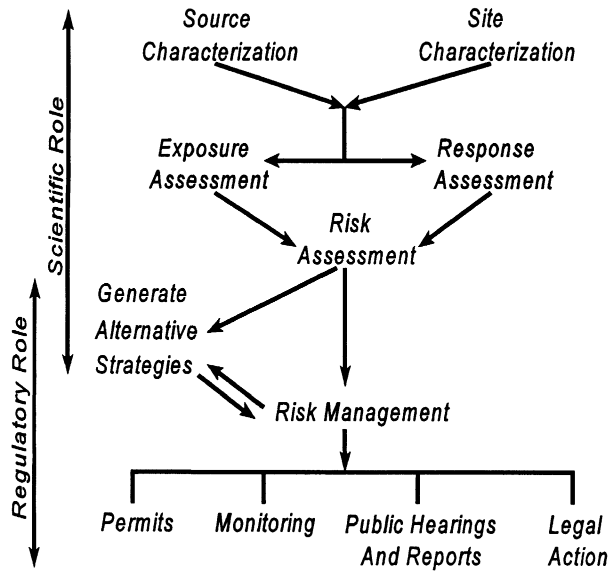

FIG. 2. Risk assessment process (after Baumgartner and Duedall, 1990).

of the steps in this process, and the scientific methodology for obtaining the necessary data, are quite similar to the process used by the U.S. EPA to develop water-quality standards and the water-quality–based approach for toxics control described earlier. The difference, if there is one, may be that under risk assessment the general application of technology standards would be abandoned as a way to control pollution.

GLOSSARY

Anthropogenic: Pertaining to human activity as distinguished from natural processes.

Aquifer: A soil stratum saturated with flowing water.

Biogeochemical: Pertaining to the differences and similarities in geographic regions as defined by biological, physical, and chemical characteristics of the environment.

Carbonate Hardness: The sum of calcium and magnesium ion concentrations in water expressed as their carbonate equivalents.

Combined Sanitary and Storm Sewer: A municipal sewer that transports water-carried household wastes and storm-water runoff from street inlets. Distinguished from separate sewers for each purpose in modern municipalities.

Diffuser: A device to spread a liquid flow over a wide expanse of space, usually on the end of a pipe.

Digested Sludge: Slurry of dense particulates obtained from sedimentation basins in a sewage treatment plant and retained for several weeks in a heated reactor to facilitate anaerobic microbial decomposition of organic matter.

Dilution: Reduction in concentration due to mixing a fluid with relatively high concentration into a fluid with a lower concentration.

Dispersion: A natural process of turbulent energy exchange resulting in mass transfer from regions of high concentration to low concentration.

Estuary: Body of water between the open ocean and a fresh-water stream in which ocean water is exchanged and diluted with stream water.

Fecundity: Success at producing offspring.

Fjord: A type of estuary, usually narrow and deep, characterized by a sill extending from the seabed to near the surface.

Henry's Law: The linear relationship between the equilibrium concentration of noble gases in adjoining gaseous and aqueous phases through a constant specific for each gas.

Initial Dilution: Dilution of a waste in the near-field flow region of an effluent discharge pipe due to turbulence caused by the effluent being pumped into the stream with high energy, generally through many small outlets.

Metric Ton (t): One thousand kilograms, thus 2205 pounds or 1.1 U.S. tons.

Mixing Zone: A portion of a water body where waste-water streams are dispersed and pollution-control standards are relaxed.

Riparian: Of, situated, or dwelling on the bank of a river or other body of water.

Spawning Habitat: Section of a water body used by fish to deposit and fertilize eggs.

Taxa: Categories in a hierarchical classification system of species.

Xenobiotic: Of or pertaining to an organic compound that is foreign in the evolutionary experience of organisms and possessing an adverse biotic effect on organisms, e.g., a synthetically produced pesticide.

4.1
Introduction

All known phenomena in the physical world are aspects of only four basic forces: gravity, electromagnetism, the strong force, and the weak force. While these forces appear to have very different characters, all of them are based on quantum field theories (QFTs) exhibiting some form of *local gauge symmetry*. Although the historical development was different, with hindsight local gauge invariance is now seen not as a fundamental principle but as a consequence of the more basic principles of Lorentz invariance and cluster decomposition, as well as the axioms of quantum mechanics. Section 4.2 first reviews how the concepts of a QFT and of local gauge symmetry naturally arise before they are applied to the prototype electroweak model of electrons, e^-, positrons, e^+, and electron-neutrinos, ν_e. Section 4.3 discusses a series of extensions of this model to include quarks and the strong interaction, family replication and quark mixing, and CP violation. Experimental tests and constraints on the Standard Model (SM) are the subject of Section 4.4. Finally, Section 4.5 describes limitations of the minimal model and goes beyond Section 4.3 to incorporate neutrino mass and mixing. It also discusses accidental symmetries and their possible violation by nonrenormalizable corrections.

4.2
Principles and Theoretical Foundations of the Standard Model

Rather than reviewing how the SM emerged historically as the correct theory of weak and electromagnetic interactions, we first discuss the relevance of QFTs in general (Section 4.2.1) and gauge theories in particular (Section 4.2.2), before specializing in the electroweak gauge theory in Section 4.2.3. Key features like non-Abelian gauge symmetry, spontaneous symmetry breaking and the Higgs mechanism, renormalizability, and anomaly cancellation in chiral gauge theories are covered.

4.2.1
Quantum Field Theories

The mathematical framework to study relativistic particles and their interactions is provided by QFTs. A particle can be defined as an irreducible unitary representation (irrep) of the inhomogeneous Lorentz group (Poincaré group), which is characterized (classified) by its mass, m, and either its spin (the eigenvalue of the square of the angular momentum operator, $\vec{J}$) or

ISBN: 978-3-527-40691-3

in the massless case its helicity,[1] h (the eigenvalue of the third component, J_3, of $\vec{J}$). It is convenient to introduce quantum mechanical operators, $a^\dagger$ and a, respectively creating and annihilating particles of a particular species with a specific relativistic four-momentum (energy-momentum) and spin (including its direction). This serves to satisfy (also in nonrelativistic theories) the general scientific requirement that distant experiments should yield independent results (locality), that is, quantum mechanical probabilities factorize (cluster decomposition). The most general Hamiltonian is then a sum of products of any number of $a^\dagger$ and a operators, which are recalled to be defined in momentum space.

However, a relativistic theory requires, in addition to particles transforming according to representations of the Poincaré group, also Lorentz-covariant scattering amplitudes (S-matrix). Invariance under Lorentz transformations (boosts) presents an obstacle, because (according to Noether's theorem) there must be a conserved vector related to them, but (unlike linear and angular momentum operators) boost generators fail to commute with the Hamiltonian. This complication introduces an additional condition (with no counterpart in nonrelativistic theories), which often takes the form of a causality requirement, that is, Hamiltonian densities at spacelike separation ought to commute. The important point is that causality conditions are expressed in configuration (position) space.

Therefore one integrates the creation and annihilation operators over all spatial momenta[2] $\vec{p}$ (Fourier transformation)

$$\phi_l(x) = \int \frac{d^3p}{(2\pi)^{3/2}} \frac{1}{\sqrt{2p^0}} \times (u_l\, a_{\vec{p}}\, e^{-ipx} + v_l\, a^\dagger_{\vec{p}}\, e^{ipx}) \qquad (1)$$

yielding functions of space-time with a set of discrete Lorentz and spinor indices (collectively called l) giving rise to finite-dimensional nonunitary (unless a Lorentz scalar) and in general reducible representations of the homogeneous Lorentz group. The Fourier transforms (1) are the quantum fields. The Hamiltonian is now a sum of products of quantum fields (and their Hermitian adjoints) and one can construct Lorentz scalars in much the same way as one constructs rotational scalars by the use of Clebsch–Gordon coefficients.

The causality condition on the Hamiltonian translates into a similar commutation relation (or anticommutation relation for fermions) for fields and this in turn imposes constraints on the coefficients, u_l and v_l. In the course of solving these constraints, one encounters the fundamental theorems of QFT:

Field equations: Every free field must satisfy the second-order differential wave equation, $(\partial^\mu \partial_\mu + m^2)\phi_l(x) = 0$ (Klein-Gordon equation), and many fields must obey other first-order differential equations or algebraic constraint equations, as well.

Antiparticles: Antiparticles (Dirac, 1928) exist for any particle species (not just for spin-1/2 fermions as in the Dirac formalism) with an additive conserved quantum number (e.g. electric charge, Q).

---

[1] In contrast to the massive case, the commutator algebra of symmetry generators (Lie algebra) does not restrict the possible (real) eigenvalues of J_3, but there is a topological restriction allowing only half-integer of integer values of h.

[2] $p^0 = \sqrt{m^2 + \vec{p}^2}$ is the particle energy; x_0 appearing in $px \equiv p^0x_0 - \vec{p}\vec{x}$ denotes time multiplied by the speed of light.

Spin-statistics connection: Fields describing particles with (half)-integer spin are (fermions) bosons.

CPT theorem: Any QFT is invariant under the combined operations of charge (particle–antiparticle) conjugation (C), parity (space) reflexion (P), and time reversal (T).

4.2.2
Local Gauge Symmetries

In some cases it is impossible to find any solution to the constraints on u_l and v_l. In particular, no four-vector field, A^μ, can be constructed from the annihilation and creation operators for a particle of helicity ± 1 and $m = 0$ (Weinberg, 1965). Of course, one might use some other Lorentz representation, such as an antisymmetric tensor field, $B^{\mu\nu}$, which does allow a solution. However, the interactions in such a theory have a faster falloff at large distances than the inverse-square law of the electrostatic coulomb force. Such interactions may well exist in nature, but they would be strongly suppressed relative to inverse-square law interactions. But while it may suffice to have a covariantly transforming four-vector field, A^μ, to construct a Lorentz-invariant theory, this is not actually necessary. Indeed, under a general homogeneous Lorentz transformation, Λ, one finds

$$U(\Lambda)A^\mu(x)U^{-1}(\Lambda) = \Lambda^{\nu\mu}A_\nu(x) + \partial^\mu\Omega(x) \tag{2}$$

That is, the A^μ in this case transforms covariantly up to an extra term, where $\Omega(x)$ is a linear combination of $a^\dagger$ and a operators. Therefore, if for arbitrary functions, $\omega(x)$, we require invariance under local (space-time-dependent) ‘‘gauge’’ transformations of the form

$$A^\mu(x) \longrightarrow A^\mu(x) - \partial^\mu\omega(x) \tag{3}$$

then the failure of A^μ to transform covariantly would be immaterial. Thus, local gauge invariance provides us with an additional option to construct long-range forces mediated by particles of $h = \pm 1$ and $m = 0$, and (if present) we should expect gauge-invariant theories to play a dominant role at large distances. This is precisely what is observed and the electromagnetic, strong, and weak forces, are all gauge theories invariant under the replacement (3).

This discussion generalizes straightforwardly to the case of gravity. No symmetric rank-two tensor field, $h^{\mu\nu}$, can be constructed from the annihilation and creation operators for a particle of $h = \pm 2$ and $m = 0$ (Weinberg, 1965). To construct an inverse-square law (Newton's law) one still needs to work with $h^{\mu\nu}$, where the failure to transform covariantly is cured by requiring invariance under general coordinate transformations as in the General Theory of Relativity (Einstein, 1916) generalizing the local gauge transformation (3).

The mathematics of all this generalizes further to massless particles of higher Helicities, $h > 2$. Now, Noether's theorem implies that conserved quantities must be associated with these transformations, which are electric charge (and generalizations thereof) for gauge theories and energy-momentum conservation in the case of gravity. There would be associated conserved quantities for the case $h > 2$, but the abundance of conservation laws would rule out the possibility of nontrivial scattering processes of any kind. Thus, the physics of this does not generalize beyond gravity. It is not yet known whether the only other possible case, $h = \pm 3/2$, is realized in nature.[3] If it is, the corresponding transformations generalizing the local gauge transformation (3) are the local "supersymmetry" transformations. Supersymmetry (Golfand and Likhtman, 1971; Wess and Zumino, 1974) is an active subfield of elementary particle physics and among the leading candidates of possible physics that may modify the SM at higher energies.

The historical development was, of course, rather different. The theory of electromagnetism (Maxwell, 1865) was not constructed from Lorentz and local gauge invariance but rather gave rise to these concepts (Lorentz, 1909).

4.2.3
Gauge Group of Electroweak Interaction

The gauge symmetry must and does (Fock, 1926) persist after the field A^μ is coupled to matter. In quantum electrodynamics (QED), one therefore extends the gauge transformation (3) to electrons and positrons to undergo the local $U(1)$ (phase) transformation (e is the electromagnetic coupling constant)

$$\Psi(x) \longrightarrow e^{\pm ieQ\omega(x)}\Psi(x) \tag{4}$$

In the minimal electroweak theory, one assumes that the electron combines with the electron-neutrino to form a doublet, extending the Abelian $U(1)$ gauge symmetry of QED to some (in general) non-Abelian symmetry group. In non-Abelian gauge theories, particles can be transformed into other kinds of particle, making them suitable candidates for describing the weak interaction that can transform, for example, electrons into neutrinos, or neutrons into protons. Positivity of quantum mechanical probabilities implies that the associated Lie algebra is the direct sum of commuting compact simple and $U(1)$ subalgebras. These have been classified[4] by Cartan (1894), leaving only a few possibilities.

To see what these are, a unique feature of the weak interaction (not shared by the other known forces) must now be mentioned, namely that electroweak gauge transformations act distinctly on left- and right-handed particles (chirality). This possibility arises if one postulates invariance under proper Lorentz transformations only (i.e., excluding parity reflections) with respect to which left- and right-handed particles form separate irreps. There is presently no piece of experimental evidence that would incontrovertibly require the existence of a right-handed neutrino and it is excluded from the minimal theory. And since right-handed particles are not independent from left-handed antiparticles, we may restrict our attention to the left-handed triplet of fields, $(\nu_e, e^-, e^+)_L$, with the understanding that the physics of right-handed particles and antiparticles is determined in terms of the left-handed ones.

Now the largest possible symmetry group that may act on this triplet is $U(3) = SU(3) \times U(1)$, but such a theory would imply lepton number violation at rates that are in conflict with observation. The largest possible subgroup of $U(3)$ consistent with lepton number is $U(2)_L \times U(1)_R = SU(2)_L \times U(1)_L \times U(1)_R$ with $SU(2)_L$ (isospin) acting nontrivially on the doublet of fields, (ν_e, e^-). The diagonal linear combination of $U(1)_L$ and $U(1)_R$ would give rise to a long-range force

---

[3] The cases $h = 0$ and $h = \pm 1/2$ do not present the kind of complications discussed here.

[4] For an extensive discussion with emphasis on the application to particle physics, see Slansky (1981).

(unless spontaneously broken) coupled to lepton number, but experiments provide no evidence in its favor and it is dropped. The gauge group for this leptonic model (Weinberg, 1967; Salam, 1968) is then

$$G = SU(2)_L \times U(1)_Y \tag{5}$$

with the remaining combination, $U(1)_Y$, coupling to "hypercharge," Y. The hypercharge assignment must reproduce the observed electric charges, so that (in an appropriate normalization)

$$Y \equiv Q - T_3 \tag{6}$$

where T_3 generates the $U(1)$ subgroup of $SU(2)_L$. T_3 must be traceless for each irrep, and one can take $T_3 = \mathrm{diag}(1/2, -1/2)$ ($T_3 = 0$) and consequently $Y = -1/2$ ($Y = +1$) when acting on the doublet (singlet).

4.2.4
Gauge Bosons

Local gauge invariance requires vector bosons to transform in the defining (adjoint) representation of the gauge group, that is, there must be precisely one gauge boson for each group generator. Thus, there is an isotriplet, $\vec{W}_\mu$, transforming under $SU(2)_L$, and an isosinglet, B_μ, for hypercharge. The linear combinations with definite mass and electric charge (shown as superscript) are

$$W^\pm_\mu = \frac{1}{\sqrt{2}}(W^1_\mu \mp iW^2_\mu) \tag{7}$$

$$Z^0_\mu = \cos\theta_W W^3_\mu - \sin\theta_W B_\mu \tag{8}$$

$$A_\mu = \sin\theta_W W^3_\mu + \cos\theta_W B_\mu \tag{9}$$

where the weak mixing angle, θ_W, is defined so that A_μ can be identified with the photon, that is, it couples to Q and describes the electromagnetic current. Similarly, the $W^\pm$ bosons produce charged current processes, such as observed in radioactive β decays, and the doublet–singlet structure of the SM reproduces the vector minus axial-vector ($V - A$) law of the weak interaction. On the other hand, at the time when the SM was under construction (Weinberg, 1967; Salam, 1968) no process indicating the presence of the Z^0 boson was known, and the associated neutral current is a genuine prediction of the model. Denoting the gauge coupling constants for $SU(2)_L$ and $U(1)_Y$, respectively, by g and g', one finds the relations

$$e = g\sin\theta_W = g'\cos\theta_W = \frac{gg'}{\sqrt{g^2 + g'^2}} \tag{10}$$

An important property of non-Abelian gauge theories (Yang and Mills, 1954) (not shared by Abelian ones) is the appearance of nonlinear terms in the Lagrangian density

$$\mathcal{L} = -\frac{1}{4}\left(\partial_\mu \vec{W}_\nu - \partial_\nu \vec{W}_\mu - g\vec{W}_\mu \times \vec{W}_\nu\right)^2 - \frac{1}{4}\left(\partial_\mu B_\nu - \partial_\nu B_\mu\right)^2 \tag{11}$$

This implies the existence and precise form and strength of triple and quartic gauge boson self-interaction vertices.

The gauge-invariant interactions of vector bosons with leptons (and other spin-1/2 and spin-0 matter particles) are implemented by replacing the ordinary derivatives acting on the matter fields by gauge-covariant derivatives

$$D_\mu = \partial_\mu + ig\vec{T}\vec{W}_\mu + ig'YB_\mu \tag{12}$$

4.2.5
Spontaneous Symmetry Breaking

If the short-range weak force is to be described by the $W^\pm$ and Z^0 bosons, these would have to be massive. Simply adding a mass term to the Lagrangian (11) would break local gauge invariance, which (as discussed) is unacceptable. This is a very severe problem, which touches upon the basic principles of QFTs as reviewed in Section 4.2.1. Indeed, a massless vector boson has only one degree of freedom (dof) which is characterized by its helicity, h, and which cannot be altered by a proper Lorentz transformation.[5] On the other hand, a massive vector boson is characterized by the three spin states of an ordinary spatial vector.

The solution to this problem involves the phenomenon usually called spontaneous symmetry breaking (SSB), although the symmetry of the Lagrangian remains fully intact. But the lowest energy (vacuum) state of the theory is degenerate, with various possible ground states related by the symmetry of the Lagrangian. Whichever is the actual vacuum state and whatever determines it, the physical consequences are indistinguishable because of the symmetry but the latter may be obscured or entirely hidden.

The SSB idea applied to *continuous, global* symmetries in QFTs (i.e., excluding local gauge symmetries) reveals the existence of a massless spin-0 field (Nambu–Goldstone boson) for each broken symmetry generator (Nambu, 1960; Goldstone, 1961). This can be proved (Goldstone, Salam and Weinberg, 1962) in general (Goldstone theorem).

For example, consider a doublet of complex scalar fields

$$\Phi(x) = \frac{1}{\sqrt{2}} \begin{pmatrix} \phi_1(x) + i\phi_2(x) \\ \phi_3(x) + i\phi_4(x) \end{pmatrix} \tag{13}$$

with $\phi_i = \phi_i^\dagger$ and with Lagrangian

$$\begin{aligned} \mathcal{L}_\Phi &= \partial_\mu \Phi^\dagger \partial^\mu \Phi - m_\Phi^2 \Phi^\dagger \Phi - \tfrac{1}{2}\lambda^2 (\Phi^\dagger \Phi)^2 \\ &= \tfrac{1}{2}\partial_\mu \phi_i \partial^\mu \phi_i - \tfrac{1}{2} m_\Phi^2 \phi_i \phi_i - \tfrac{1}{8}\lambda^2 (\phi_i \phi_i)^2 \end{aligned} \tag{14}$$

where here and in the following summation over i is understood. $\mathcal{L}_\Phi$ is manifestly invariant under continuous $SO(4) = SU(2) \times SU(2)$ rotations in the space spanned by the ϕ_i. The minimum energy state receives no contribution from the kinetic energy (the first term in $\mathcal{L}_\Phi$). For $m_\Phi^2 > 0$, the minimum of the potential, V (the negative of the last two terms in $\mathcal{L}_\Phi$), is reached for vacuum expectation values (VEVs) $\langle \phi_i \rangle = 0$, which define a unique and trivially $SO(4)$ symmetric vacuum. For $m_\Phi^2 < 0$, however, the ground state condition is

$$|\langle \Phi \rangle| = \sqrt{-\frac{m_\Phi^2}{\lambda^2}} \equiv \frac{v}{\sqrt{2}} \tag{15}$$

which has many solutions and none of them possesses $SO(4)$ symmetry.[6] We may choose, $\langle \phi_i \rangle = 0$ for $i = 1, 2, 4$ and $\langle \phi_3 \rangle = v$, or we define a new field variable, $\eta \equiv \phi_3 - v$ so that $\langle \eta \rangle = 0$, and write instead

$$\Phi(x) = \frac{1}{\sqrt{2}} \begin{pmatrix} r\phi_1(x) + i\phi_2(x) \\ v + \eta(x) + i\phi_4(x) \end{pmatrix} \tag{16}$$

---

[5] To reach the second dof characterized by $-h$, one needs to invoke a parity transformation.

[6] One may object that there are nonzero matrix elements of the Hamiltonian, H, between different such individual vacuum solutions and that the linear superpositions that one must take to diagonalize H will then be symmetry eigenstates (including the lowest energy state). But for macroscopic systems these off-diagonal matrix elements are much smaller (and in infinite volume theories like QFTs they even vanish) than any imperceptibly small symmetry violating perturbation, which would diagonalize H in the individual basis. Moreover, vacuum states should also satisfy the principle of cluster decomposition (see Section 4.2.1) and one can show that general linear combinations do not.

The potential now reads

$$V = -\frac{\lambda^2 v^4}{8} + \frac{\lambda^2 v^2}{2}\eta^2 + \frac{\lambda^2 v}{2}\eta\phi_i\phi_i + \frac{\lambda^2}{8}(\phi_i\phi_i)^2 \tag{17}$$

showing a mass term for η ($m_\eta = \lambda v$), while the ϕ_i are massless in accord with the Goldstone theorem.

4.2.6
Higgs Mechanism

If the field (16) is assumed to transform nontrivially under $SU(2) \times U(1)$ gauge transformations, one can arrange for a particular transformation U to pass to a gauge (unitary gauge) such that

$$U\Phi(x) = \frac{1}{\sqrt{2}}\begin{pmatrix} 0 \\ v + H(x) \end{pmatrix} \tag{18}$$

that is, $\phi_1(x)$, $\phi_2(x)$, and $\phi_4(x)$ can be eliminated. If we apply this to the $SU(2)_L \times U(1)_Y$ electroweak gauge theory, we must replace the derivatives in Eq. (14) by the covariant derivatives (12), which introduces extra gauge boson dependent terms. The bilinear ones of these are

$$\Delta\mathcal{L} = -\frac{1}{8}v^2\left[g^2\left(W_\mu^1\right)^2 + g^2\left(W_\mu^2\right)^2 + \left(g' B_\mu - g W_\mu^3\right)^2\right] \tag{19}$$

showing that, as anticipated, the $W_\mu^\pm$ Eq. (7) and Z_μ^0 Eq. (8) bosons are indeed mass eigenstates, with mass, respectively, given by

$$M_W = \frac{1}{2}gv, \quad M_Z = \frac{1}{2}\sqrt{g^2 + g'^2}\,v \tag{20}$$

while the photon (9) remains exactly massless. This shows how the puzzling mismatch of d.o.f. counting mentioned at the beginning of Section 4.2.5 is rectified: the extra (longitudinal) dof carried by a massive gauge boson is provided by a scalar dof of what in the context of the breaking of the corresponding *global* symmetry would have been a Goldstone boson (would-be Goldstone boson). This is the Higgs mechanism (Englert and Brout, 1964; Higgs, 1964; Guralnik, Hagen and Kibble, 1964) and the dof represented by η is the yet to be discovered Higgs boson, H, with mass, $M_H = \lambda v$.

The covariant derivatives will also induce trilinear and quadrilinear terms producing couplings of two gauge bosons to respectively, one and two Higgs bosons. These are fixed in terms of the gauge couplings g and g'.

We have chosen an isodoublet of complex scalars, but the Higgs mechanism would also work with other nontrivial representations. But if in the course of SSB the electron is to acquire a mass term, as well, the only renormalizable possibility (see Section 4.2.7) is indeed a nonderivatively coupled $SU(2)_L$ doublet (which can combine with the lepton doublet to form a singlet) with hypercharge $Y = -1/2$ (to cancel the hypercharges of the electron and the positron). This allows to add to the theory, a Yukawa term (Yukawa, 1935)

$$\mathcal{L}_Y = -\sqrt{2}\lambda_e \overline{(\nu_e, e)}_L \Phi e_R + \text{H.c.} \tag{21}$$

where the overline notation is introduced to form a Lorentz-invariant scalar product for fermions and adding the Hermitian conjugate assures a real valued Lagrangian. If again the Higgs field, $\Phi(x)$, is replaced by its VEV (15) a mass term for the electron arises,

$$m_e = \lambda_e v \tag{22}$$

4.2.7
Infinities

Quantum mechanical amplitudes for physical processes can be computed in an expansion in powers of the coupling constants (perturbation theory) and are given by a sum of Feynman diagrams (Feynman, 1949) translating into concrete mathematical expressions. If one attempts to calculate higher order radiative corrections to these processes (containing closed particle loops) one frequently encounters divergent expressions. One can ''renormalize'' a theory if the infinities match a set of infinite counterterms that one may add to the Lagrangian density defining the theory. In this case, one can absorb all infinities into redefined coupling constants, masses, and fields, provided one works with the most general Lagrangian and the complete set of counterterms allowed by the assumed symmetries.

The number of counterterms may in principle be infinite. There is a stricter sense of renormalizability, which refers to field theories that need only a finite number of counterterms and which (for historical reasons) are the ones actually called *renormalizable*. The coefficients of the counterterms in this case are restricted to be either dimensionless[7] or their dimension is a positive power of mass (power counting renormalizability). In gauge theories one still needs to demonstrate that gauge invariance constrains the infinities in the same way as the interactions. This has been achieved first for QED (Dyson, 1949) and later for non-Abelian theories ('t Hooft and Veltman, 1972) including those with spontaneously broken gauge symmetries (Lee and Zinn-Justin, 1972) showing that the SM is renormalizable in the stricter sense.

There is another class of infinities (Adler, 1969; Bell and Jackiw, 1969) that can arise and for which there are no counterterms to absorb them. They appear in Feynman diagrams containing a closed spin-1/2 fermion triangle with gauge bosons attached (possibly including gravitons) of which at least one couples chirally – just like the $SU_L \times U(1)_Y$ gauge bosons in the SM. Such diagrams can be interpreted as corrections to the three-gauge-boson vertices. Since there are no corresponding divergences in the corrections to the four-gauge-boson vertices or to the vertices generated by the covariant derivatives, the subtle structure required by gauge invariance (e.g., in Eq. (11)) breaks down. This phenomenon of symmetry violation by quantum effects (anomaly) does not necessarily spoil the mathematical consistency of the theory (see Section 4.5.3 for an example), but *chiral gauge anomalies* of the type encountered here do so.

It is perhaps surprising that symmetries of the action can be violated by the interactions derived from this very same action. Fujikawa (1979) has given an interpretation of chiral anomalies, which reveals their fundamental nature. In the space-time approach (Feynman, 1948) to quantum mechanics, amplitudes are given as integrals over all possible path histories (path integral formulation) weighted by a complex phase factor given in terms of the action. The chiral anomaly is here seen as the Jacobian determinant (which can be written as an extra phase factor) arising from a change of integration variables of the form of a local gauge transformation. The nontrivial Jacobian by itself would not affect the perturbation theory because it is field-independent and would pose no problem. But it is infinite and needs regularization in the process of which (gauge) field-dependence is introduced. For this reason, in addition to a gauge-invariant action, one also has to require a gauge-invariant path integral measure (more strictly, only the combination of the two needs to be gauge-invariant).

---

[7] As is customary among elementary particle physicists, we are using physical units in which, by definition, the fundamental values of the speed of light, c, and of Planck's constant, $h/(2\pi)$, are exactly equal to one. The dimensions of mass, energy, linear momentum, and inverse length are then the same.

The model of leptons (Weinberg, 1967; Salam, 1968) described in this section is plagued by chiral gauge anomalies and is therefore – as it stands – inconsistent. However, one may add additional fermionic dofs to the model that may precisely cancel the anomalies. These dofs are provided by the quarks discussed in Section 4.3.2.

4.3
The Standard Theory

Section 4.3.1 extends the model to include the muon and tau sectors whose existence is not explained in the SM but which incidentally help to determine the basic coupling parameters, respectively, of the weak and strong interactions, with great precision. The quark sector and the modern theory of the strong interaction (quantum chromodynamics (QCD)) are added in Section 4.3.2, completing the particle content of the SM. Sections 4.3.3 and 4.3.4 are dedicated to quark mixing and CP violation, respectively.

4.3.1
Lepton Replication and Muon Decay

Besides Yukawa interactions as, for example, in $\mathcal{L}_Y$, the leptonic model has only four adjustable parameters, namely, the gauge couplings, g and g', as well as from the Higgs Lagrangian (14) the Higgs-self coupling, λ, and the only fundamental parameter with dimension of mass in this theory, m_Φ. The combination of the latter two in Eq. (15) can be determined experimentally with very good accuracy. This is because of the existence of the muon, which forms (with its antiparticle and the left-handed muon-neutrino, ν_μ) the same left-handed $SU(2)_L$ doublet and right-handed singlet structure with the same hypercharges as the electron, providing an exact duplication except for an approximately 200 times larger value for the corresponding Yukawa coupling (21), λ_μ as compared to λ_e. Thus, the μ^- is much heavier and can decay into a ν_μ, e^-, and $\overline{\nu}_e$ with an amplitude[8], which to good approximation is proportional to g^2/M_W^2. According to Eq. (20), this determines the Higgs VEV,

$$v = \frac{2M_W}{g} = \sqrt{\frac{1}{\sqrt{2}G_F}} = 246.22\ \text{GeV} \tag{23}$$

where $G_F = 1.166367 \pm 0.000005 \times 10^{-5}$ GeV^{-2} (4 parts per million precision), is the four-fermion coupling constant appearing in the original Fermi theory (Fermi, 1934) of the weak interaction.

It should be mentioned that the extraction of fundamental parameters to such high precision requires the calculation of higher order corrections. These are often difficult and lengthy computations but are feasible within renormalizable field theories. For example, in the case of the Fermi constant, one needs the muon lifetime formula to fourth-order (two-loop) precision (Marciano and Sirlin, 1988; van Ritbergen and Stuart, 2000).

---

[8] The Lagrangian (21) and the gauge interactions are such that the total number of e^- and ν_e minus e^+ and $\overline{\nu}_e$ entering and leaving any Feynman diagram must be the same (electron number conservation) and likewise for muons. This is why an antineutrino is emitted together with an electron.

The relations (10) allow to fix another combination of couplings since the QED fine structure constant

$$\alpha \equiv \frac{e^2}{4\pi} = \frac{1}{137.0359997 \pm 0.0000001} \tag{24}$$

is known to within 700 parts per trillion. It is extracted from the anomalous magnetic moment of the electron (see Section 4.4.2) and is based on an eighth-order (four-loop) calculation (Gabrielse *et al.*, 2006).

The gauge boson masses (20) are then (to first order) determined by the weak mixing angle alone,

$$\begin{aligned} M_W &= \frac{\sqrt{4\pi\alpha(M_Z)}}{2\sin\theta_W} v \approx \frac{38.59\ \text{GeV}}{\sin\theta_W} \\ &\approx 86 \pm 7\ \text{GeV} \qquad (25) \\ M_Z &= \frac{\sqrt{4\pi\alpha(M_Z)}}{2\sin\theta_W\cos\theta_W} v \approx \frac{77.18\ \text{GeV}}{\sin 2\theta_W} \\ &\approx 96 \pm 6\ \text{GeV} \qquad (26) \end{aligned}$$

These equations use the value, $\alpha^{-1}(M_Z) \approx 127.9$, appropriate for high-energy (weak-scale) observables instead of the low energy value in Eq. (24). This is because leading radiative corrections – those enhanced by large logarithms of the form $\ln M_Z/m_f$, where m_f is a fermion mass – have been taken into account. Effectively, these logarithms lead to the concept of the energy scale (μ) dependence[9] (running) of the coupling constants (Stueckelberg and Petermann, 1953; Gell-Mann and Low, 1954), described by the Callan–Symanzik β-function (Symanzik, 1970; Callan, 1970)

$$\mu^2 \frac{d}{d\mu^2}\alpha(\mu) = \beta(\mu) \tag{27}$$

Note, that α grows with μ (screening), and so $\beta > 0$. The last step in the relations (25) and (26) shows the predictions for the value $\sin^2\theta_W = 0.20 \pm 0.03$ obtained by the 1978 experiment (Prescott *et al.*, 1978) in electron–deuteron fixed-target scattering (see Section 4.4.2). The $W^\pm$ (Arnison *et al.*, 1983a, Banner *et al.*, 1983) and Z^0 (Arnison *et al.*, 1983b, Bagnaia *et al.*, 1983) bosons were discovered in 1983 in proton–antiproton collisions at the Super Proton Synchrotron (SPS) at the European Organization for Nuclear Research (CERN) near Geneva, Switzerland. The reconstructed masses, $M_W \sim 80\,\text{GeV}$ and $M_Z \sim 92\,\text{GeV}$, were in perfect agreement with the predictions (25) and (26).

The most general amplitude for muon decay (Michel, 1950) is described by 19 real parameters (Michel parameters), which reduce to 6 parameters if the outgoing neutrinos are not observed. The Michel parameters have been used to confirm the $V-A$ structure of the SM. The muon sector also played a crucial role in the first observation of a neutral current process. The 1973 discovery (Hasert *et al.*, 1973) at CERN was based on a single event in $\nu_\mu e^-$ elastic scattering.

The lepton sector is completed by yet another replication, composed of the $\tau^\pm$ and the ν_τ. The $\tau^\pm$ is about 17 times heavier than the $\mu^\pm$, and is the only known lepton heavy enough to decay into hadrons, providing a valuable laboratory for detailed and quantitative studies of the strong interaction (Davier, Hocker and Zhang, 2006).

---

[9] There are various definitions arising from different calculational (renormalization) schemes, which differ by higher order terms. Values quoted here correspond to what is known as the *modified minimal subtraction* ($\overline{\text{MS}}$) scheme ('t Hooft, 1973).

4.3.2
Quarks and Quantum Chromodynamics

It was stressed in Section 4.2.7 that the leptonic model by itself has a gauge anomaly, which can be cured by adding additional fermions (quarks). As can be seen from Eq. (6), a left-handed quark doublet (u, d) with hypercharge $Y = +1/6$ and two antiquark singlets $\overline{u}$ ($Y = -2/3$) and $\overline{d}$ ($Y = +1/3$) correspond to $Q_u = +2/3$ and $Q_d = -1/3$. These give a contribution to the pure (cubic) hypercharge anomaly of $Y^3 = N_C(2 - 64 + 8)/216 = -N_C/4$. If one chooses $N_C = 3$ (the number of "colors") this cancels the contribution, $Y^3 = -1/4 + 1 = 3/4$, from electron-type leptons. Doublets with other kinds of quarks (flavors) (c, s) and (t, b) along with their antiquarks are needed to cancel the anomaly contributions from the muon and tau sectors. Anomaly cancellation for other gauge boson combinations can also be checked.

Neither the color quantum number nor the free quarks have ever been observed directly. Qualitatively this can be understood if one assumes that there is another non-Abelian gauge interaction with gauge group $SU(3)_C$, which is acting on color triplets of quarks and color antitriplets of antiquarks[10], and if this new gauge interaction became stronger at large distances[11] so that it would be too costly in energy to isolate a quark (confinement hypothesis). For this, the β-function of QCD would have to be negative (antiscreening) in contrast to the case of QED (see Section 4.3.1) and any other renormalizable QFT. Non-Abelian gauge theories (if not coupled to too many matter fields) have indeed this property (Gross and Wilczek, 1973a; Politzer, 1973).

The reason why the $SU(3)_C$ gauge bosons (the gluons) have not been observed directly is not because they are very massive, but rather because they are massless and confined into colorless hadrons (Weinberg, 1973; Gross and Wilczek, 1973b). The known hadrons are quark–antiquark bound states (mesons) or bound states of either three quarks or three antiquarks (baryons and antibaryons). Other possibilities such as bound states of four quarks and an antiquark (pentaquarks) or purely gluonic states (glueballs) have been speculated about and in some cases their mass predicted, but they have not yet been uncontroversially observed. Both gluons and quarks can be indirectly observed in high-energy collisions as directionally clustered collections of hadrons (jets). For example, the gluon was discovered (Berger *et al.*, 1979; Bartel *et al.*, 1980) in 1979 at the Positron Electron Tandem (PETRA) Ring Accelerator (PETRA) at the German Electron Synchrotron (DESY) in Hamburg as planar three jet events, which could be interpreted as the radiation of a gluon by one of the quarks (gluon Bremsstrahlung). This completes the elementary particle spectrum of the SM, which is summarized in Table 4.1.

By precisely measuring the total production rate of jet events one can not only determine N_C (to which it is proportional to first order) but also

$$\alpha_s \equiv \frac{g_s^2}{4\pi} \qquad (28)$$

---

[10] Triplets and antitriplets of $SU(3)$ are complex conjugates of each other and form mathematically inequivalent irreps. The only other gauge group in Cartan's classification (Cartan, 1894) with a three-dimensional irrep (for $N_C = 3$) is $SU(2)$, but its irreps are (pseudo)real and therefore would give a hadron spectrum different from what is observed.

[11] Conversely, it ought to become weaker at short distances (asymptotic freedom) in agreement with experiments in deep inelastic electron–nucleon scattering (Bloom *et al.*, 1969).

Tab. 4.1 Standard model particles.

Multiplet			**Spin**	**SU(3)$_C$**	**SU(2)$_L$**	**U(1)$_Y$**	
Higgs			**0**	**1**	**2**	$\frac{-1}{2}$

			1	8	1	0	
$\vec{W}$			1	1	3	0	
B			1	1	1	0	

where g_s is the strong gauge coupling associated with $SU(3)_C$ and which enters at second order. Examples for such measurements include hadron production in e^+e^- annihilation at sufficiently high energy, the τ lepton lifetime, and various Z^0 decay observables (see Section 4.4.1).

QCD by itself individually conserves the number of quarks of each flavor (minus the number of each antiflavor). Moreover, QCD perturbation theory also conserves P and C invariance (just like QED), but (unlike in QED) these are generally expected to be broken non-perturbatively (see Section 4.3.4).

4.3.3
Quark Mixing

When one adds to the u (up) and d (down) quarks of the first family the second generation s (strange) and c (charm) quarks, then the Yukawa couplings (21) become 2×2 matrices. These complex matrices can be brought to diagonal form with real eigenvalues (the quark masses) by means of bi-unitary[12] transformations (changes of basis). The weak interaction, however, is not diagonal in this new (mass) basis whenever the left-handed unitary transformation, U_L^u, acting on up and charm quarks differs from U_L^d, acting on down and strange quarks. As a result, the linear combinations

$$\begin{aligned} d' &= \cos\theta_c d + \sin\theta_c s \\ s' &= -\sin\theta_c d + \cos\theta_c s \end{aligned} \tag{29}$$

of mass eigenstates d and s are the ones that actually form the $SU(2)_L$ doublets with u and c, respectively. Here, θ_c is the so-called Cabibbo angle (Cabibbo, 1963), and the right-handed transformation matrices, U_R^u and U_R^d, have been used to ensure that $u' = u$ and $c' = c$ remain unchanged. In the SM,

---

[12] In general, different matrices are necessary for the left- and right-handed quark fields. Each matrix must be unitary, $U^\dagger = U^{-1}$, so that the quark kinetic energy terms maintain their canonical forms.

U_R^u and U_R^d have no observable effect, which can be traced to the fact that there are only left-handed $SU(2)_L$ doublets. Thus, in the quark sector there is a numerically smaller Fermi constant, $G_F \to G_F \cos\theta_c$, more effective than in the lepton sector, with $\theta_c \approx 13^\circ$. Flavor changing charged current transitions between the first two families such as kaon (light mesons containing an s quark) β decays, $K^- \to \pi^0 e^- \overline{\nu}_e$, are possible but suppressed by $\sin^2\theta_c \approx 0.05$.

Flavor changing neutral current (FCNC) transitions, such as K^0–$\overline{K^0}$ oscillations or $K^0 \to \mu^+ + \mu^-$ decays, are also predicted. However, the contributions from two full generations of quarks tend to cancel each other leaving only a small residual effect, which can mostly be attributed to the differences in quark masses. Historically, this cancellation (Glashow-Iliopoulos-Maiani (GIM)mechanism) was the basis for the prediction (Glashow, Iliopoulos and Maiani, 1970) of the c quark and an estimate of its mass before the 1974 discovery of the first c–$\bar{c}$ bound state (the J/Ψ) almost simultaneously at the Alternating Gradient Synchrotron (AGS) at the Brookhaven National Laboratory (BNL) (Aubert *et al.*, 1974) and at the Stanford Positron Electron Accelerating Ring (SPEAR) at the Stanford Linear Accelerator Center (SLAC) (Augustin *et al.*, 1974).

4.3.4
CP Violation

Upon inclusion of the t (top) and b (bottom) quarks, 3×3 Yukawa (mass) matrices and the possibility of CP violation arise (Kobayashi and Maskawa, 1973). CP violation typically occurs in the presence of complex phases leading to different quantum mechanical interference effects between charge-conjugate amplitudes. Many phases in the Cabibbo–Kobayashi–Maskawa (CKM) matrix (Cabibbo, 1963; Kobayashi and Maskawa, 1973)

$$V_{\mathrm{CKM}} = U_L^u U_L^{d\dagger} \tag{30}$$

can be removed by redefinitions. Indeed, no diagonal phase transformation of the form $U_R = U_d = \mathrm{diag}(\alpha_1, \alpha_2, \alpha_3)$, affects the real masses (and corresponding quark-Higgs couplings) or anything else except for V_{CKM} itself. These can be used (with the exception of one redundant overall phase redefinition) to remove phases from V_{CKM} (in the three quark generation case a total of five phases can be eliminated). Being defined as the product (30) of two unitary matrices, V_{CKM} is itself unitary, and since it is unconstrained otherwise it has nine (real) parameters. Of these only four are then observable, which can be interpreted as three mixing angles (generalizing θ_c) and one observable (CP violating) phase, $e^{i\delta}$. The same counting reveals $(N-1)^2$ parameters for an N generation V_{CKM} of which $(N-1)(N-2)/2$ are complex phases. Therefore, as long as $e^{i\delta} \neq \pm 1$, the three generation SM predicts CP nonconservation in the electroweak sector. Combining the fact that CP violation occurs for three but not for two generations of quarks with the small observed values of V_{CKM} elements connecting the three generations with each other, one expects rather small CP violating effects even for δ not very close to 0 or π. CP violation has been observed in kaons and in mesons containing b-quarks. All results can be understood in terms of a common value of the CKM phase δ.

There is another source of CP (and P) violation from the QCD sector. A term may be added to the QCD Lagrangian, which in some sense extends the gauge coupling to complex values, with an imaginary part proportional to a real parameter θ (QCD θ angle). It can be written as a total derivative, which renders it harmless in QCD perturbation theory because it does not modify the Feynman rules[13]. Even nonperturbatively it may be absorbed by a chiral phase redefinition of the quark fields but at the expense of having to allow complex quark masses, modifying the phase counting above. The QCD θ angle would give, for example, a contribution to the CP violating electric dipole moment of the neutron, which has not yet been observed. This implies a stringent bound, $\theta \lesssim 10^{-10}$. It is an open question why θ is so small (strong CP problem).

4.4
Experimental Tests

After the discoveries of the weak neutral current (Hasert *et al.*, 1973), the $W^{\pm}$ (Arnison *et al.*, 1983a; Banner *et al.*, 1983) and Z^0 (Arnison *et al.*, 1983b; Bagnaia *et al.*, 1983) bosons, and the observation (Prescott *et al.*, 1978) of parity violation in deep inelastic electron–deuteron scattering (see Section 4.4.2), the SM was widely accepted as the correct theory of electroweak interactions, at least to some first approximation. High precision measurements were then needed to establish the SM as a renormalizable field theory and at the level of quantum corrections. Since the $SU(2)_L$ gauge coupling usually enters in the combination $g^2/4\pi^2 \approx 0.01$, one typically has to achieve relative accuracies of better than 1% in genuine electroweak observables.

4.4.1
Z^0 Pole Physics

Z^0 bosons can be produced copiously in e^+e^- annihilation experiments if the center of mass energy is tuned to M_Z (Z resonance). The high statistics achievable on the Z^0 pole was exploited by the Large Electron Positron (LEP) collider at CERN and the Stanford Linear Collider (SLC) at SLAC (Z factories). A joint document (ALEPH, DELPHI, L3, OPAL, SLD Collaborations, LEP Electroweak Working Group, SLD Electroweak and Heavy Flavour Groups, 2006) combines the results and accounts for common systematic and theoretical uncertainties in the interpretation of the individual experiments.

The LEP program recorded about 17 million Z^0 decays and included an energy scan around the Z^0 pole. The fit to the Z^0 resonance lineshape resulted in a 23 parts per million determination of $M_Z = 91.1876 \pm 0.0021$ GeV. Together with the fine structure constant (24) and the Fermi constant appearing in Eq. (23) this fixes three of the four fundamental electroweak input parameters mentioned in Section 4.3.1. Even though the Higgs boson has not been discovered yet, the missing input parameter, M_H, can be constrained by a global fit to all electroweak precision data (see Section 4.4.3). In addition to M_Z, the Z^0 lineshape scan also yielded 0.9 permille determinations of the total Z^0 decay width, $\Gamma_Z = 2.4952 \pm 0.0023$ GeV, and the resonance peak cross section for hadronic final states, $\sigma_{\text{had}} = 41.541 \pm 0.037$ nb. The cross sections for specific quark or lepton flavors, f, are then expressed relative to σ_{had} as ratios, R_f. The observables, Γ_Z, σ_{had}, and R_ℓ ($\ell = e, \mu, \tau$), serve as the theoretically cleanest determinations of α_s. If one subtracts the partial Z^0 decay widths into hadrons and charged leptons from Γ_Z

---

[13] The fact that a total derivative term in the Lagrangian can still have a nontrivial physical effect is best understood in the path integral formulation. One points to the existence of extended space-time-dependent (topological) field configurations (such as the so-called instantons), which one has to include (Belavin *et al.*, 1975).

one obtains the "invisible" Z^0 width, Γ_{inv}, which in the SM represents the decay width into neutrinos. Conversely, by computing the SM decay width into one standard neutrino, one can use the measured Γ_{inv} to extract the number of massless neutrinos, $N_\nu = 2.985 \pm 0.009$, which rules out further generations of fermions (unless their properties are qualitatively different from the three known ones). By measuring the cross-section asymmetry, $A_{FB}(f)$, for fermions f going into the forward hemisphere of the detectors relative to the backward direction (forward–backward asymmetry), the LEP Collaborations obtained a number of observables, which are proportional to lepton-Z vector couplings, v_ℓ. Since (to leading order) the v_ℓ are proportional to the combination $1 - 4\sin^2\theta_W$ and $\sin^2\theta_W \approx 0.23$ is numerically close to 1/4, these observables have an enhanced sensitivity to $\sin^2\theta_W$ and allow permille level determinations. This also applies to the final state τ polarization asymmetry, $A_{\text{pol}}(\tau)$, a measurement that included information from the angular distribution, as well.

The SLC operated with a 75% polarized e^- beam and percent level polarimetry permitting competitive measurements of $\sin^2\theta_W$ with a much smaller number of approximately 600 000 Z^0 bosons. This is because left-right (polarization) asymmetries (A_{LR}) are also proportional to v_ℓ, while being much larger than leptonic LEP asymmetries (yielding better data statistics). They are also cleaner (only counting of hadrons or leptons is required) than the quark asymmetries at LEP, which need to tag the flavors of heavy quarks and distinguish quarks from antiquarks. The combination of measurements of the weak mixing angle at Z^0 pole energies yields

$$\sin^2\theta_W(M_Z) = 0.23124 \pm 0.00017 \qquad (31)$$

The results obtained from the Z factories are in remarkable agreement with the SM predictions. In particular, the decay properties of the Z^0 boson and its couplings to leptons and quarks have been verified at the subpercent level tightly constraining any possible physics beyond the SM. On the other hand, direct contributions to the scattering amplitudes from outside the SM are suppressed relative to the resonating Z^0 amplitude and are best studied away from the Z^0 pole.

One possibility is to upgrade the colliders to higher energies as was done with LEP (LEP 2), which operated up to 209 GeV (ALEPH, DELPHI, L3, OPAL Collaborations, LEP Electroweak Working Group, 2006). Here one can study directly the electroweak energy scale, but high precision measurements are generally difficult owing to small data samples. Nevertheless, various key measurements were achieved, most notably the very precise measurement of $M_W = 80.376 \pm 0.033$ GeV. Similarly, the proton–antiproton collider Tevatron at the Fermi National Accelerator Laboratory (FNAL) (FNAL) near Chicago is producing collisions up to 2 TeV. It provided a comparable measurement of $M_W = 80.429 \pm 0.039$ GeV (Abazov *et al.*, 2004; Aaltonen *et al.*, 2007), and was also able to discover the very massive t quark (Abe *et al.*, 1995; Abachi *et al.*, 1995) and determine its mass, $m_t = 170.9 \pm 1.8$ GeV (Tevatron Electroweak Working Group, 2007). The Tevatron experiments are expected to increase their data samples by another order of magnitude before the final shutdown of the collider. But complementary measurements are also possible at much lower energies if sufficient precision can be achieved (see Section 4.4.2).

4.4.2
Low Energy Measurements

The 1978 deep inelastic scattering (DIS) experiment (Prescott *et al.*, 1978) of polarized electrons from deuterium at SLAC was crucial in establishing the SM. Rival models based on different gauge groups or with different $SU(2)_L \times U(1)_Y$ irrep assignments could not simultaneously explain contemporary ν-scattering results or were altogether inconsistent with the observed parity nonconservation in eD-DIS. At energy (momentum transfer) scales Q of about 1 GeV, the parity violating interference term between the photon and the Z^0 is suppressed by $Q^2/M_Z^2 \sim 10^{-4}$ relative to the parity conserving QED cross section. In other words, an asymmetry measurement of the order of 10^{-5} corresponds to a 10% determination of the Z^0 mediated amplitude.

The same idea has later been applied (Anthony *et al.*, 2005) to e^-e^- (Møller) scattering at even lower momentum transfer, $Q^2 = 0.026\,\text{GeV}^2$. Just like at the Z^0 pole the parity violating asymmetry, A_{PV}, is here further suppressed by v_ℓ yielding a very small $A_{PV} = (-1.31 \pm 0.17) \times 10^{-7}$. Owing to the enhanced sensitivity to the weak mixing angle, this yields $\sin^2\theta_W(Q) = 0.2397 \pm 0.0013$, the most precise value away from the Z resonance. The central value is higher than the one in Eq. (31) establishing that $\sin^2\theta_W$ is a running parameter (see Figure 4.1) just like the QED coupling α discussed in Section 4.3.1 and the QCD coupling α_s.

The interference between photon and Z^0 mediated amplitudes can also induce mixing between opposite parity states in atoms. Atomic parity violation (APV) has been seen in various heavy atoms where the effect is larger but it must be enhanced further. For example, it can be isolated as a small modulation of the level mixing induced by an external electric field (Stark mixing). The most precise measurement has been obtained by a group in Boulder, CO, in cesium (Wood *et al.*, 1997) and may be interpreted as a precise measurement of $\sin^2\theta_W$ (see Figure 4.1). However, the interpretation requires a solid understanding of the structure of many-electron atoms (Ginges and Flambaum, 2004). For cesium the uncertainties associated with atomic wave functions are relatively small and comparable to the experimental ones.

Since neutrinos are electrically neutral, they are directly sensitive to the weak interactions, but their cross sections are proportional to G_F^{-2} and are very small. DIS of neutrinos from nuclei have been measured to percent accuracies but here the interpretation of the results is hampered by theoretical uncertainties from the strong interaction. These can be reduced by considering ratios of neutral and charged current cross sections and by using nuclei with (approximately) equal numbers of protons and neutrons (isoscalars). If a high-intensity, high-energy antineutrino beam is also available, one can use the ratio of differences of ν and $\overline{\nu}$ cross sections (Paschos-Wolfenstein ratio), reducing the theoretical uncertainties even further (Paschos and Wolfenstein, 1973). This was possible by studying neutrinos produced at the Tevatron and resulted in the most precise determination (Zeller *et al.*, 2002) of $\sin^2\theta_W$ from ν-DIS dominating the world average shown in Figure 4.1.

By far the most precise observable testing the SM (as opposed to fixing one of the input parameters) is the anomalous magnetic moment[14] of the muon, a_μ. At

---

[14] The term anomalous is of historical origin and refers to quantum corrections (Schwinger, 1948) to the lowest order magnetic moment g of massive particles with spin.

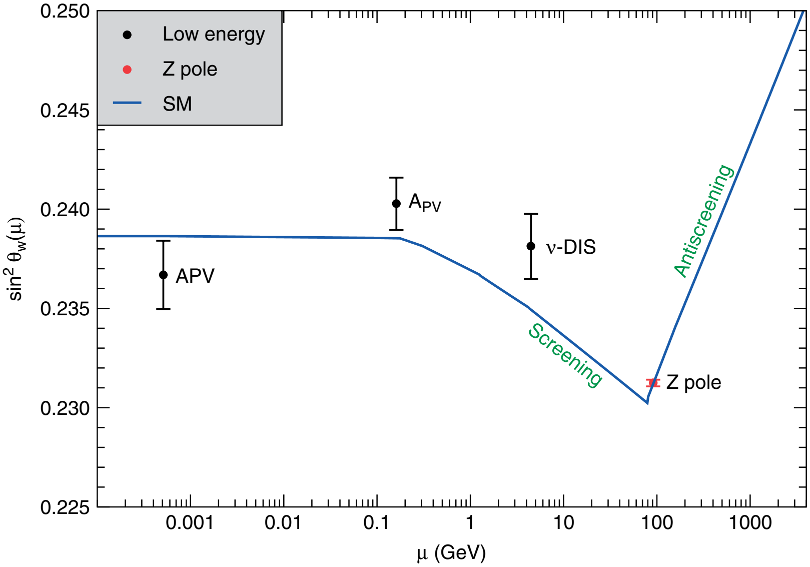

Fig. 4.1 The scale dependence of the weak mixing angle (Czarnecki and Marciano, 1998; Erler and Ramsey-Musolf, 2005) as predicted in the SM, compared to various low energy measurements and the Z^0 pole value (1.31). At $\mu = M_W$, the β-function of $\sin^2\theta_W$ changes sign because only with the inclusion of the $W^\pm$ bosons above M_W does the electroweak theory become a non-Abelian gauge theory with the characteristic antiscreening.

the level of the impressive experimental precision achieved at BNL (Bennett *et al.*, 2004),

$$a_\mu \equiv \frac{g_\mu - 2}{2} = (1165920.80 \pm 0.63) \times 10^{-9} \qquad (32)$$

receives nonnegligible corrections from the weak interaction and is easily affected by new physics contributions. The SM prediction (Miller, de Rafael and Roberts, 2007) of a_μ is not inconsistent with Eq. (32), but there is a tantalizing difference at the level of three standard deviations. Conclusions as to whether this deviation is from new physics at higher energy scales must await further theoretical work because the interpretation of a_μ is complicated by hadronic contributions entering at two-loop order (where it can be constrained by experimental data) and at three-loop order (which are much smaller but very difficult to estimate).

4.4.3
Global Analysis

To fully exploit the information contained in the various experimental results, it is best to perform a simultaneous analysis of all data (Amaldi *et al.*, 1987; Erler and Langacker, 1995; Yao *et al.*, 2006). Some of the measurements used for such a study are shown in Table 4.2.

The low energy data and other (less precise) observables[15] are not shown in the table but included. The column denoted

---

[15] For these and many other measurements and tests, including the determination of fermion masses, the parameters in V_{CKM}, and limits on SM forbidden processes, see the Review of

Tab. 4.2 Standard model precision tests.

Observable	**Experimental value**	**SM prediction**	**Pull**	**Deviation**
Γ_Z (GeV)	2.4952 ± 0.0023	2.4968 ± 0.0010	-0.7	-0.5
σ_{had} (nb)	41.541 ± 0.037	41.466 ± 0.009	2.0	2.0
R_ℓ	20.767 ± 0.025	20.758 ± 0.011	0.4	0.5
R_b	0.21629 ± 0.00066	0.21584 ± 0.00006	0.7	0.7
R_c	0.1721 ± 0.0030	0.17228 ± 0.00004	-0.1	-0.1
$A_{FB}(\ell)$	0.0171 ± 0.0010	0.01627 ± 0.00023	0.8	1.1
$A_{FB}(b)$	0.0992 ± 0.0016	0.1033 ± 0.0007	-2.5	-2.0
$A_{FB}(c)$	0.0707 ± 0.0035	0.0738 ± 0.0006	-0.9	-0.7
$A_{\text{pol}}(\tau)$	0.1465 ± 0.0033	0.1473 ± 0.0011	-0.2	0.1
A_{LR}	0.1514 ± 0.0022	0.1473 ± 0.0011	1.9	2.4
M_W (GeV)	80.398 ± 0.025	80.375 ± 0.015	1.4	1.7
m_t (GeV)	170.9 ± 1.8	171.1 ± 1.9	-0.1	-0.8

"Pull" shows the deviation (normalized to the total experimental plus theoretical uncertainty added in quadrature) of the experimental values from the SM best fit with M_H allowed as a free parameter, while the column "Deviation" refers to the SM best fit with $M_H = 117$ GeV fixed. The agreement is generally very good and there are no major discrepancies.

The global fit can be used to constrain the SM parameters including the Higgs boson mass,

$$M_H = 77^{+28}_{-22}\ \text{GeV} \tag{33}$$

the weak mixing angle, $\sin^2\theta_W(M_Z) = 0.23119 \pm 0.00014$, and the QCD coupling, $\alpha_s(M_Z) = 0.1217 \pm 0.0017$. The constraints by group of observable in the M_H–m_t plane are shown as contours in Figure 4.2. Good agreement is observed except that the low energy data (driven mostly by the NuTeV (Zeller *et al.*, 2002) result) tend to imply larger M_H. Also, most of the 90% CL ellipse is excluded by the Higgs boson searches at LEP 2, $M_H > 114.4$ GeV (Barate *et al.*, 2003), and indeed the one-standard-deviation range (33) is already ruled out. This may be due to a statistical fluctuation or could be an early indication of loop contributions from new particles beyond the SM affecting the precision observables. Including the results of LEP 2 searches (which include a slight excess of candidate Higgs boson events) in the analysis yields the 95% CL upper bound,

$$M_H \leq 167\ \text{GeV} \tag{34}$$

Thus, if the SM is correct, then the Higgs boson is not expected to be much heavier than the massive gauge bosons, and may be producible at the Tevatron and should certainly be detected at the Large Hadron Collider (LHC). The LHC is a soon-to-be-inaugurated accelerator placed in the LEP tunnel at CERN, which will mostly study proton–proton collisions at very high energies (around 14 TeV).

Particle Properties (Yao *et al.*, 2006). This reference also contains in-depth reviews on many SM-related topics and is updated biennially.

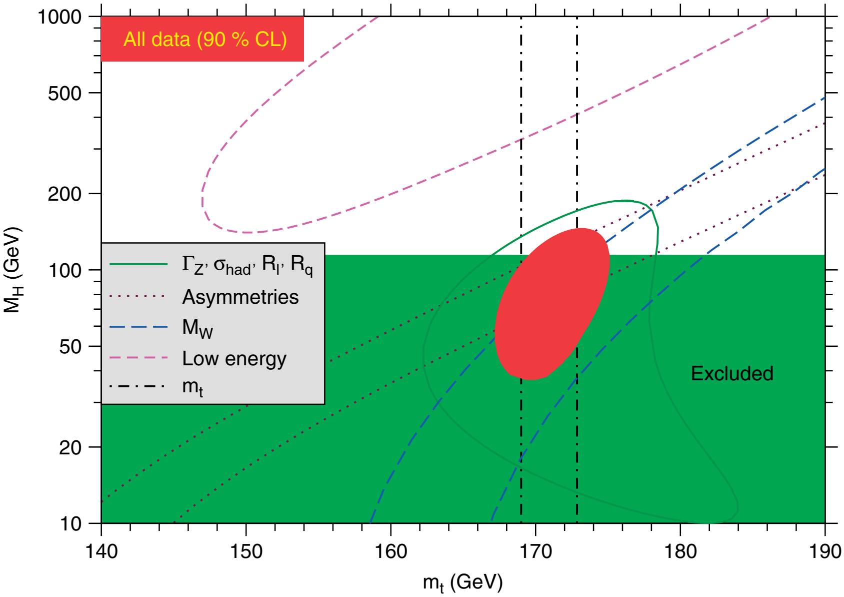

Fig. 4.2 One-standard-deviation (39.35%) uncertainties in M_H as a function of m_t for various inputs, and the 90% confidence level (CL) region allowed by all data. The 95% direct exclusion limit from LEP 2 (Barate *et al.*, 2003) is also indicated.

One can also perform a fit to the precision data alone, that is, excluding the direct m_t from the Tevatron. The result, $m_t = 175^{+10}_{-8}$ GeV, is in perfect agreement with the direct determination and provides an impressive confirmation of the SM at the level of radiative corrections.

4.5
Beyond the Minimal Model

Despite all its successes, the SM is widely believed to be correct only up to small nonrenormalizable (see Section 4.2.7) correction terms suppressed by some high energy scale Λ_{new}. This is because the mass parameter, m_Φ, in the Higgs potential generally receives large radiative corrections of the order of Λ_{new}, destabilizing the electroweak scale. Moreover, the gauge group, the irreps, and the values of the input parameters are chosen in an ad hoc way to conform with observation, but are not understood at any deeper level.

4.5.1
Accidental Symmetries and Nonrenormalizable Corrections

Whatever may be the underlying theory beyond the SM that cures these problems, at the electroweak scale one can organize it in an expansion in inverse powers of Λ_{new}, where each term (operator) contains only SM fields and where the unsuppressed (renormalizable) terms define the SM. The coefficients of the nonrenormalizable operators are to be adjusted to reflect the full theory (matching). In other words, extra heavy particles and fields are integrated out (their low energy effects are included as quantum mechanical averages) leaving their footprints in these coefficients. The SM is then considered as the low energy limit (effective field theory) of the more fundamental theory. Since at present one can only speculate as to what this theory might be, one may alternatively take the coefficients of the nonrenormalizable operators to parameterize arbitrary extensions of the SM constrained only by the local SM gauge symmetries.

In addition to these nonnegotiable local gauge symmetries, the renormalizable SM Lagrangian happens to have additional symmetries, which arise simply because any term that would violate them would also violate local gauge invariance. For example, electron number, muon number[16], and tau number are (at least perturbatively) conserved, and likewise the total quark number and thus baryon number. And as discussed in Section 4.3.4, the two generation SM conserves CP in the electroweak sector, leading to the suppression of CP violation in the full three generation model. Thus, one can understand such symmetries as *accidental* without the need to postulate them as additional physical principals. But by the same token, one would generally expect them to be broken by nonrenormalizable terms.

4.5.2
Lepton Number Nonconservation and Neutrino Mass

At order $\Lambda_{\text{new}}^{-1}$ baryon number is still accidentally conserved, but one can form Lorentz and locally gauge-invariant terms (Weinberg, 1979) out of any two lepton doublets and two Higgs doublets. Replacing each Higgs doublet by the VEV (1.15) yields a sum of terms, which can be interpreted as mass terms for neutrinos,

$$\mathcal{L}_M = -\sum_{ij} \frac{\lambda_{ij}}{\Lambda_{\text{new}}} \overline{\nu_i^c} \nu_j \, v^2 \tag{35}$$

But unlike the mass terms for charged leptons and quarks, which originate from the Yukawa terms (21) and connect left- and right-handed fields (Dirac mass terms), $\mathcal{L}_M$ connects the left- and right-handed components of conjugate fields (Majorana mass terms).

As a result, Majorana mass terms (Majorana, 1937) for neutrinos violate lepton number (the number of leptons minus antileptons) by two units and the same holds true for the corresponding trilinear and quadrilinear neutrino–Higgs interactions. This implies the important prediction of the possibility of neutrinoless double β decays ($0\nu\beta\beta$ decays), such as $K^- \to \pi^+ e^- e^-$ and more importantly of nuclei. $0\nu\beta\beta$ decays are searched for in experiments with large volume detectors but have not been observed so far.

Another consequence of $\mathcal{L}_M$ is the lepton number conserving but lepton flavor number violating process of neutrino oscillations (the change of one ν flavor into another over long flight paths), provided the matrix of parameters, λ_{ij}, has nonvanishing off-diagonal entries, in which case the mass and weak interaction eigenstates of neutrinos are not the same.[17] This mirrors the situation from the quark sector, and indeed a neutrino mixing matrix (Maki, Nakagawa and Sakata, 1962), V_{MNS}, analogous to V_{CKM} in Eq. (30), arises. The only difference is that left-handed fields are not independent of right-handed antifields so that the counting of observable phases is modified. The result is that there are $N_\nu - 1$ additional (CP violating) phases (Majorana phases) because, in contrast to the quark sector, phase redefinitions of right-handed fields do not enter here. While it appears to be extraordinarily difficult to design an experiment to measure the two Majorana phases (for $N_\nu = 3$), several of the other parameters in V_{MNS} have already been measured in experiments studying neutrinos originating from the sun (Cleveland *et al.*, 1998), the earth's atmosphere (Fukuda *et al.*, 1998), nuclear reactors (Eguchi *et al.*, 2003), and particle accelerators (Aliu *et al.*, 2005). What is observed in these experiments is the disappearance (rate decrease) of neutrinos of a particular flavor from a source with known flavor composition. Conversely, one may detect a neutrino flavor not initially present in the source (appearance experiment). On the other hand, the sum of all neutrino flavors appears to be unchanged (Ahmad *et al.*, 2001), as is expected if V_{MNS} is indeed the (only) origin of neutrino oscillations. It is conceivable that the extra phase in V_{MNS} that has its direct analog in V_{CKM} (Dirac phase) may also be accessible in future ν oscillation experiments. In any case, all experimental results are consistent with neutrino mass differences of the order of 10^{-1} eV (from atmospheric neutrinos) and 10^{-2} eV (from solar neutrinos) and generally large mixing angles. Assuming that the λ_{ij} are of $\mathcal{O}(1)$ or smaller,[18] one obtains estimates, $\Lambda_{\mathrm{new}} \lesssim \mathcal{O}(10^{15}\ \mathrm{GeV})$ and $\lesssim \mathcal{O}(10^{16}\ \mathrm{GeV})$, respectively. This is interestingly close to the Planck scale, $M_P \sim \mathcal{O}(10^{18}\ \mathrm{GeV})$, defined as the scale where quantum corrections to gravity are no longer negligible and where fundamental and far reaching modifications to current theories of elementary particles are expected.[19]

---

[16] These forbid processes such as $\mu \to e\gamma$.

[17] Of course, this also requires that the neutrino masses differ from each other. Hence, neutrino oscillation amplitudes are proportional to neutrino mass differences.

The term (35) was introduced without reference to any particular model of the physics at higher energy scales. The most important (because very simple) concrete realization is the so-called seesaw mechanism (Yanagida, 1979; Gell-Mann, Ramond and Slansky, 1979; Mohapatra and Senjanovic, 1980) in which right-handed neutrinos, ν_R, are added to the SM. They are singlets under the SM gauge group and one would generally expect them to have very large (Majorana) masses (there is no symmetry reason why they should be of the order of the electroweak scale). The role of Λ_{new} is played here by the right-handed neutrino mass scale, and the left-handed neutrino masses are generated by mixing terms analogous to Eq. (21). The term (35) would now be the result of integrating out the ν_R and one arrives at the SM as an effective field theory as discussed at the beginning of this section.

Alternatively, since the ν_R do not participate in the SM gauge interactions, one may also assume that for some reason they cannot have Majorana masses. In this case, one would be left with the Yukawa terms (21) and Dirac neutrino masses, and V_{MNS} would have the same form as V_{CKM}.

4.5.3
Baryon Number Nonconservation and Proton Decay

At order $\Lambda_{\mathrm{new}}^{-2}$ there are interaction terms (Weinberg, 1979; Wilczek and Zee,

---

[18] The λ_{ij} cannot be much larger than one, since their β-functions (see Section 4.3.1) would drive them back to order unity at the electroweak scale even if they started out much larger at Λ_{new}.

[19] Additional modifications may become necessary at additional scales between M_Z and M_P.

1979) that violate both baryon and lepton number. These involve one lepton and three quark fields and predict proton decay rates at $\mathcal{O}(\Lambda_{\text{new}}^{-4})$. The proton lifetime, τ_p, can be studied with large water detectors, but so far proton decay has not been observed and a lower (mode-independent) limit, $\tau_p > 2 \times 10^{29}$ years (Yao *et al.*, 2006), could be set. On dimensional grounds, τ_p is roughly of the order $\Lambda_{\text{new}}^4/m_p^5$ ($m_p = 938$ MeV is the proton mass), so that (assuming that all relevant coupling constants are of order unity) $\Lambda_{\text{new}} \gtrsim \mathcal{O}(10^{15}$ GeV), which is not inconsistent with the scales indicated by ν oscillations.

A realization of these model-independent observations is the *Grand Unified theories* (Langacker, 1981) in which quarks and leptons are conjectured to inhabit the same irreps of a larger gauge group, the simplest possibility being $SU(5)$. This implies proton decay (e.g. $p \to e^+\pi^0$), with the role of Λ_{new} being played by the masses of the additional gauge bosons predicted by the larger local gauge symmetry (SSB induced by extra Higgs fields would have to be at work).

Baryon number is violated in the SM even without the nonrenormalizable operators. As mentioned in Section 4.2.7, anomalies can violate the otherwise conserved quantities. In the SM, this happens both to baryon and lepton number (but not the difference), and can be understood as an instanton effect ('t Hooft, 1976). However, this is an extremely small (by any standards) quantum mechanical tunneling effect (from one vacuum to a gauge transformed vacuum) and is therefore only of academic interest.

Even though proton decay has not yet been observed, baryon number violation is a pressing problem: if baryon number is exactly conserved, then the baryon asymmetry of the universe (BAU), that is, why the universe contains more baryons than antibaryons (no large concentrations of antimatter are observed), would be difficult to understand. Moreover, baryon number violation is necessary but not sufficient to produce the BAU (Sakharov, 1967); a fairly strong source of CP violation beyond the CKM phase δ is necessary, as well. Thus, there is a large variety of reasons to strongly suspect that there is physics beyond the SM.

Glossary

Action: The action is defined to generate the classical equations of motions as its stationary "points" (Euler–Lagrange equations). It is particularly useful to construct theories that are invariant under some symmetry such as gauge invariance. A quantity called *action* also enters the weight factor in the path integral formalism, but is not always identical to its classical counterpart.

Anomaly: Symmetry violation by quantum effects. Gauge anomalies may appear in chiral theories, in which case they spoil their mathematical consistency. Anomalies of other symmetries are permissible and may lead to interesting physical effects.

Chiral Theory: A theory that fundamentally distinguishes left-handed and right-handed particles and fields (handedness).

Feynman Diagrams: Effective and intuitive way to visualize the perturbative contributions to quantum mechanical amplitudes. Each line in a Feynman diagram represents a particle. Each diagram translates into a concrete mathematical expression.

Gauge Symmetry: Gauge invariance of the first kind is invariance under global (space-time-independent) phase multiplications and their non-Abelian generalizations.

Gauge invariance of the second kind is the generalization to local (space-time-dependent) transformations.

Hamiltonian: Symmetry generator of time translations and thus one of the elements of the Poincaré algebra. It is an operator with energy eigenvalues. In QFTs it usually takes the form of a space integral over a Hamiltonian density, which is also often referred to simply as *Hamiltonian*.

Lagrangian: The action usually takes the form of a time integral over a function called the *Lagrangian*. The Hamiltonian (density) can be obtained in terms of the Lagrangian (density).

Loops: Closed line in a Feynman diagram. A loop represents virtual particles of arbitrary energy and momentum over which one has to sum (integrate). Feynman diagrams with loops are often divergent.

Path Integral: Space-time approach to quantum mechanics in which amplitudes are given as functional integrals over all possible path histories weighted by a complex phase factor given in terms of the action.

Poincaré Group: The fundamental symmetry group of space-time consisting of translations in space and time, rotations, and Lorentz boosts. The Poincaré group can be generated by *infinitesimal* symmetry transformations. The corresponding symmetry generators form the associated Poincaré algebra.

Regularization: Technique to organize the divergent parts of Feynman diagrams. Physical results should not depend on the regularization method.

Renormalizable Theory (Modern Sense): Theory in which all divergences can be absorbed by counterterms.

Renormalizable Theory (Strict Sense): Theory in which all divergences can be absorbed by a *finite* number of counterterms.

Renormalization: The process to absorb the divergences in counterterms. Only the finite sum of the divergent Feynman diagrams and infinite counterterms are physically meaningful.

INTRODUCTION

Weather exerts a powerful influence over human affairs, intimately touching the lives of all living beings and affecting the surrounding physical environment. During pleasant conditions it is hardly noticed; with the development of adverse conditions, however, the weather becomes the foremost topic of discussion on account of its significant economic and social impacts. Although the weather cannot be controlled, timely and accurate communication of impending changes are important for decisions at the personal, business, and government levels. Such decisions include, for example, determining proper dress; travel decisions; scheduling of activities, resources, and equipment; operation of transportation and utility systems; deployment of government resources; and, in rare situations, evacuations and emergency response for the protection of life and property. The nature and quality of these decisions depends upon a reliable and accurate assessment of future weather conditions—the weather forecast.

Throughout history civilizations have endeavored to foretell future weather conditions. The first forecasting methods involved keen nonquantitative observation of local conditions and how these observations were related to future weather events (Godske *et al.*, 1957). The Greek civilization built a tower of winds containing sculptures that described in graphical form the types of winds and weather they typically brought to Athens. Local weather folklore and indigenous weather knowledge is also based on the local forecast method. For example, the Basotho, inhabitants of the mountain kingdom of Lesotho in southern Africa, have developed many local forecast tools for weather and climate (Pepin, 1996). These local forecast tools include observations of cloud development, coverage, height, and color; the behavior of animals and birds; human physical conditions; the presence of a halo around the moon; the shape of the moon in its new phase; wind direction; the length of the rainy season in summer; and the mildness of winter. Some of these forecast tools are supported by scientific understanding and are used today, while others have no scientific basis and are considered to be meteorological folklore.

Development of quantitative observations of weather elements at a fixed point allowed further advances in the use of the local method of forecasting. Quantitative observations of rainfall commenced in the 15th century in Korea, temperature and pressure were first measured in the 17th century in

Europe, and the vertical temperature structure was first observed during the 18th century in Scotland. In the United States, Ben Franklin carefully observed that precipitation in an east-coast storm traveled northeastward from Philadelphia to Boston, synthesizing that midlatitude storms moved opposite to the direction of the surface wind on their cold side. In the 19th century, cloud species were scientifically classified; humidity and wind measurements were started; detailed vertical profiles of temperature, pressure, and humidity were made; and self-recording instruments were introduced. By applying the local method to these observations in the 19th century, scientists formulated early ideas of air masses, fronts, cyclones, and midlatitude weather. Further advances were made in the early 20th century with the establishment of a formal single-station forecast method that was employed during the Second World War. Radar and electrical observations made at single stations were also incorporated into the local forecast method during wartime. Adaptations of the local forecast method appear in many general and introductory textbooks in meteorology and indicate forecasts based on values and changes of barometric pressure, wind speed, and direction.

The local forecast method is currently applied as an important supplement to numerical prognoses of weather. A form of the local method known as model output statistics (Glahn and Lowrey, 1972) utilizes numerical forecasts of meteorological variables and multiple-regression techniques to predict temperature, precipitation, cloud cover, wind direction and speed, and other forecast variables at individual stations. With an appropriate developmental database, model output statistics partially accounts for model errors and local effects. This method is described further in Sec. 2.4 of this article. Forecasters also employ the local forecast method to incorporate their experience and understanding of local and regional influences on weather systems to tailor forecasts more precisely, and to predict and warn of small space- and time-scale phenomena that cannot be resolved by observing systems, numerical forecasts, and statistical techniques.

With the establishment of national meteorological services and meteorological observing stations in Europe and North America in the 19th century, and the communication of these observations to a central location, the synoptic method of weather forecasting emerged and began to develop (Kutzbach, 1979). By plotting and analyzing simultaneous meteorological observations over a region, meteorologists began to define and describe the eastward-moving migratory high- and low-pressure systems of midlatitudes, the relationship between the wind and pressure distribution, variations of the pressure field, squall lines, and their associated precipitation, cloud, and wind. Forecasts made by extrapolation from these analyses met with modest success that decreased westward across both Europe and North America because of a lack of upstream observations over the Atlantic and Pacific Oceans. It is interesting to note that a similar westward decrease of forecast skill still occurs today across North America and Europe because of a similar lack of upstream observations.

Synoptic analysis and forecasting methods advanced during the early part of the 20th century as further investigations revealed the air-current structure of midlatitude low-pressure systems or cyclones, the identification of fronts and air masses, and the conceptualized life cycle of the polar-front cyclone and its relationship to the larger-scale circulation (Bjerknes and Solberg, 1922). Better availability of upper-air meteorological measurements led to the use of vertical atmospheric soundings of temperature and water vapor to forecast clouds, precipitation, temperature, thunderstorms, fronts, air masses, and fog. Analyses of the upper air flow revealed the jet stream, the large-scale wave motions of the midlatitude westerlies, and their relationship to surface cyclones and anticyclones (Palmén and Newton, 1969). From the analyses of upper-air wave patterns, Rossby (1939) provided a simplified theoretical model that predicted the movement and energy propagation of the large-scale waves in the midlatitude westerlies, and Sutcliffe and Forsdyke (1950) illustrated application of a simplified model that explained the formation of midlatitude cyclones and anticyclones.

With new observations, theoretical tools, and conceptual models, and an archive of synoptic analyses both at the surface and in the upper air, the synoptic method of forecasting began to assert itself as the primary forecast method in the mid-20th century. Synoptic forecasting methods employed in weather services included weather types and analogs; various types of extrapolation using nonphysical and quantitative physical reasoning, statistical techniques; and tropospheric models incorporating dynamical, thermodynamical, and synoptic experience (Petterssen, 1940, 1957; Riehl *et al.*, 1952; Bergeron, 1959). These techniques were used to prepare prognostic synoptic maps of surface and upper-air systems as well as forecasts of individual weather elements.

Despite the development and incorporation of local and synoptic forecasting methods into national weather services, advances in weather-forecasting skill were limited. Meager progress was attributed to poorly trained forecasters, numerous forecasting techniques, inability to determine the forecast problem, and the lack of a focused effort to address the fundamental scientific problems of meteorology (Willett, 1951). It was recognized that future forecasting progress would result from scientific weather forecasting: a completely mathematical and physical forecast of the atmosphere based on scientific meteorological principles.

Scientific weather forecasting was described in a landmark article nearly a century ago by Vilhelm Bjerknes (1904). On the basis of an initial-value problem approach, Bjerknes indicated that observations of the initial state of the atmosphere combined with knowledge of the physical laws governing future changes of the initial state provided a scientific basis for weather prediction. Obstacles to the successful implementation of this plan in 1904 were inadequate observations in space and time, incomplete knowledge of the physical laws, and a lack of sufficient mathematical knowledge and computing resources. Implementation of the Bjerknes approach to scientific forecasting through numerical integration of the physical laws by L. F. Richardson (1922) was unsuccessful, and this poor result deterred further work on the problem. Significant progress has been made in overcoming these obstacles during the past century, with the most rapid progress occurring during the past 40 years through advances in observing systems, computing technology, and mathematical techniques that have culminated in operational numerical weather prediction (Thompson, 1983; Shuman, 1989; Wiin-Nielsen, 1991). With the Bjerknes/Richardson plan in operation around the world, weather-forecasting skill in midlatitudes has advanced in predictive range and accuracy (Bengtsson, 1991). Forecast errors still result from inadequate observations in space and time, incomplete knowledge of the physical laws and processes, and a lack of sufficient computing resources to resolve the large range of spatial and temporal scales of meteorological phenomena.

In this article the practice of weather forecasting by operational numerical weather prediction in national weather services in the Northern Hemisphere midlatitudes is described. This practice involves observation of the four-dimensional structure of the atmosphere, assimilation of the data into a numerical forecast model for initial conditions, forecasting with a numerical model, and statistical and ensemble forecasting. The various observing systems that provide initial data for numerical forecasts are described first. Next, the theoretical principles and their application to operational numerical weather prediction are discussed. Applications of numerical prediction such as statistical and ensemble forecasting are reviewed, and the article concludes with an assessment of forecast skill and a discussion of the limits of predictability of a nonlinear dynamic system.

1. OBSERVATIONS OF WEATHER SYSTEMS

1.1 Time and Space Scales of Weather Systems and Sampling Considerations

Meteorological observations are essential for the analysis of weather systems and specification of the initial state of the atmosphere for operational numerical weather prediction. Observations and analyses have revealed a large variety of weather systems whose spatial and temporal scales typically increase together and range over seven orders of magnitude (Table 1). Of critical importance is that the smallest systems have the shortest duration, are typically the most intense, and may often require emergency

Table 1. Approximate time and space scales of selected weather systems (adapted from Fujita, 1986).

System	Time scale	Space scale
Dust devil	10 s	10 m
Tornado	10 min	100 m
Microburst	10 min	1 km
Mesocyclone	1 h	10 km
Thunderstorm	1 h	10 km
Supercell thunderstorm	3 h	50 km
Low-level jet streak	12 h	500 km
Mesoscale convective system	24 h	500 km
Warm front	2 d	1 000 km
Jet streak	3 d	1 000 km
Hurricane	5 d	1 000 km
Cold front	5 d	1 000 km
Anticyclone	10 d	2 000 km
Midlatitude cyclone	10 d	2 000 km
Short wave	10 d	5 000 km
Long wave	>0.5 month	10 000 km

response to protect life and property. In addition, weather systems and processes of all scales interact nonlinearly with each other. This nonlinear interaction and the large range of weather-system space and time scales imposes constraints on observing-system design in order to measure, analyze, and predict meteorological phenomena.

Weather observations sample a continuous four-dimensional atmosphere at discrete temporal and spatial resolution. A physical constraint of this discretization, world geography and politics, and the historical development of national and international observing networks is that large portions of the world are poorly sampled. An unavoidable consequence of this discretization is that complete four-dimensional measurements of atmospheric structure essential for the conduct of the Bjerknes/Richardson method of scientific weather forecasting are difficult to realize. This results in incomplete specification of the initial state of the atmosphere and errors in specification of the smallest scales of motion. Analysis errors are propagated across scales by nonlinear interaction during numerical forecasts and degrade forecast accuracy in space and time.

1.2 Observing Systems

Sampling issues and technological advances have guided development of a global observing system for weather forecasting. This system combines *in situ* and remote-sensing observing-system platforms distributed on the Earth's surface, in the atmosphere, and in space to optimize the temporal and spatial sampling of meteorological observations. The local and synoptic forecast methods and numerical weather prediction rely on observations gathered by a variety of operational observing-system platforms for the analysis and specification of the initial state of the atmosphere. The various platforms are operated by national weather services with observations first transmitted to national weather-service centers and then to other forecasting centers by a global telecommunications system for worldwide use in weather analysis and numerical forecasting.

1.2.1 *In situ* Observations One cornerstone of the observing system is *in situ* measurements made by surface stations. Surface observations of the horizontal wind, temperature, pressure, water vapor, clouds, precipitation, snow cover, and visibility are made at nearly hourly intervals by national and international networks of manual and automated stations on land. These hourly observations are augmented more frequently in rapidly changing weather conditions. Over the oceans, merchant, military, research, and weather service ships as well as fixed and drifting buoys provide the basic meteorological observations noted above and contribute additional observations of sea-surface temperature and salinity, ocean waves, and currents. The land-surface observing network is relatively dense in the populated midlatitudes of the Northern Hemisphere, and observation density decreases over tropical land areas, the polar regions, and less affluent countries of the world (Fig. 1). Oceanic observations are sampled with less spatial resolution than land areas, with the highest density over the North Atlantic and Pacific Ocean trade routes, sparse sampling over the tropical oceans, and very sparse sampling over the Southern Hemisphere oceans. The surface-observing network provides the highest spatial- and temporal-resolution measurements of meteorological variables of any observing system deployed worldwide.

A second cornerstone of the observing system is *in situ* measurements of the upper atmosphere made by balloon-borne instru-

ment packages known as pilot balloons, rawinsondes, and dropwinsondes. Through visual tracking, pilot balloons measure wind speed and direction in clear air. Rawinsondes are tracked by radar to obtain horizontal wind observations. During their ascent they transmit pressure, temperature, and relative humidity measurements to ground stations at regular intervals, furnishing detailed vertical profiles of atmospheric structure. Dropwinsondes are similar to rawinsondes and are deployed by special observing aircraft in remote ocean regions where significant weather is occurring, such as hurricanes or typhoons and intense wintertime ocean storms. They transmit the same meteorological information as rawinsondes during their descent.

Upper-air balloon-borne observations are routinely made every 12 hours using a network of stations that is more sparse than the surface land-observing network (Fig. 1); dropwinsonde measurements are made infrequently at higher spatial resolution. With the exception of a few weather ships, ships of opportunity, and islands, the world oceans are poorly sampled by pilot balloons, rawinsondes, and dropwinsondes. Although high-resolution vertical profiles of the atmosphere are obtained by rawinsonde, twice-daily ascents and coarse spatial resolution limit these measurements to describing weather systems that last at least one day and are no smaller than approximately 1000 km in spatial scale.

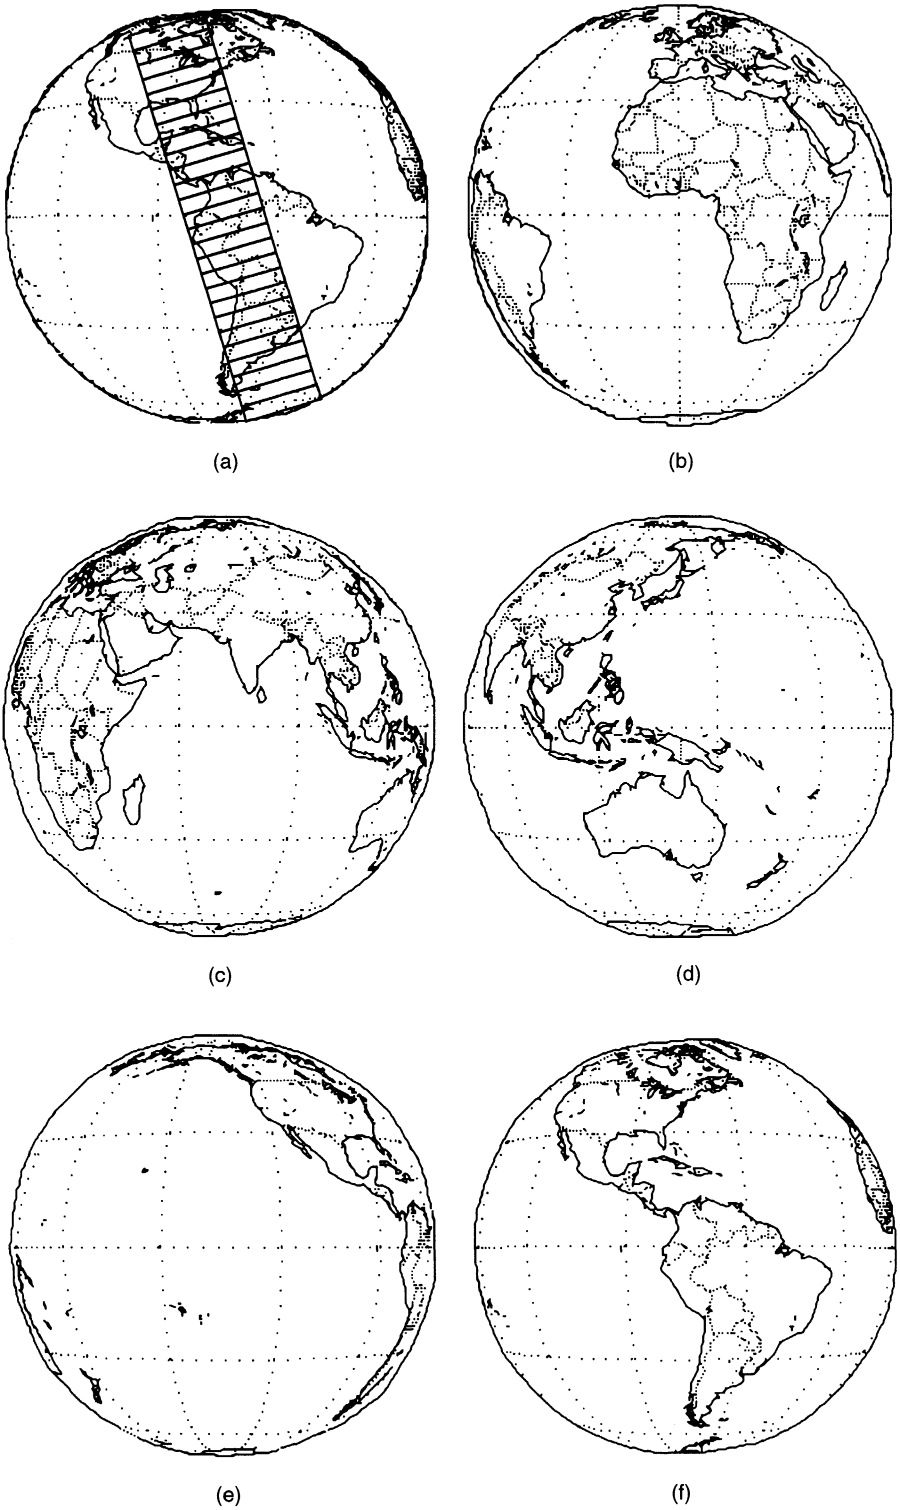
Other *in situ* upper-air measurements are made by wide-body jetliners. Advanced wide-body jets make observations of temperature and horizontal wind speed and direction at nearly minute intervals along their routes. These observations provide detailed resolution of conditions during climbout and descent and along the flight path in the upper troposphere and lower stratosphere. Vertical profiles are concentrated at major world airports, and flight-level observations are clustered along major air routes. The high temporal and spatial resolution of the observations defines the structure of smaller-scale phenomena only to the extent that they lie along flight paths (Fig. 1).

1.2.2 Remote-Sensing Observations A third cornerstone of the world observing system is passive remotely sensed radiation measurements by satellite platforms in polar and geostationary orbits. Polar-orbiting satellites from the United States and the former Soviet Union orbit the Earth every 100 min in sun-synchronous orbits that are inclined 98.8° from the equator at an altitude of approximately 850 km. This nearly pole-to-pole orbit allows different satellites to pass over the equator at a defined local solar time. As the Earth rotates beneath the satellite, different swaths of approximately 2600 km are viewed with each orbit. Examples of these swaths can be seen in Fig. 1 (middle right) and Fig. 2 (upper left).

Geostationary satellites are located over the equator and orbit the Earth at an altitude of approximately 36 000 km. At this orbit altitude, the satellite completes one revolution of the Earth every 24 h and remains fixed over the equator at a specific longitude. Five geostationary satellites, from the United States, Japan, India, and Europe, are positioned at specific longitudes with the view from each satellite shown in Fig. 2. Meteosat, the European geostationary satellite, is located at 0° longitude; Insat, the Indian satellite, is located over 75° E longitude; GMS, the Japanese satellite, is located over 140° E longitude; and GOES-West and East, two U.S. satellites, are located at 135° W and 75° W longitude, respectively.

A combination of both polar-orbiting and geostationary satellites is necessary to view the entire globe, with each satellite furnishing a unique perspective of the Earth. For example, animation of successive geostationary satellite images shows cloud and circulation features in motion, but animation cannot be performed with polar-orbiting satellites that view a different Earth scene on each orbit. Geostationary satellites cannot measure Earth radiation at latitudes poleward of approximately 70° latitude on account of the spherical nature of the Earth; however, polar-orbiting satellites regularly view a large portion of the polar regions with every orbit.

Visible and infrared imagery from the first polar-orbiting and geostationary satellites in the 1960s furnished a global perspective of weather systems, revolutionized weather analysis and forecasting, and provided qualitative meteorological information over formerly data-sparse regions such as the oceans and Southern Hemisphere. Satellite imagery immediately became indispensable for analysis over data-sparse regions and for short-term forecasts of weather phenomena such as tropical storms, jet streams, upper-level disturbances, convective storms, clouds, and precipitation. Imagery was utilized to monitor the quality of numerical model initialization and forecasts, providing qualitative guidance where weather systems are poorly defined in model initial analyses and where model prognoses diverge from interpretations of satellite imagery. In particular, the analysis and monitoring of tropical cyclones by satellite imagery led to improved warnings, and to the development of pattern-recognition techniques to forecast intensity changes and storm motion and to direct more accurately aircraft missions supplying critical observations of tropical storm environment and structure. The global perspective of satellite imagery also cultivated conceptual advances in understanding extratropical-storm structure, land-based convective storms, and circulation links between the tropics and extratropics, and sowed the seeds of global interdependence that led to future international experiments (Kidder and Vonder Haar, 1995; Bader *et al.*, 1995; Scofield and Purdom, 1986).



(a) (b) (c) (d) (e) (f)

FIG. 2. Schematic views of Earth scenes viewed from (a) a polar-orbiting satellite, (b) METEOSAT, (c) INSAT, (d) GMS, (e) GOES-West, and (f) GOES-East.

In addition to the qualitative and conceptual qualities of satellite imagery that revolutionized weather analysis and forecasting, a fundamental advantage of satellite platforms is their ability to observe and provide quantitative measurements of meteorological variables over poorly sampled portions of the Earth. Satellite remote sensing supplies tens of thousands of multispectral radiation measurements over data-sparse areas of the globe, which are converted to meteorological variables through retrieval techniques. Using remotely sensed radiances in the ultraviolet, infrared, and microwave portions of the electromagnetic spectrum on polar-orbiting and geostationary satellites, precipitation rates and vertical profiles of temperature, water vapor, and trace gases have been retrieved along with measurements of the Earth's radiation budget (Ferriday and Avery, 1994; Kidder and Vonder Haar, 1995). Additional variables derived from satellite remote sensing include the temperature of the land and sea surface, surface winds, sea level, sea ice, snow cover, soil moisture, precipitation rate, the pressure and temperature at cloud top, the amount of clouds covering the sky, and the amount of water vapor and liquid water in an atmospheric column. Severe-storm forecasters make use of further derived meteorological fields such as horizontal and vertical temperature gradients, indices that measure static stability, and horizontal wind fields derived from thermal gradients to forecast convective storms. Satellite-derived meteorological variables are routinely incorporated into data-assimilation systems to produce initial conditions for numerical forecast models (Fig. 1, middle left and right). Recent advances have allowed radiance measurements to be directly assimilated into numerical forecast models without the need for retrieval calculations.

Satellite retrieval techniques for determining meteorological variables have the highest quality in clear and partly cloudy atmospheres (Kidder and Vonder Haar, 1995). While cloud contamination degrades the accuracy of vertical profiles of atmospheric variables, the cloud field itself has been used to advantage for the generation of meteorological data. Successive images from geostationary satellites in the visible, infrared, and water-vapor absorption portions of the electromagnetic spectrum are used to determine cloud-motion wind vectors at lower and upper tropospheric levels. Height assignment of a wind vector is based on cloud-top temperature and its relationship to the background vertical temperature profile as well as other information that includes past history of the clouds tracked, experience of a manual operator, and correspondence with numerical model analyses. Cloud wind data can also be used to infer the temperature field through application of the geostrophic thermal wind relationship in midlatitudes. Winds estimated from successive water-vapor images complement cloud-tracked winds from infrared imagery in that water-vapor winds can be determined in regions of clear air where water-vapor imagery is able to discern circulation features. Cloud and water-vapor motion winds derived from geostationary satellites over data-sparse regions are routinely incorporated into numerical forecast models at forecasting centers worldwide (Fig. 1, middle left).

Future efforts at satellite remote sensing include active systems such as the Laser Atmospheric Wind Sounder (LAWS) and the Global Positioning System (GPS). Spaceborne LAWS systems measure backscattered radiation from aerosols and clouds to infer horizontal wind and cloud-top heights. LAWS wind measurements from a polar-orbiting platform will be able to resolve the global wind field with approximate horizontal resolution of 100 to 300 km and vertical resolution of 300 to 1000 m, and cloud-top heights to within 50 m at approximately 50-km horizontal resolution (Baker *et al.*, 1995). Observing-system simulation experiments have indicated that lidar wind measurements substantially improve analyses and forecasts over sparsely sampled areas of the globe such as the Southern Hemisphere and the tropical oceans. With the easing of cold war tensions, the military GPS, a network of orbiting satellites that allow precise measurement of location on Earth, has become available for nonmilitary applications. Research projects are applying GPS technology to determine horizontal winds through balloon tracking, vertically integrated water vapor, and vertical temperature and pressure profiles through measurement of the deviation of GPS signals passing through the atmosphere (Businger *et al.*, 1996; Ware *et al.*, 1996).

Active remote-sensing components of the global observing system are Doppler weather radar and wind profilers (Doviak and Zrnic, 1993; Strauch *et al.*, 1987). Doppler weather radars are fixed systems that measure backscattered microwave radiation to infer precipitation amount and intensity, and vertical profiles of the horizontal wind where appropriate microwave scattering bodies are present. Depending on radar operations and atmospheric conditions, horizontal wind and precipitation amount and intensity estimates are available every 5 min with a horizontal resolution of 250 m and vertical resolution of 300 m in the United States. Outside the United States Doppler weather radar is widely deployed in Europe and Asia but is not as common elsewhere.

Doppler wind profilers measure backscattered VHF and UHF radiation resulting from refractive-index gradients to infer vertical profiles of the horizontal wind in the troposphere and stratosphere. Nearly 50 wind profilers are installed across the United States with an approximate horizontal resolution of 300 km, a sampling frequency of 10 h^{-1}, and vertical resolution of 300 m. Outside the United States, nearly 40 wind profilers have been installed in South America, Europe, Asia, Australia, the Indonesian Archipelago, and tropical islands in the Pacific Ocean.

Other remote-sensing techniques, some of which are employed operationally, are microwave radiometers, sodar, lidar, and synthetic-aperture radar. Surface-based passive microwave radiometers measure thermodynamic profiles of temperature and water-vapor content throughout the lower troposphere with nearly continuous temporal resolution, but less vertical resolution than rawinsondes. Synthetic-aperture radar successfully measured sea-surface winds and rainfall with high spatial resolution for a brief period on a polar-orbiting satellite. Sodar or acoustic radar surface stations actively measure the structure, depth, and horizontal winds in the boundary layer of the atmosphere. Surface-based lidar or optical radar determines depth, temperature, water vapor, and gas constituents in the boundary layer by measuring backscattered energy from aerosols and air molecules. Infrared lidar is capable of measuring horizontal wind in the boundary layer (Golden *et al.*, 1986). A small number of passive microwave and active sodar and lidar systems are operational at various locations around the world.

The modern weather-forecasting observation system is a combination of *in situ* and both passive and active remote-sensing methods and systems. These systems are employed to measure atmospheric variables required for analysis of the current state of the atmosphere and climate. Advances in technology coupled with scientific analysis of the observation problem have played important roles in creating and developing the new observing systems. These advances continue to address the ongoing problem of incomplete observations of the four-dimensional state of the atmosphere.

2. NUMERICAL WEATHER PREDICTION

2.1 Historical Background

The scientific basis for modern numerical weather prediction, wherein future states of the atmosphere evolve from preceding ones according to known physical laws, originated with the initial-value problem approach described by Vilhelm Bjerknes (1904). In this approach, initial conditions of the atmosphere combined with knowledge of the three equations of motion on a rotating Earth, the first law of thermodynamics, the continuity equation (or conservation of mass) for air, the equation of state for air, and an equation for water vapor constitute a specification of the forecast problem where there are as many variables as equations. Bjerknes pointed out that exact analytical integration of this system of partial differential equations was impossible and indicated that graphical and numerical methods, particularly finite-difference methods, would have to be employed. L. F. Richardson (1922) began a "scheme of weather prediction," based upon finite-difference integration of the system of equations set forth by Bjerknes and performed the first detailed attempt at numerical weather prediction. Richardson pioneered formulation of finite-difference equations, solution techniques, and use of a three-dimensional grid upon which meteorological variables were tabulated and prognoses stored (Charney, 1950). Prediction of a 145-mbar pressure rise in 6 h for a point in western Europe suggested difficulties with the Richardson method, and these difficulties were later ascribed to imbalances between the mass and wind fields in the initial conditions (Charney, 1951; Lynch, 1992; CAeM Working Group, 1992). Although Richardson's noble attempt to solve numerically the predictive equations of atmospheric motion was not entirely successful, the advances he made paved the way for future progress in numerical prediction.

Observational, theoretical, and technical advances led to the birth of modern numerical weather prediction after the Second World War. A comprehensive *in situ* surface and observing system network was in place after the war that furnished a spatially dense set of initial conditions over continental regions of the Northern Hemisphere. Introduction of the barotropic vorticity equation by Rossby (1939) explained the relationship between the configuration and movement of the upper-level waves in the midlatitude westerlies (called Rossby waves) and the strength of the zonal wind. Downstream wave amplification commonly observed on upper-air analysis maps was also explained by the dispersive nature of Rossby waves, wherein energy propagation occurred by the faster group velocity rather than with the slower phase speed of ridge and trough movement (Rossby, 1938, 1940). Further theoretical advances included the analysis of baroclinic instability of waves in the midlatitude westerlies, the quasi-geostrophic approximation of atmospheric motion, the filtering of gravity waves from meteorological motions, and development of an equivalent barotropic model of the atmosphere (Charney, 1947, 1948, 1949; Charney *et al.*, 1950; Eliassen, 1949). Advances in mathematical theory by Courant *et al.* (1928) provided a theoretical basis for finite-difference solutions to approximate the continuous partial-differential-equation solutions of the meteorological equations. These observational and theoretical advances along with development of electronic computers created the opportunity to renew the work of Richardson in the mid 1940s.

Two numerical weather prediction programs were begun in the United States and Sweden with much collaboration between them. Recognizing the limited computing resources and the desire to avoid diagnosing complicated systems, the programs began with simplified models and gradually added increasing complexity (Charney, 1951; Wiin-Nielsen, 1991). The first successful forecasts were made with a one-level equivalent barotropic model (Charney *et al.*, 1950; Staff Members, 1952) that took 24 h of computation to complete a 24-h forecast. With slightly faster electronic computers, computation time decreased such that in 1954 the Swedish program performed the first barotropic forecasts completed in time for use by operational forecasters. Extension of numerical weather prediction models to include baroclinic effects (Charney and Phillips, 1953) and a successful forecast of a strong midlatitude storm along the east coast of North America convinced the United States to begin operational numerical weather prediction in 1955 (Shuman, 1989). Although the first operational forecasts began with more complicated baroclinic models, poor performance guided operational prediction back to the simpler equivalent barotropic model.

With numerical weather prediction established operationally, development and refinement of the analysis of observations, numerical methods, and models continued. Objective analysis, methods to interpolate irregularly spaced observations to a regular grid for numerical forecasts, were developed by Panofsky (1949) and developed further by Gilchrist and Cressman (1954), Bergthórsson and Döös (1955), and Cressman (1959). Advances in numerical methods and incorporation of a terrain-following vertical coordinate system led to improved forecasts and the development of more complicated models based on the so-called primitive equations discussed by Bjerknes in 1904 (Charney, 1955; Phillips, 1957). A hemispheric forecast model with six vertical levels based on the primitive equations was developed in the 1960s (Shuman and Hovermale, 1968), and its operational performance nearly equaled the skill of manually produced forecast maps. With this success, primitive-equation models established themselves as the primary tool for numerical weather prediction, and descendents of these models are still in use today (Shuman, 1989; Bengtsson, 1991).

During the past 40 years operational numerical weather prediction has evolved from a one-level equivalent barotropic model solved over continental domains on a relatively coarse grid mesh of approximately 400 km (the typical spacing of the upper air rawinsonde network that provides initial conditions for the forecasts) to global- and local-scale multilevel primitive-equation models solved on grid meshes as fine as 10 km. Throughout this advancement, the basic procedures of numerical weather prediction have remained unchanged. These procedures involve

1. observations of the four-dimensional state (x,y,z,t) of the atmosphere with the highest resolution possible,
2. assimilation of data from various observing platforms to produce an initial analysis of meteorological fields,
3. initialization to balance the analyzed fields dynamically,
4. forecasting future states by integrating the model forward in time, and
5. post-processing model output to compute quantities not forecast by the model and to produce forecast maps for interpretation and verification.

Procedure **1** was discussed in the first section of this article. The remaining portions of this section describe how procedures **2–5** are carried out at national forecast centers in the Northern Hemisphere midlatitudes.

2.2 Data Assimilation

Construction of three-dimensional analyses of meteorological variables for use as initial conditions in a primitive-equation forecast model is the purpose of data assimilation. The various observing-system platforms described in Sec. 1 produce nearly continuous measurements with differing spatial and temporal resolution and error characteristics, which must be blended together to estimate initial meteorological fields. The data assimilation process in practice at meteorological centers worldwide involves quality control of observations, objective analysis of irregularly spaced observations onto a three-dimensional lattice valid at a specific time, initialization of the analysis fields if required, and a short forecast from a data assimilation/forecast model to produce a background first-guess field for the next assimilation cycle (Dey, 1989; Daley, 1991; Ghil and Malanotte-Rizzoli, 1991; Benjamin *et al.,* 1991; Lorenc *et al.,* 1991). This process has evolved to provide the most accurate initial state of the atmosphere for numerical weather forecasting. The quality of a data-assimilation–produced initial analysis depends on observation accuracy, objective analysis frequency, and the accuracy of the forecast model supplying the first-guess field for the analysis. Details of data assimilation processes vary between forecasting centers with each center using different objective analysis methods and assimilation models, and either continuous or intermittent assimilation of data.

Data assimilation begins with comprehensive quality control of meteorological data to prevent incorrect observations from influencing the analysis (Hollingsworth *et al.,* 1986; Gandin, 1988; Collins and Gandin, 1990). Meteorological data continuously received at forecast centers is produced by a variety of observing platforms, each with different types of errors. These errors may be the result of human error in measurement, or to instrument errors due to failure, improper calibration or design, or the data itself may have been incorrectly coded and transmitted. Once an observation has been received at a forecast center, it is subjected to a number of quality-control inspections. Such checks search for gross errors such as incorrect coding, time, or location, and consistency of observations with neighboring observations, climatology, and a background first-guess field. After passing the gross-error checks, the observations are examined to see if they are dynamically consistent with themselves through use of the geostrophic relationship between the wind and height fields, the hydrostatic relationship between the temperature and height fields, and the geostrophic thermal wind relationship between the geostrophic wind and temperature fields. These quality-control inspections have advanced to the point where they are capable of discerning instrument errors, which can then be corrected (Hollingsworth *et al.,* 1986). Observations that pass scrutiny are then sent along to the objective analysis portion of the process.

Objective analysis has advanced remarkably from its initial beginnings with polynomial interpolation of irregularly spaced observations to a regular grid (Panofsky, 1949). Gilchrist and Cressman (1954) adapted polynomial interpolation to operational use and introduced the concept of a region of influence of observations by weighting observations on the basis of their distance from an analysis point. They also suggested the usefulness of having a prior estimate of the analysis field known as a first-guess field. Bergthórsson and Döös (1955) developed a technique that incorporated the suggestion of Gilchrist and Cressman and is the forerunner of current operational statistical interpolation methods. This technique uses a background first-guess field that is subtracted from the observations to produce observation increments. Weighted combinations of observation increments are then used to correct the background first-guess field within a particular distance from an analysis point. Cressman (1959) modified the Bergthórsson and Döös method to include successive corrections to the background first-guess field, with each iteration employing a reduced region of influence to define small-scale structure better. Global-scale objective analysis was developed in the late 1960s through an interpolation technique involving Hough function solutions to LaPlace's tidal equation.

When numerical weather prediction began in the early 1950s, most of the weather observations necessary to depict the three-dimensional structure of the atmosphere were from rawinsondes available twice daily at the synoptic times of 0000 and 1200 UTC. Technological developments in observational platforms such as satellites began to supply new observations over poorly sampled regions; however, these observations were made at asynoptic times and provided data of a different character than rawinsondes. Asynoptic data included portions of a meteorological observation such as vertical temperature profiles without wind information from satellites or just wind information from aircraft or cloud drift winds. Statistical interpolation techniques were developed and implemented (Gandin, 1963; Dey, 1989) to define mathematically the blending of various meteorological data streams into a three-dimensional analysis of the atmosphere. In this technique, estimates of observation and first-guess (model forecast) error are quantified as weighting values based on the ratio of the observation error to the first-guess error. Using these weighting values, the method blends observations of varying quality with the background first-guess field to produce an analysis whose mean square error is statistically minimized. The statistical analysis allows a defined number of local observations within a region to influence an analysis point. In addition, the statistical analyses are multivariate such that multiple types of local observations can influence the value of a particular analysis variable through various meteorological relationships.

Spectral statistical interpolation methods have been introduced into operational data assimilation systems in recent years to incorporate asynoptic data better and to determine more accurately analysis values over the globe (Derber *et al.,* 1991; Parrish and Derber, 1992). This method uses the entire global observation database to analyze model variables directly within the horizontal and vertical coordinates of the forecast model through statistical methods involving appropriate weights for various observing systems. By conducting the analysis in model coordinates, the number of information-losing interpolations between analysis and model coordinate systems is reduced, and, more importantly, dynamical constraints specific to the forecast model are incorporated into the interpolation. These attributes result in smoother corrections to the first-guess field and a better fit of the analysis to the observations, and they produce such a good balance between the wind and mass fields that initialization of the analysis fields to remove high-frequency oscillations prior to forecasting is no longer necessary. Use of this technique has allowed inclusion of satellite radiance measurements directly into the analysis, eliminating the need for retrieval calculations. Improvements to the analysis from this technique have reduced the root mean square error between the 6-h forecast and rawinsonde measurements to 16 m for geopotential height and 0.75 K for temperature, values that approach instrument error. Forecasts produced from spectral statistical interpolation generated analyses have shown improved performance.

Analyses produced by statistical interpolation methods often have imbalances between the mass and momentum fields that when integrated in a forecast model create high-frequency oscillations. These oscillations may have larger amplitude than meteorologically important motions and may not decay rapidly enough that at the next statistical interpolation step in the data assimilation cycle, good data may be rejected. The initialization step in data assimilation is designed to adjust the mass and momentum fields within consistent dynamical constraints to achieve balanced analyses and avoid rejection of good data in the assimilation system (Bengtsson, 1991). With the development of the spectral statistical interpolation method of objective analysis, initialization of the analyses is no longer required at some forecast centers.

Two variations of data assimilation systems have developed at various forecast centers: intermittent and continuous. Figure 3 illustrates an example of a 6-hourly intermittent data assimilation system. Analyses are performed every 6-h at 00, 06, 12, and 18 UTC using data accumulated during a 6-h window surrounding a particular analysis time. The 6-h window allows for delays in transmission of important observations from less accessible regions of the globe. A 6-h forecast from the previous analysis cycle provides first-guess fields for a statistical interpolation method that blends quality-controlled data with the first guess. Depending on the type of statistical interpolation method, analyses are either incorporated directly into a forecast model or initialized before forecasting begins. Forecasts from these analyses are made for operational requirements and to provide a first-guess field for the next analysis cycle. In continuous forward data assimilation, observations are assimilated directly into an assimilation/forecast model in near real time after they are received at a forecast center and subjected to quality control. The data assimilation model is run continuously; and at each time step in the forward integration, new observations are inserted and the analyses are updated and adjusted to the new observations over a period of hours. Through these methods, a nearly continuous analysis of the four-dimensional state of the atmosphere is maintained.

2.3 Forecast Models

Operational numerical weather prediction models solve the governing or primitive equations of atmospheric motion and pro-

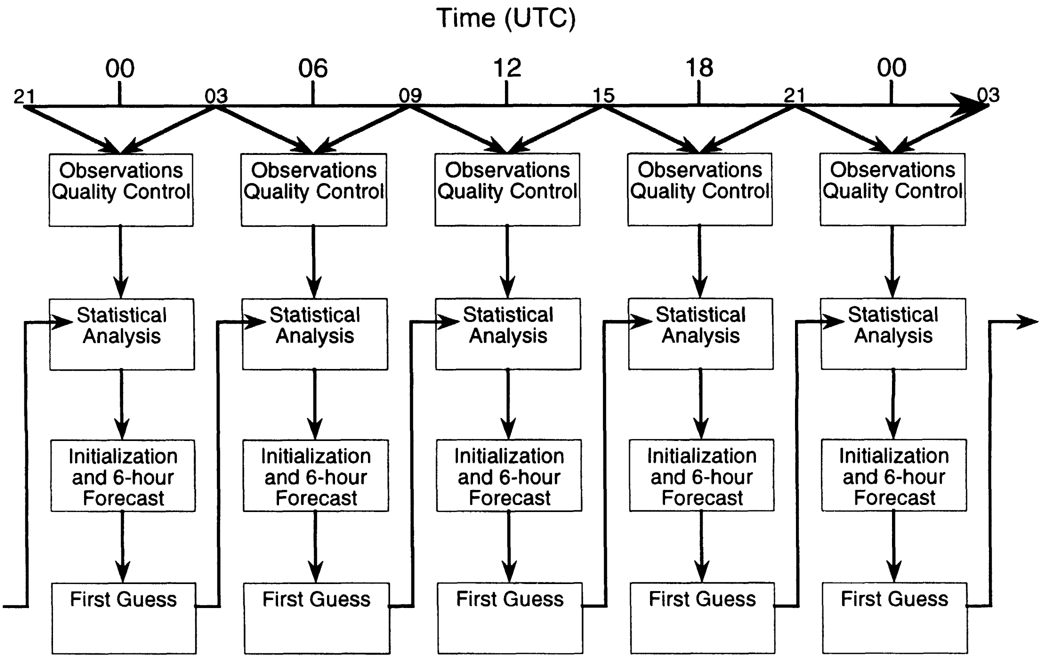


FIG. 3. Schematic illustrating a 6-hourly intermittent data assimilation system. Arrows indicate flow of time, data, and assimilation-system steps.

cesses over domains ranging from the globe to small regions on the order of a few hundred square kilometers (e.g., Haltiner and Williams, 1980; Pielke, 1984). The governing equations include three momentum components, the first law of thermodynamics, mass conservation, and water vapor. As discussed in the article METEOROLOGY AND CLIMATOLOGY, through application of the hydrostatic approximation to the vertical momentum equation, vertical motion becomes a diagnostic quantity, and, more importantly, sound waves and other nonmeteorological motions are filtered while meteorologically important Rossby waves and gravity waves are retained. The resulting equations are often solved using a vertical coordinate system called sigma coordinates (Phillips, 1957). The sigma coordinate is a normalized pressure vertical coordinate that allows the Earth's topography to be incorporated as part of the bottom boundary.

The primitive equations are the horizontal momentum,

$$\frac{D\mathbf{V}}{Dt} = -\nabla\phi - f\mathbf{k} \times \mathbf{V} - RT\nabla(\ln p_s) + \mathbf{F}; \tag{1}$$

hydrostatic,

$$\frac{\partial\phi}{\partial\sigma} = -\frac{RT}{\sigma}; \tag{2}$$

thermodynamic,

$$\frac{DT}{Dt} = \frac{RT\omega}{c_p p_s \sigma} + \frac{H}{c_p}; \tag{3}$$

mass conservation,

$$\frac{Dp_s}{Dt} = -p_s(\nabla\cdot\mathbf{V}) - p_s\frac{\partial\dot{\sigma}}{\partial\sigma}; \tag{4}$$

water vapor,

$$\frac{Dq}{Dt} = E - P; \tag{5}$$

and the definition of the sigma vertical coordinate;

$$\sigma = p/p_s, \tag{6}$$

where the operator D/Dt is the Lagrangian or material derivative following air parcel motions in (x,y,σ) space, ∇ is the two-dimensional gradient operator on a constant-σ surface, $\mathbf{V} = (u,v,0)$ is the horizontal velocity vector, ϕ is geopotential height, f is the Coriolis parameter, $\mathbf{k}$ is the unit vertical vector, R is the gas constant for dry air, T is temperature, p_s is air pressure at the Earth's surface, p is pressure, $\mathbf{F}$ represents frictional effects, c_p is the specific heat at constant pressure, ω is the Lagrangian derivative of pressure, H is heat addition and subtraction per unit mass, $\dot{\sigma}$ is the Lagrangian derivative of the vertical coordinate σ, q is specific humidity, E is evaporation, and P is precipitation. Sigma coordinates, by virtue of incorporating p_s, the air pressure at the Earth's surface, represent the Earth's surface topography and have a value of 1 at the Earth's surface and 0 at the top of the atmosphere. Sources and sinks of the prognostic variables are often referred to as model physics. Model physics includes momentum changes due to frictional effects, energy gain and loss resulting from the transfer of sensible heat at the surface and latent heat release during phase changes of water vapor, precipitation processes, and processes involving short-wave and long-wave radiation.

The lack of an analytical solution for the primitive equations requires numerical techniques to solve the equations at a finite number of locations arranged in a three-dimensional lattice over a particular domain. The three-dimensional atmospheric structure is subdivided as a sequence of horizontal slices arranged on top of each other at discrete intervals in the vertical. Almost all operational models employ the terrain-following vertical coordinate [Eq. (6)] that is based on the ratio of pressure at a level to the pressure at the Earth's surface. Sigma surfaces in forecast models are not regularly spaced; they are closely spaced near the ground and in the upper troposphere to resolve heat and momentum transfers between the atmosphere and the Earth's surface and to resolve the jet stream, the tropopause, and upper tropospheric frontal zones (Fig. 4). Hybrid sigma-pressure and sigma-theta (where theta is potential temperature) vertical coordinates have been developed that combine the terrain-following qualities of sigma coordinates in near-surface layers with the advantages of

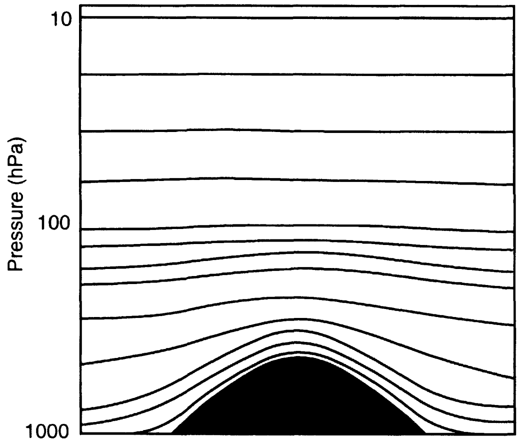

FIG. 4. Schematic showing the vertical distribution of sigma vertical coordinate levels in an operational numerical forecast model containing a mountain at the lower boundary.

pressure or isentropic coordinates in the free atmosphere (CAeM, 1992; Bleck and Benjamin, 1993). The eta vertical coordinate (Mesinger, 1984; Mesinger and Black, 1992), a more generalized version of the sigma vertical coordinate, has also been incorporated in operational weather-prediction models. Instead of defining mountains in sigma coordinates as smoothed terrain, in eta coordinates, mountains are depicted as a sequence of steps with vertical faces that resolve regions of steep topography more accurately. Operational models typically contain between 30 and 40 vertical levels and use finite differencing to approximate vertical derivatives. Terrain height commensurate with the horizontal and vertical resolution of the model is also specified.

On each vertical coordinate surface, meteorological fields are defined as either grid-point values or coefficients of spherical harmonic functions. Regional models use grid-point formulations and employ finite-difference or finite-element methods to approximate horizontal derivatives. Some global domain models also use finite differences but require careful treatment of pole-point singularities in spherical coordinates. Spectral methods have been adopted for use in global models and recently extended to regional models because of advantages in calculating the horizontal derivatives of nonlinear advective terms, the treatment of the pole in spherical geometry, and the ability to implement efficient time-integration methods that allow increased horizontal resolution for similar computation cost. Spectral models represent meteorological variables as amplitudes of spherical harmonic functions of varying wave numbers in the east-west and north-south directions around the globe. These functions are typically truncated at wave numbers 126 or 213 giving approximate equivalent grid-point resolution of under 100 km, rivaling the resolution of many limited-area models. In spectral models, the horizontal momentum equations are reformulated to predict the divergence of the horizontal velocity and vorticity (the vertical component of the curl of the momentum), quantities that are better represented in spherical harmonics. However, model physics is calculated in grid-point space, necessitating transformations between spectral and grid-point representations with each time step of the model.

Time integration of the primitive equations is accomplished by first reformulating the Lagrangian equations into Eulerian partial-derivative format where the time tendency of either momentum, temperature, surface pressure, or water vapor is produced by horizontal and vertical advection and by Lagrangian sources and sinks. The time tendency terms are approximated by time-integration methods such that successive forward jumps in time can be made that satisfy numerical stability considerations (Courant *et al.*, 1928). Advances in time-integration methods have allowed forward time steps to be increased while maintaining numerical stability, with a typical forward time step averaging approximately 1–5 min. A 24-h forecast requires between 300 and 1000 time steps involving numerical solution of the primitive equations over the three-dimensional model lattice. With approximately two million entries in a three-dimensional lattice, a 24-h forecast for five variables over 1000 time steps will require on the order of one trillion calculations. This extraordinary magnitude of calculations to forecast just one day ahead demonstrates the importance of computer limitations such as computational speed, memory, and storage capacity to the operational forecasting process.

The horizontal and vertical lattice spacing of forecast models determines the minimum scale of motion and weather-system size that can be resolved. Weather systems and physical processes smaller than the resolvable scale, such as individual thunderstorms, are not directly predicted by operational forecast models, and the effects of unpredicted sub-grid-scale motions on resolvable circulations are parametrized to maintain physical consistency with the full range of atmospheric motions.

Sub-grid-scale processes that are parametrized are model physics such as surface and boundary-layer processes, radiation and energy-transfer processes, and large-scale stratiform and convective scale precipitation. Surface processes include sources and sinks of momentum, energy, and water vapor that occur over various bottom boundaries such as land, mountains, water, and ice. The importance of momentum and energy sources and sinks makes appropriate specification of the atmosphere–surface interface an important component of forecast models. The surface boundary conditions used in sub-grid-scale calculations are determined from satellite, ship, buoy, and surface observations of water temperature, snow cover, and surface conditions. Sources and sinks of momentum occur through surface friction and the effects of mechanically and thermodynamically generated turbulent eddies near the Earth's surface. Sensible and latent heat transfer are sources and sinks of energy and water vapor with latent heat transfer being a vital component of the hydrological cycle. Soil, surface energy, and water-balance models have been incorporated within forecast models to calculate the redistribution of heat and momentum and changes in static stability more accurately. Boundary effects due to mountains include the contribution of gravity waves, internal atmospheric oscillations that are produced by flow over mountains in a stably stratified atmosphere. These oscillations transfer momentum vertically into the stratosphere, producing a sink of lower-atmospheric momentum. Radiation processes include the diurnal cycle of solar insolation and its attenuation by albedo and cloud effects, while long-wave radiation parametrizations consider the absorption and emission of infrared radiation by greenhouse gases and clouds.

Precipitation is an important source and sink of energy and water vapor and tends to occur on scales smaller than model resolution. Two types of precipitation are parametrized: large-scale stratiform and convective-scale or thunderstorm precipitation. Large-scale stratiform precipitation occurs in a stably stratified atmosphere and results from the large-scale lifting of air until it has cooled to saturation. Large-scale precipitation parametrization algorithms initiate falling snow or rain from a saturated layer that can evaporate as it falls, simulating the gradual descent of precipitation from altostratus clouds in warm fronts. The algorithm computes the amount of condensed water vapor, latent heat release, evaporative cooling, and precipitation reaching the ground. Convective precipitation parametrizations quantify the bulk effects of thunderstorms on the larger-scale mass, momentum, energy, and water vapor fields. These algorithms first determine if an unstable stratification with respect to a saturated atmosphere will lead to buoyant updrafts. If buoyant updrafts are diagnosed, then the method quantifies momentum transfer inside and outside convective clouds, the amount and location of latent energy release, and the amount of precipitation created while adjusting the thermal and water-vapor fields to stabilize the atmosphere.

A number of different convective precipitation methods have been utilized at operational forecast centers to quantify convective precipitation forecasts and the influence of convective scale motions on the atmosphere. Convective scale motions affect tropical and midlatitude prediction because much of the tropical atmosphere responds to differential solar heating through convective overturning. These overturning motions force ascending branches of global-scale circulations in the tropics. Variations of tropical convection change the location and intensity of these tropical circulations, which, in turn, affect the extratropical circulation and short-term climate.

As future states of the atmosphere are calculated, model output is post-processed to create graphics of forecast fields. Figures 5 and 6 show examples from global- and regional-scale models to illustrate the kinds of graphical products available to weather forecasters. A 120-h forecast produced by the global model of the U.S. National Centers for Environmental Prediction is shown in Fig. 5. The forecast shows fields of mean–sea-level

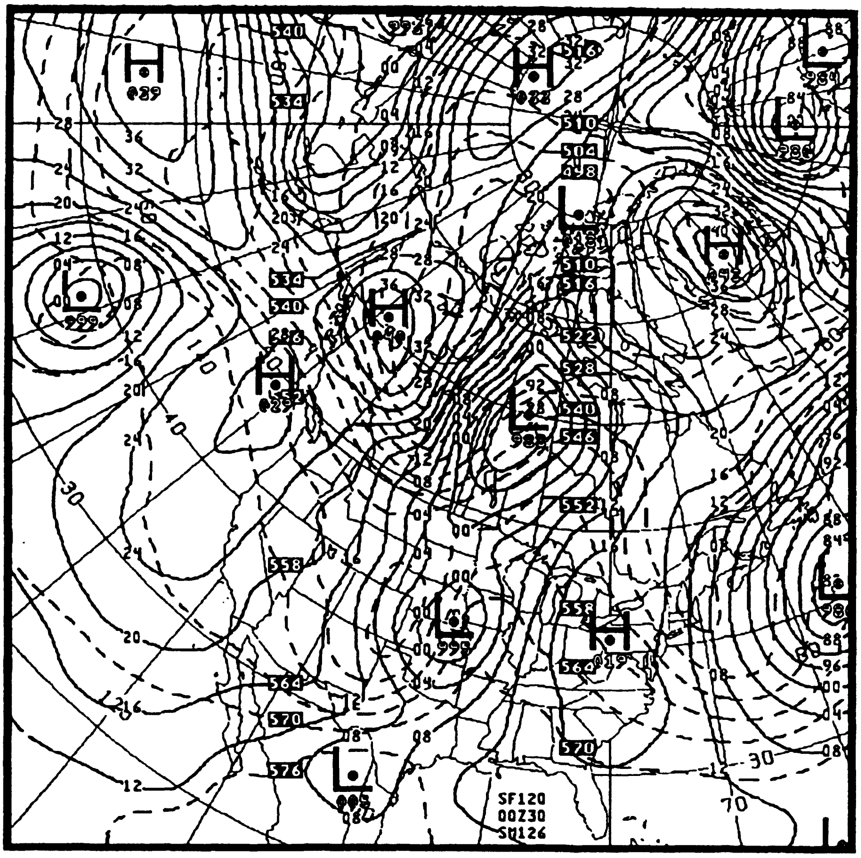

FIG. 5. An operational forecast from the U.S. National Centers for Environmental Prediction Medium Range Forecast Model, a global spectral model with triangular truncation of 126 waves and 28 vertical sigma levels. The forecast was made from initial conditions at 00 UTC 25 October 1996 and is valid 120 h later at 00 UTC 30 October 1996. The figure shows analyses of mean-sea-level pressure (solid contours every 4 mbar with the one's and ten's digit labeled, such that 24 ⇒ 1024 mbar) and the thickness between the 1000- and 500-mbar pressure levels (dashed contours every 6 dekameters and labeled with white numbers on a black rectangle such that 540 ⇒ 5400 m). The thickness field represents the mean temperature in the lower troposphere with higher values indicating warmer conditions. Figure courtesy of U.S. National Centers for Environmental Prediction.

pressure isobars as solid contours every 4 mbar, and the 1000- to 500-mbar thickness contoured every 60 m in dashed contours for a portion of the Northern Hemisphere. The mean sea-level pressure distribution depicts the forecast position and intensity of migratory and semipermanent low- and high-pressure systems while the 1000- to 500-mbar thickness field describes the lower mean tropospheric temperature distribution. Overlaying the two fields allows forecasters to determine the position, movement, and development of fronts, the important process of temperature advection for forecasting temperature variations, clouds, and precipitation, and the relationship of pressure features to the thermal field that allows forecasters to subjectively determine future development of pressure systems.

Forecasts from regional-scale models usually provide more meteorological detail, but for a shorter forecast projection. Figure 6 shows a 48-h forecast from a regional-scale model of the U.S. National Centers for Environmental Prediction. This four-panel forecast displays

1. 500-mbar geopotential height and absolute vorticity isopleths,
2. mean sea-level pressure and 1000- to 500-mbar thickness,

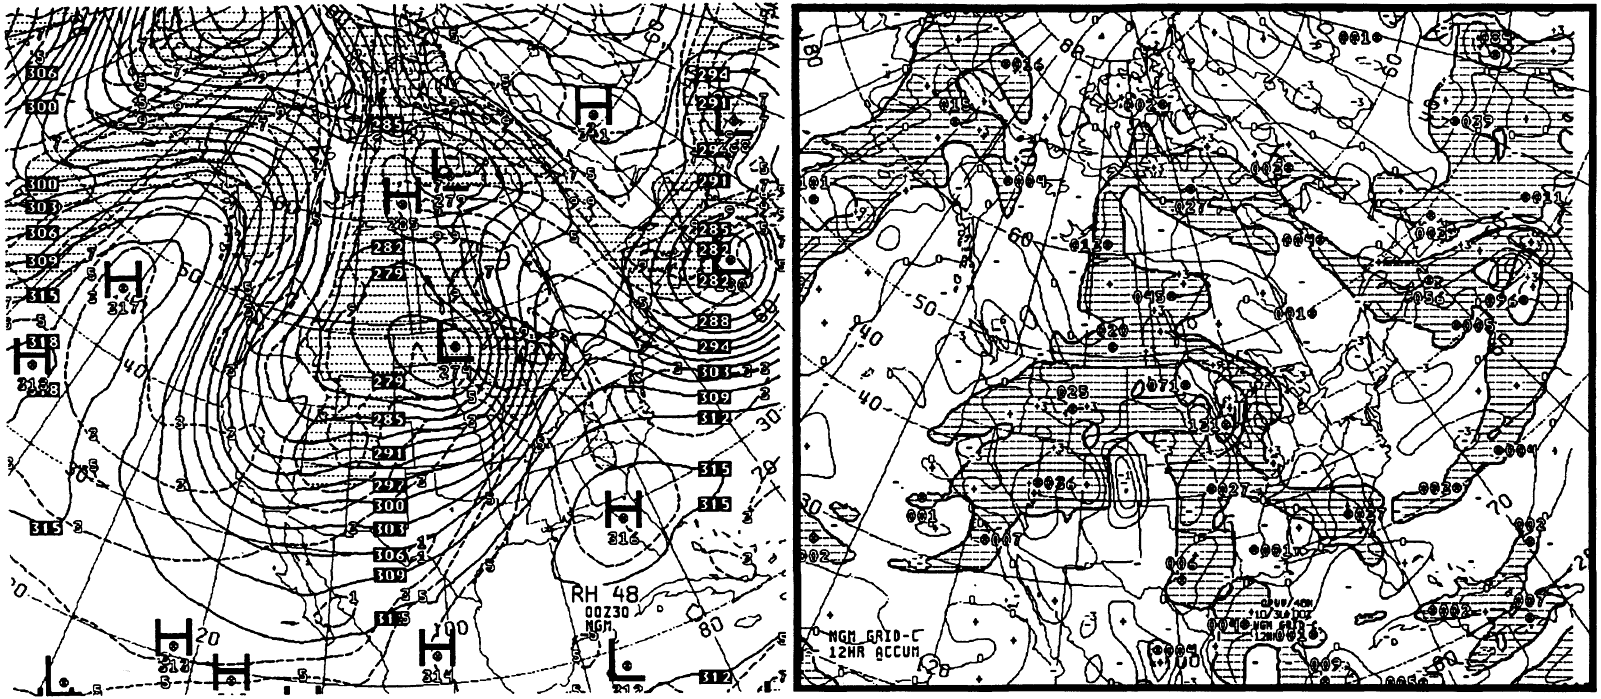

FIG. 6. 48-h operational forecast from initial conditions at 00 UTC 28 October 1996 by the U.S. National Centers for Environmental Prediction Regional Analysis and Forecast System, a hemispheric grid-point model with 80-km horizontal resolution over North America, 200 km over the remainder of the hemisphere, and 16 vertical sigma levels. Upper left panel shows 500-mbar geopotential heights (solid contours every 6 dekameters and labeled with white numbers on a black rectangle such that 540 ⇒ 5400 m) and absolute vorticity (dashed contours every $2 \times 10^{-5}\ s^{-1}$). Upper right panel shows mean-sea-level pressure (solid contours every 4 mbar with the one's and ten's digit labeled, such that 24 ⇒ 1024 mbar) and the thickness between the 1000 and 500 mbar pressure levels (dashed contours every 6 dekameters and labeled with white numbers on a black rectangle such that 540 ⇒ 5400 m). Lower left panel shows 700-mbar geopotential heights (solid contours every 3 dekameters and labeled with white numbers on a black rectangle such that 300 ⇒ 3000 m) and the average relative humidity from the surface to approximately 500 mbar (dashed contours every 20% with values over 70% shaded and the units digit suppressed). Lower right panel shows 700-mbar vertical velocity (thin solid contours every 3 μbar s^{-1}, with "+" denoting ascent and "−" descent) and 12-h accumulated precipitation from 12 UTC 29 October to 00 UTC 30 October [contoured every 12.7 mm (half inch); with shading between 0.254 mm (0.01 in.) and 12.7 mm (half inch); no shading between 12.7 mm (half inch) and 25.4 mm (1 in.); and shading from 25.4 to 38.10 mm (1.5 in.) and alternating every 12.7 mm thereafter]. Precipitation maxima are shown by crosses within a circle and are labeled in hundredths of inches such that 131 ⇒ 1.31 in. = 33.27 mm. Figure courtesy of U.S. National Centers for Environmental Prediction.

3. 700-mbar geopotential heights and 1000- to 500-mbar relative humidity, and
4. 700-mbar vertical velocity and 12-h accumulated precipitation ending at the forecast time.

The familiar mean-sea-level pressure and 1000- to 500-mbar thickness map is included while other forecast fields provide information on meteorological processes such as vorticity advection, a process that produces vertical motion and the development of low- and high-pressure systems. Relative-humidity fields indicate where saturation is forecast and gives an assessment of cloud fields associated with fronts and low-pressure systems. Vertical-velocity forecasts denote where ascent and descent are forecast; this information is important for the forecasting of precipitation and convective scale systems. The 12-h accumulated quantitative precipitation forecast describes the distribution and amounts of precipitation produced by both the stratiform and convective-scale precipitation algorithms. Many other model forecast fields are available from forecast centers worldwide, and they provide a vast amount of information that forecasters use to produce weather forecasts ranging from the next few hours to two weeks.

2.4 Statistical Forecasting

Numerical models provide predictions of model-equation variables such as wind, temperature, specific humidity, geopotential height, quantitative precipitation amount, and pressure. Weather forecasters, however, need to predict meteorological quantities that are not explicitly forecast by the models for public, businesses, government, and transportation interests. These quantities include, for example, visibility, obstructions to visibility, cloud amount, ceiling height, precipitation type and amount, probability of precipitation, thunderstorm probability, maximum and minimum temperatures, frontal windshift, surface wind, clear-air turbulence, snow amount, solar energy, and sunshine. In order to meet these needs, statistical techniques are applied to create forecasts of meteorological variables not forecast by numerical models (Klein *et al.*, 1959; Klein, *et al.*, 1982).

Two approaches commonly utilized in statistical forecasting are perfect prognosis and model-output statistics (Carter *et al.*, 1989; CAeM, 1992). Perfect prognosis defines statistical relationships between observed weather elements and predictor weather elements that are observed concurrently or at previous observation times. For example, a statistical relationship may be defined between observed visibility at time t and observed temperature and dew-point temperature at the same time (t) and/or at a previous time $t - dt$. Once these relationships have been defined through multiple linear-regression equations, the equations are applied with model forecast conditions taking the place of the concurrent or antecedent observations used to define the statistical relationship. Substitution of model prognosis conditions for observed conditions is equivalent to having a perfectly observed prognosis in the statistical relationship. Perfect prognosis relies on the accuracy of the substituted model prognoses and cannot correct for model biases and the diminishment of forecast accuracy with time. Model-output statistics (MOS) is a variation of the perfect prognosis method wherein statistical relationships are defined from predictor weather elements obtained from model forecasts as opposed to observed conditions. In application, MOS is applied to forecast model output, and these forecasts can partly account for model systematic errors and the degradation of forecast accuracy with time.

Application of perfect prognosis or MOS to forecasting individual weather elements requires a development sequence. A meteorological variable to be forecast is first defined on the basis of user needs and the ability of a statistical method to forecast that quantity. The meteorological variable may be a continuous variable such as temperature or a categorical value such as precipitation type that consists of liquid, freezing, or frozen categories. Depending on the choice of perfect prognosis or MOS, each meteorological variable requires an appropriate historical developmental dataset of observations or model forecasts, respectively, from which relationships with potential predictors of that variable can be defined. This training dataset must be large enough to create a sample size that ensures statistical stability of the defined relationships. Next, a particular statistical method such as multivariate linear regression, regression estimation of event probabilities, multiple discriminant analysis, or classification and regression trees is chosen. Equations are developed to quantify the statistical relationships between predictors and the meteorological variable of interest, and these relationships are tested on a training dataset. The equations are next tested on an independent dataset to establish how well these relationships perform in operational forecasting, to measure how well the method forecasts extreme events, and to discover strengths and weaknesses that will require further refinement.

Examples of MOS forecasts produced from global and regional forecast systems of the U.S. National Centers for Environmental Prediction for O'Hare Airport in Chicago, Illinois, are shown in Tables 2 and 3. Global model statistical guidance provides 7-d forecasts of maximum and minimum temperature, 12-h probability of precipitation, a conditional probability of snow, percentage of cloud cover, wind speed, and a 24-h probability of precipitation that can be compared with climatological values. Similar weather elements are forecast for O'Hare from the regional scale model with greater temporal resolution over a 48-h time period. Additional weather elements forecast from the regional scale model are dew-point temperature, cloud amount categories, wind direction, categorical quantitative precipitation amount, thunderstorm probability, categorical precipitation type, probability of freezing precipitation and snow, categorical snow amount and probability, and categorical ceiling, visibility, and obstructions to visibility.

An advantage of statistical forecasting methods is their ability to interpret model forecast variables in terms of operationally important weather elements. Both perfect prognosis and MOS techniques offer strengths and weaknesses. Perfect prognosis techniques suffer from decreases of model forecast skill at greater forecast projections. Perfect prognosis can be applied to different models and models undergoing continual development because the technique employs observational data and is independent of a forecast model. MOS is directly coupled to model forecasts with performance suffering if the model is changed by continual development; however, MOS offers the advantage of partly accounting for model systematic errors. Statistical forecast guidance developed from these two techniques at forecast centers worldwide has been shown to offer skillful forecasts of weather elements (Carter *et al.*, 1989; CAeM, 1992) and is an important element in the human–computer integration in weather forecasting.

2.4.1 Stochastic-Deterministic Forecasting The weather forecasting approach outlined by Bjerknes (1904), applied by Richardson (1922), adopted by world forecasting centers, and described in this article follows an initial-value or deterministic approach to the forecast problem. In this approach it is assumed that accurate specification of the initial state coupled with a sufficiently detailed and accurate forecast model will produce an optimal weather forecast. Over the last 15 years, numerical model resolution and skill have increased to the point where a

6-h first-guess forecast can now indicate observational errors. However, accurate specification of the initial state is hindered by geographical and technical limitations of the global observing system and approximations within data assimilation systems and forecast models, as well as the inherent nonlinearity of the forecast equations. Thus the "best" weather forecast is only an estimate of the atmosphere's future state.

Lorenz (1963) pointed out that even with a perfect model, inability to specify initial conditions accurately results in increasingly divergent (with time) forecasts from slightly different initial conditions, producing a range of possible forecast outcomes. Recognition of the chaotic nature of apparently deterministic dynamical systems such as the atmosphere, and of initial analysis uncertainties that reduce forecast skill with increasing forecast projection, led to the adoption of a stochastic-deterministic viewpoint of atmospheric prediction (Lorenz, 1965, 1969; Tracton and Kalnay, 1994; Toth and Kalnay, 1993; Molteni *et al.*, 1996). Implementation of this viewpoint, called ensemble prediction, is based on multiple predictions from slightly different initial conditions with a deterministic forecasting system. If the ensemble is large enough and is generated by reasonably accurate forecast models from initial conditions that are representative of initial analysis uncertainty, the ensemble average will yield a better forecast than one high-resolution control forecast. The ensemble-average forecast is more accurate because it is assumed that varying initial analysis errors will tend to cancel in a large ensemble average. Ensemble forecasting provides a statistical measure of forecast uncertainty by quantifying the range of multiple forecasts and defining the probability of occurrence of a particular forecast through clustering and averaging of multiple forecasts. Knowledge of forecast spread and probability of occurrence of various scenarios allows forecasters to assign confidence to portions of their weather forecasts.

Ensemble forecasting requires knowledge of analysis errors. Unfortunately, analysis errors are not known, and different techniques are employed to estimate them at world forecast centers. One approach assumes that the most important component of the analysis error results from the most energetic and rapidly growing errors. These errors are introduced in the data assimilation cycle, which contains errors from observations and the model-derived first-guess forecast, and grow faster than amplifying weather systems to contaminate forecasts. Growing errors are estimated by first identifying analysis differences between arbitrarily perturbed and unperturbed forecasts and then using these differences to produce perturbations in the subsequent analysis cycle. By continuing this cycle in time and varying the initial arbitrary perturbation, this technique breeds estimates of the fastest-growing analysis errors. A second approach employs mathematical techniques to estimate the maximum-growing analysis error structures through consideration of model formulation and perturbation energy. Initial analysis perturbations are then dynamically defined from the maximum-growing error structures. In both approaches the estimated perturbations are applied to vary initial conditions for the ensemble members.

Ensemble forecasts are routinely produced at forecast centers in Europe and North America for both short-range (0–48 h, Brooks *et al.*, 1995) and long-range forecasts with a variety of limited-area and global-domain models. Ensembles of 10–50 members are currently produced at individual operational forecast centers; and as computer speed and capacity increase, model resolution along with the number of ensemble members will multiply. Forecast centers are sharing ensembles and finding that the larger sample size of shared ensembles performs better than an individual forecast-center ensemble based on a single model and data assimilation system. This result supports increased cooperation between world forecast centers because model formulation and data assimilation system diversity improves the definition of atmospheric analysis uncertainty and the ability to establish an envelope of future atmospheric states.

A challenge in ensemble forecasting is the communication of multidimensional information to forecasters. The time domain is shown through multiple maps and clusters of forecast fields while uncertainty is portrayed by probability maps of meteorological variables. An example of the time variation and probability envelope of 500-mbar geopotential height for a 7-d forecast produced by a 17-member ensemble of the United States National Centers for Environmental Prediction for the Northern Hemisphere is shown in Fig. 7. The figure is an example of limited contour analysis that portrays midlatitude and subtropical circulations associated with the 564- and 585-dekameter geopotential height contours of the 500-mbar pressure surface. Thin light contours at higher latitudes represent individual members of the 564-dekameter contour with thin darker contours at lower latitudes depicting members of the 585-dekameter contour. The ensemble indicates confidence in the forecast where the thin lines of a particular height contour are close together and less confidence where the thin lines show large divergence from each other. Separation and orientation of both contours with respect to each other indicates the geostrophic wind speed and direction. The figure also includes climatological values (thickest contours) and the high-resolution control forecast (medium thickness contours) of the two contours. This day-7 forecast is fairly confident of the midlatitude circulation over the North Pacific Ocean, North America, and the Atlantic Ocean. Divergent 564-dekameter contours over Europe suggest less confidence in the forecast, with possible solutions ranging from warm and dry to cool and stormy. The range of solutions for the subtropical circulation indicates confidence over northern Africa and southern Asia, and relatively high confidence regarding a ridge over southern North America and the flow over the western North Atlantic Ocean. Increasing uncertainty is noted in the trough/ridge structure over the central North Pacific Ocean, with much uncertainty concerning the subtropical cir-

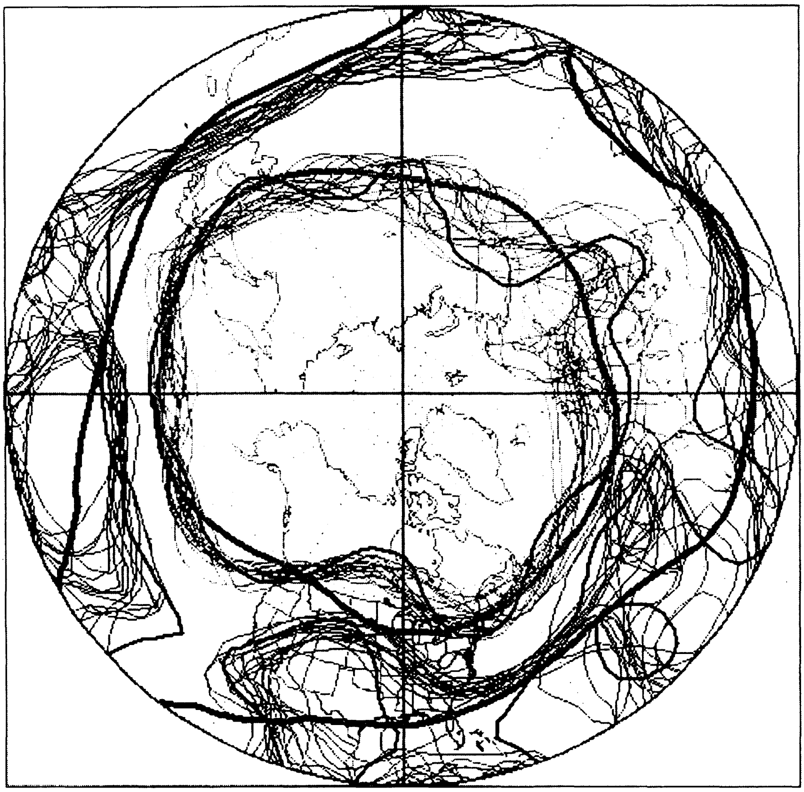

FIG. 7. Ensemble forecast of day-7 500-mbar geopotential heights over the Northern Hemisphere produced by the U.S. National Centers for Environmental Prediction Ensemble Prediction System and created by the United States NOAA Environmental Research Laboratory Climate Diagnostics Center (http://www.cdc.noaa.gov). The ensemble contains 17 members all valid at 00 UTC 14 October. Twelve members are from 00 UTC runs of the Medium Range Forecast Model (MRF) and 5 from 12 UTC runs of the aviation version of the MRF. The 564-dekameter height contours are shown as thin light lines at higher latitudes and the 585-dekameter height contours are shown as darker thin lines at lower latitudes. Climatological values of these contours are shown by the thickest line and the high-resolution control-run forecast is shown by the medium-thickness lines. The ensemble indicates confidence in the forecast where the thin lines of a particular height contour are close together and less confidence where the thin lines show large divergence from each other.

culation over the eastern North Atlantic Ocean. Graphical products such as Fig. 7 provide forecasters with meteorological information to assign confidence to a particular forecast.

3. FORECAST EVALUATION

3.1 Model Performance and Predictability

Forecasts made by operational centers are routinely evaluated to measure the long-term trend in forecast skill, impacts of changes to the forecast system, and the performance of a particular forecast. Evaluations consist of verification statistics of meteorological fields by a variety of scoring techniques. A result of these evaluations has demonstrated that the investment in numerical weather prediction systems at world forecast centers during the past few decades has produced significant improvement in weather forecasts.

An example of this prodigious improvement is shown in Fig. 8, a time-series graph of the skill of 36-h forecasts of 500-mbar geopotential height over North America. The skill score shown in Fig. 8 is a modified version of the S1 skill score of Teweles and Wobus (1954), which indicates improved skill with a higher score. The figure shows a dramatic increase in the ability to forecast

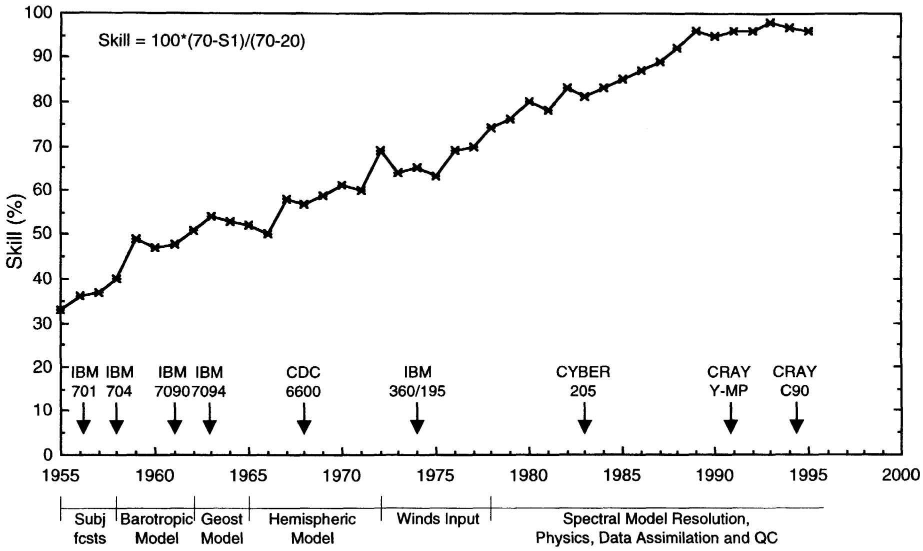

FIG. 8. Skill of 36-h forecasts of the 500-mbar geopotential height field over North America in forecasts made by the U.S. National Centers for Environmental Prediction. Noted on the graph are acquisition dates and types of computing systems and the type of operational-forecasting technique or numerical model. Figure courtesy of E. Kalnay, U.S. National Centers for Environmental Prediction.

the 500-mbar circulation from approximately 33% to a sustained 95% correct since 1989. The skill score may also be viewed from the perspective of the length of predictive skill. For example, as measured by the correlation of circulation anomalies between forecast and observed maps, current 5-d forecasts of 500-mbar circulation are as skillful as 36-h forecasts made in the 1960s (Peixoto and Oort, 1992). These measures also indicate that forecasts of the 500-mbar circulation show predictive skill to day 7, and forecasts of the stratospheric circulation (50 mbar) exhibit skill past day 10 (Bengtsson, 1991).

A result of this lengthening of the time of forecast skill is the positive impact and increased confidence society places in weather forecasts. A prominent example of this positive impact is the major winter snowstorm of 12–14 March 1993, which paralyzed the eastern seaboard of North America with heavy snowfall, blizzard conditions, coastal flooding, high winds, and tornadoes (Kocin *et al.*, 1995; Uccellini *et al.*, 1995; Caplan, 1995). Achievements of forecasts made by models from operational forecasting centers in Europe, Asia, and North America were

1. indications of a major winter storm in the correct time and place as early as 5 d beforehand,
2. 3-d warning of the strength and severe nature of the storm, and
3. 2-d warning of the areal extent and amount of snow.

Forecasters were able to warn the public well in advance of the storm such that this particular case heralds the longest lead time for warning of a severe storm in the history of the U.S. National Weather Service.

The increase in forecast skill has not been evenly distributed over the globe, which partially reflects the type and distribution of observations shown in Fig. 1. Bengtsson (1991) showed that the limit of predictability of circulation and temperature forecasts for the Southern Hemisphere lagged the Northern Hemisphere by approximately 2 d, which is suggestive of the reduced spatial sampling by the global observing system in the Southern Hemisphere. Errors are also larger over the eastern ocean basins and western continents of the Northern Hemisphere midlatitudes (Arpe and Klinker, 1986; CAeM, 1992) connoting the lack of upstream observations over the oceans and the ability of forecast models to simulate, accurately, cyclone development, maturation, and decay along the two primary midlatitude oceanic storm tracks.

Quantitative precipitation is a difficult problem in numerical weather prediction because precipitation occurs on time and space scales smaller than the circulations that produce precipitation (e.g., Ray, 1986). Progress in precipitation forecasting has been achieved through systematic increases in model horizontal and vertical resolution and through improvements in precipitation algorithms. The quality of areal precipitation forecasts produced by two regional scale models of the U.S. National Centers for Environmental Prediction, the 80-km/16-level Regional Analysis and Forecast System and the recently implemented 29-km/50-level Mesoeta model, are shown in Fig. 9. The quality is measured by the equitable threat score, which indicates the percentage of grid points that were correctly forecast to receive a particular threshold amount of precipitation. Figure 9 indicates that the accuracy of areal precipitation forecasts is relatively low and decreases with increasing precipitation amount. However, it is encouraging to note that the accuracy for heavy precipitation amounts has nearly doubled for the Mesoeta model. Since most heavy-precipitation events are associated with convective-type precipitation, the increase in accuracy indicates the importance of high model resolution and appropriate precipitation algorithms to capture precipitation processes better.

An example illustrating the issues discussed in the verification section is shown through the verification of the two forecasts presented in Figs. 5 and 6. Figure 10 shows the verifying analyses of mean sea-level pressure and 1000- to 500-mbar thickness for 00 UTC 30 October produced by the Regional Analysis and Forecast System of NCEP. Comparison of Fig. 10 with the 5-d forecast shown in Fig. 5 indicates that the spatial distribution of high- and low-pressure systems was predicted reasonably well over North America and the adjacent oceans. Intensity forecasts of individual systems are fairly accurate; however, the strength of the major

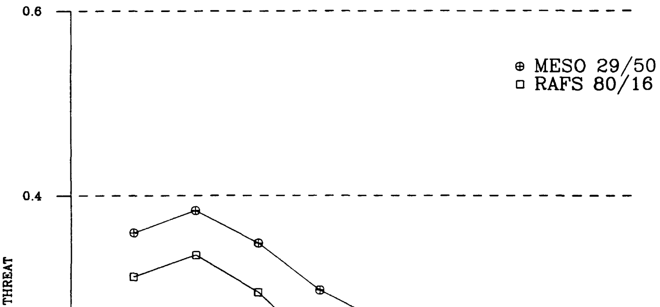

FIG. 9. Equitable threat scores for precipitation from two regional-scale forecast models from the U.S. National Centers for Environmental Prediction for the period 1 March 1995 to 29 February 1996. Square data points are for the Regional Analysis and Forecast System running at 80-km horizontal resolution and 16 vertical sigma levels (RAFS 80/16). Circled data points are for the mesoscale Eta model running at 29-km horizontal resolution and 50 vertical Eta levels (MESO 29/50). The equitable threat score is on the ordinate. The abscissa contains two lines of information. The top line of the abscissa shows threshold categories of precipitation (in inches) that are defined for computation of the equitable threat score. The second line of the abscissa indicates the number of model grid points that received this threshold amount of precipitation. An 80-km grid from the NCEP Eta model was used to compute the scores for both models. For example, 233 568 grid points were forecast to receive at least 0.01 in. of precipitation during the period 1 March 1995 to 29 February 1996. The equitable threat score is calculated separately for each threshold category with a higher score indicating increasing skill. Figure courtesy of E. Kalnay, U.S. National Centers for Environmental Prediction.

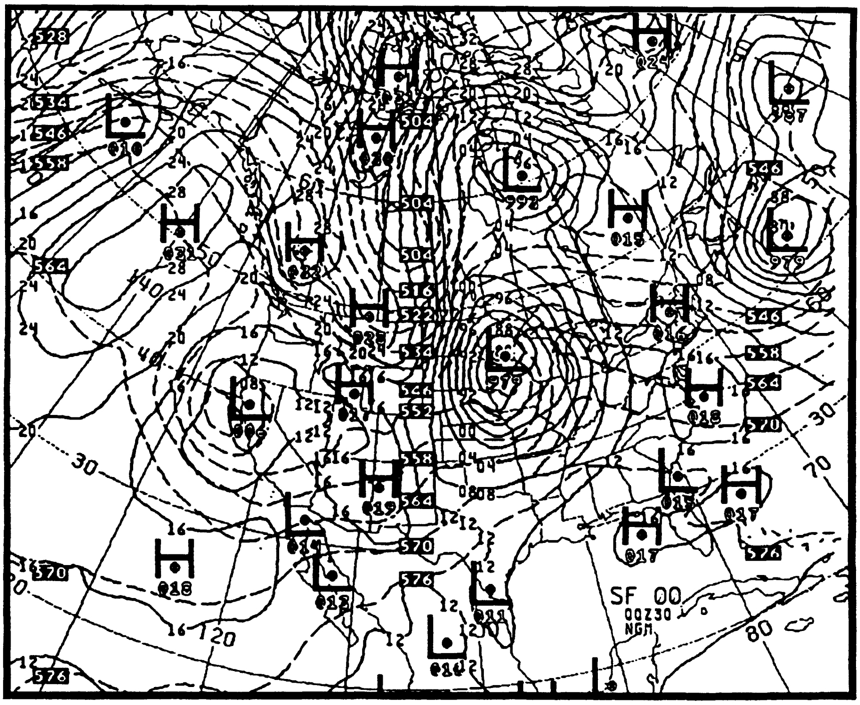

FIG. 10. Analysis from the U.S. National Centers for Environmental Prediction Regional Analysis and Forecast System for 00 UTC 30 October 1996. Shown are mean-sea-level pressure (solid contours every 4 mbar with the one's and ten's digit labeled, such that 24 ⇒ 1024 mbar) and the thickness between the 1000- and 500-mbar pressure levels (dashed contours every 6 dekameters and labeled with white numbers on a black rectangle such that 540 ⇒ 5400 m). Figure courtesy of U.S. National Centers for Environmental Prediction.

low-pressure system over the central United States is underforecast, and a low-pressure system over California is not forecast at all. These problems illustrate difficulties in forecasting downstream of a nearly data-void ocean because the synoptic features of the major storm in the central United States and over California were over the central Pacific Ocean 5 d earlier at initialization time for Fig. 5. Comparison of Fig. 10 with the upper right panel of Fig. 6 reveals that the 48-h forecast from the regional scale model performed well with regard to the intensity and position of the low- and high-pressure systems over the map domain. In particular, the difficulty in accurately predicting the low-pressure system over California exemplifies the problems faced by west-coast forecasters in Europe and North America with the intensity and timing of synoptic scale weather systems.

The advancements made during the past century have realized the vision of Vilhelm Bjerknes and L. F. Richardson to forecast the weather on the basis of the principles of physics. Weather forecasting has made scrupulous use of many branches of physics and mathematics to solve the problems of initial conditions, to create accurate forecast models, and to determine the range of forecast probability. These advances have increased the length of forecast skill to slightly greater than 1 week at present. Lorenz (1969) estimated the limit of deterministic predictability to lie between 2 and 3 weeks because of inherent limitations in the ability accurately to determine and initialize all scales of motion. Progress toward that goal has been substantial during the past decades, and with the development of ensemble prediction systems, it will be possible to assess a probabilistic range of weather forecasts for short-range (1 to 2 weeks) and short-term climate for future seasons (McPherson, 1994).

GLOSSARY

Absolute Vorticity: Rotation about a local vertical axis that includes wind motion relative to the Earth and the Coriolis parameter, which is the amount of rotation a local vertical axis makes with respect to the Earth's axis rotation.

Albedo: The amount of incident radiation that is reflected.

Altostratus Cloud: A middle-level cloud located between 3000 and 6000 m characterized by a layered structure and a dull gray color.

Analog: A weather pattern that bears similarities to another pattern.

Anticyclone: A high-pressure system that circulates clockwise in the Northern Hemisphere and counterclockwise in the Southern Hemisphere.

Baroclinic Instability: A theory that describes how infinitesimal perturbations in a flow characterized by temperature gradients and vertical changes in wind speed and direction can grow exponentially.

Barotropic Vorticity Equation: An equation that describes how changes in the rotation of the wind can change in an atmosphere characterized by no temperature gradients. The equation states that the absolute vorticity is conserved following the motion of an air parcel.

Boundary Layer: The layer of the atmosphere, typically 1–2 km thick, that is closest to the ground and conveys the effects of friction and of sensible and latent heat between the ground and the atmosphere.

Clear-Air Turbulence: Atmospheric flow in which the velocity changes direction and magnitude rapidly and erratically in air that is free from clouds.

Convective Storms and Precipitation: Storms and precipitation produced by buoyant updrafts and characterized by strong vertical motions in statically unstable air. Thunderstorms are a subset of convective storms.

Coriolis Parameter: A quantity that expresses the amount of rotation a local vertical axis makes with respect to the Earth's axis of rotation.

Cyclone: A low-pressure system that circulates counterclockwise in the Northern Hemisphere and clockwise in the Southern Hemisphere. There are tropical cyclones and midlatitude cyclones and each is produced and maintained by different atmospheric processes.

Dew-Point Temperature: The temperature to which air must be cooled in order for saturation and the formation of dew to occur. The dew point is a temperature measure of the amount of water vapor in the air.

Discretization: The process whereby a continuous variable is subdivided into distinct measurements at particular points in space and time.

Divergence: A concept that describes the magnitude of air parcels separating from each other or coming together in a particular region or volume of air.

Dropwinsonde: An instrument package typically dropped from an airplane and carried down by parachute that measures temperature, relative humidity, and wind speed and direction, and telemeters these measurements to a receiving site.

Equivalent Barotropic Model: A forecast model based on the barotropic vorticity equation in which wind speed but not direction is allowed to vary with elevation.

Finite Differencing: A numerical method developed from Taylor series expansion that expresses continuous derivatives as the quotient of differences of the variables contained within the derivative.

Geostrophic Thermal Wind: A concept that relates changes of the geostrophic wind with height to the strength of the horizontal temperature gradient.

Geostrophic Wind: An approximation to the true wind where the wind speed is proportional to the strength of the horizontal pressure gradient and blows at a constant speed parallel to straight isopleths of pressure. The geostrophic wind is defined as the balance between the horizontal pressure gradient and the Coriolis forces.

Gravity Waves: A wave disturbance produced by the restoring force of gravity and exhibiting oscillatory motion about a level due to the displacement of an air parcel from a state of hydrostatic balance.

Hydrostatic Balance: A state where vertical accelerations of air parcels are absent because of the balance between gravity and the vertical pressure gradient force.

Initial-Value Problem: A class of problems in which the solution proceeds from initial values.

Numerical Weather Prediction: Weather prediction that uses numerical approximations to integrate the laws of physics forward in time.

Objective Analysis: Techniques that interpolate irregularly spaced meteorological observations to a regularly spaced lattice.

Polar-Front Cyclone: A low-pressure system in middle latitudes that forms and develops along the polar front, a thermal boundary in the midlatitudes that separates polar air from milder midlatitude air.

Quasi-geostrophic: An approximation to the governing equations of atmospheric flow in which the flow is assumed to be in nearly hydrostatic and geostrophic balance. Departures from hydrostatic and geostrophic balance allow for the development of vertical motion, divergence, cyclones, and anticyclones.

Rawinsonde: An instrument package carried aloft by balloon that measures temperature and relative humidity, telemeters these measurements to a ground station, and is tracked to measure wind speed and direction.

Ridge: A feature of a contour field in which an axis of local maximum exists.

Squall Lines: Convective storms organized in a line.

Static Stability: A measure of an air parcel's resistance to vertical displacements. Positive static stability means that an air parcel displaced from its original position will return to that position due to the restoring force of gravity. Static stability can change as a result of temperature and water vapor changes in the atmosphere.

Stratiform Precipitation: Precipitation that is produced from the widespread lifting of air under statically stable conditions.

Synoptic: Depiction, viewing, and analysis of many synchronous weather observations.

Temperature Advection: A process in which air parcels of different temperature are blown across a region.

Trough: A feature of a contour field in which an axis of local minimum exists.

Vorticity: Rotation of the wind about a local vertical axis.

INTRODUCTION

Whiskers and dendrites are fine filamentary crystals with a very high aspect ratio of length to the diameter, and they can be formed from a vapor or a liquid phase (Kurz and Fisher, 1992; Trivedi and Kurz, 1994; Wagner, 1970; Givargizov, 1978). The filamentary nature of dendrites is illustrated in Fig. 1, from the studies by Trivedi and Somboonsuk (1984), which shows an array of dendrites in a thin sample of directionally solidified (i.e., solidified under a positive temperature gradient in the liquid) transparent system of succinonitrile-acetone. The shape of the dendrite front and the dendrite tip radius do not vary significantly for different dendrites in an array. Thus, a definite criterion exists for dendrite tip-radius selection. On the other hand, the formation of silicon whiskers from a vapor is illustrated in Fig. 1(b), which shows that there is no unique selection process, and a range of diameters is formed with the thinner whiskers growing at a lower rate (Givargizov, 1978).

The importance of dendritic growth comes from the fact that most alloys freeze with a dendritic structure. This dendritic freezing is accompanied by solute redistribution, which can either result in microsegregation or lead to the formation of a new phase in the interdendritic region. Either of these effects will significantly alter the properties of the solidified material. From a practical viewpoint, the characteristics of dendritic structures strongly influence the properties of cast and welded materials. Significant theoretical and experimental studies have thus been carried out to correlate quantitatively the dendrite growth rate and dendrite tip radius with the liquid undercooling.

The importance of whiskers can be seen through the consideration of the cohesive strength of the material. The theoretical strength of metals, calculated by determining the stress required to move lattice planes along the slip planes, was estimated to be in the range $\mu/30$–$\mu/15$, where μ is the elastic modulus (Frenkel, 1926). The maximum resolved shear stress required for plastic flow in real metals, however, was found to be significantly lower, and was in the range $(10^{-3}$–$10^{-4})\mu$. The lower strength of real crystals was attributed to the presence of dislocations, which cause plastic deformation. Thus, if dislocations could be removed or minimized, the strength of the crystals could be increased significantly. Since dislocations near the surface will experience image forces that will remove them, a very fine crystal will approach its theoretical strength (Frenkel,

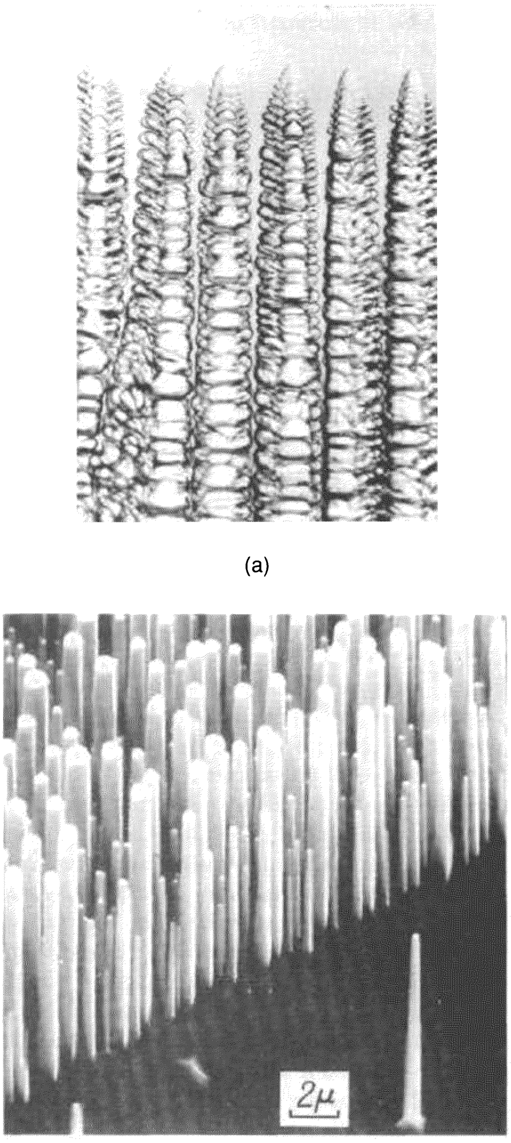

FIG. 1. (a) A dendritic array in directionally solidified succinonitrile–4.0 wt% acetone system (Trivedi and Somboonsuk, 1984); (b) silicon whiskers grown from a vapor (Givarzigov, 1978).

1926; Hirth and Lothe, 1968). Herring and Galt (1952) first showed that the strength of some of the whiskers approached the theoretical strength of the crystal. This high strength of whiskers generated much interest in their use as reinforcement materials in the design of composite materials. Specifically, whiskers of ceramic materials combine this high strength with the high modulus, low density, and high melting points of ceramics, so that ceramic whiskers can be effectively used in the design of ceramic:metal and ceramic:polymer composites. Whiskers, because of their small size, also show quantum size effects on optical, magnetic, and electrical properties so that whiskers of semiconductor materials have also been studied extensively.

The common technique for whisker production is growth from the vapor phase, and models have been developed that assume that the whisker formation is a vapor-to-solid transformation. Experimental studies by Wagner and Ellis (1964, 1965), however, have shown that whisker growth generally occurs through the formation of a liquid droplet at the advancing front of the whisker, giving rise to the vapor–liquid–solid (VLS) growth mechanism.

We shall first examine in detail the current status of the model of dendritic growth from an undercooled melt, and then examine models of whisker growth from the vapor phase.

1. DENDRITIC GROWTH

1.1 Background

The term dendrite comes from the Greek word dendron, which means tree, and like a tree the dendrite is a branched structure with primary, secondary, tertiary, and eventually higher-order branches. A microstructure of a dendrite grown from a pure undercooled succinonitrile (Huang and Glicksman, 1981) is shown in Fig. 2. Such a dendritic interface represents one of the most complicated patterns that evolve through the dynamical processes of growth. In addition, even the steady-state dendrite-growth model of an unbranched dendrite is complex since it requires proper physics to obtain a shape-preserving solution that gives a unique dendrite growth rate for a given undercooling.

Dendritic structures are ubiquitous structures in crystal growth. They can be formed by a variety of processes including growth from an undercooled melt, from a vapor, or by electrodeposition. In solidification, dendritic structures evolve under two distinctly

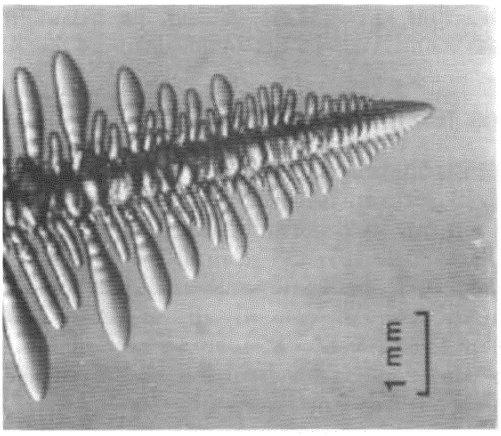

FIG. 2. A dendritic structure formed from an undercooled melt of pure succinonitrile (Huang and Glicksman, 1981).

different growth conditions, which differ in the way in which the latent heat of fusion is carried away from the interface. These are the following:

1. Growth from an undercooled melt, in which generally an equiaxed dendritic crystal forms, the latent heat of fusion being dissipated through the cooler liquid ahead of the interface. In this case the temperature gradient in the liquid at the interface is negative, whereas that in the solid is nearly zero.
2. Directional solidification or constrained growth in which a positive temperature gradient in the liquid is imposed so that the latent heat of fusion is dissipated through the solid.

Note that the dendrite growth direction and the heat flow direction are parallel for solidification in the undercooled melt condition, whereas they are antiparallel in the directional solidification process. In an equiaxed crystal, the thermal and solute fields ahead of any given dendrite can be significantly influenced by the presence of other dendrites in neighboring grains. In order to emphasize the basic physics of dendrite growth, we shall consider only the case of dendritic growth in a pure undercooled melt. In this case one obtains equiaxed dendrites, and the latent heat of fusion is dissipated through the cooler liquid ahead of the interface. The extension of this model to alloy dendrite growth is discussed by Langer (1986) and Trivedi and Kurz (1994).

During solidification of a pure melt, nonplanar structures form because they can effectively dissipate the latent heat of fusion required for growth. Consequently, dendrite growth models have been based on the solution of the thermal diffusion equation. The steady-state dendrite growth, however, is a free-boundary problem in which the shape of the interface is not known *a priori,* but must be determined in a self-consistent manner such that the solution of the diffusion equation establishes the shape that is preserved during the steady-state growth; i.e., the interface velocity V_n must satisfy the relationship $V_n = V\cos\theta$, where θ is the angle of the normal with respect to the growth axis and V is the velocity of the dendrite tip.

1.2 Self-Consistent Dendrite-Growth Model

The rigorous steady-state dendrite growth problem is governed by the following set of equations for the thermal fields in the liquid and solid:

$$\nabla^2 T_i + \left[\frac{V}{D}\right]\left[\frac{\partial T_i}{\partial z}\right] = 0, \qquad (1)$$

where $i = S$ or L, V is the axial dendrite growth rate, and D is the diffusion coefficient in the liquid. The boundary condition at the interface is governed by the Gibbs–Thomson and linear interface kinetic effects, which give

$$T_I = T_M - \left(\frac{T_M}{L}\right)\sum_{i=1}^{2}\left[\gamma(\mathbf{n}) + \frac{\partial^2\gamma(\mathbf{n})}{\partial\theta_i^2}\right]\frac{1}{R_i} - \frac{v_n}{\mu(\mathbf{n})}, \qquad (2)$$

where T_I is the interface temperature, R_i are the principal radii of curvature, θ_i are the angles between the normal $\mathbf{n}$ and the two local principal directions on the interface, and $\mu(\mathbf{n})$ is the linear interface kinetic coefficient. The other boundary condition requires that the temperature field approach the initial temperature of the undercooled liquid, T_∞, far from the interface.

The normal velocity of the interface is obtained from the condition of heat conservation at the interface:

$$v_n = D\left(\frac{c_p}{L}\right)\left[\left(\frac{\partial T}{\partial n}\right)_s - \left(\frac{\partial T}{\partial n}\right)_L\right] \tag{3}$$

in which c_p and L are the specific heat per unit volume and the latent heat per unit volume, respectively. For a crystal with cubic symmetry, the anisotropic interface energy $\gamma_n(n)$ is defined as

$$\gamma_n(n) = \gamma_0\,\bar{a}_s[1 + \epsilon_4'(n_x^4 + n_y^4 + n_z^4)] \tag{4}$$

in which ϵ_4' is the anisotropy parameter and γ_0 is the isotropic interface energy, i.e., interface energy for $\epsilon_4' = 0$. In practice, the anisotropy parameter ϵ_4' is not directly measured experimentally. The anisotropy parameter that is measured is the amplitude of the first Fourier cosine mode of $\gamma(\theta)$, where θ is the polar angle in a two-dimensional cross section of the equilibrium shape parallel to a (100) plane. If we write

$$\gamma(\theta) = \gamma_0 + \gamma_4 \cos 4\theta, \tag{5a}$$

then the ratio $\epsilon_4 = \gamma_4/\gamma_0$ can be extracted by examining the cross-sectional equilibrium shape

$$R(\theta) = R_0(1 + \epsilon_4 \cos 4\theta). \tag{5b}$$

It is then easy to work out that $\bar{a}_s = 1 - 3\epsilon_4$, and $\epsilon_4' = 3\epsilon_4/(1 - 3\epsilon_4)$, by expanding $\cos^4\theta$ and $\sin^4\theta$ in Eq. (4) in terms of $\cos 4\theta$.

1.3 Ivantsov Model

Papapetrou (1935) first showed qualitatively that an isothermal parabolic interface will grow at a constant rate and satisfy the shape-preserving constraint. A mathematical model of the steady-state dendrite growth model was subsequently developed by Ivantsov (1947), who obtained an exact solution of the steady-state diffusion equation under the boundary conditions that $T(z \to \infty) = T_\infty$, and the interface temperature T_I is constant, $T_I = T_M$, where T_M is the melting point. For a parabolic needle dendrite growth, he obtained a relationship between dimensionless undercooling Δ and the dimensionless Peclet number P as

$$\Delta = Pe^P E_1(P), \tag{6a}$$

where $\Delta = (T_M - T_\infty)(c_p/L)$ and $P = V\rho/2D$, in which ρ is the dendrite tip radius. $E_1(P)$ is the exponential integral function given by

$$E_1(P) = \int_P^\infty \frac{e^{-z}}{z}\,dz. \tag{6b}$$

For a given undercooling, the Ivantsov solution gives a continuum of solutions between V and ρ, and no specific velocity or radius is selected (Fig. 3). Experimental studies by Huang and Glicksman (1981) and Glicks-

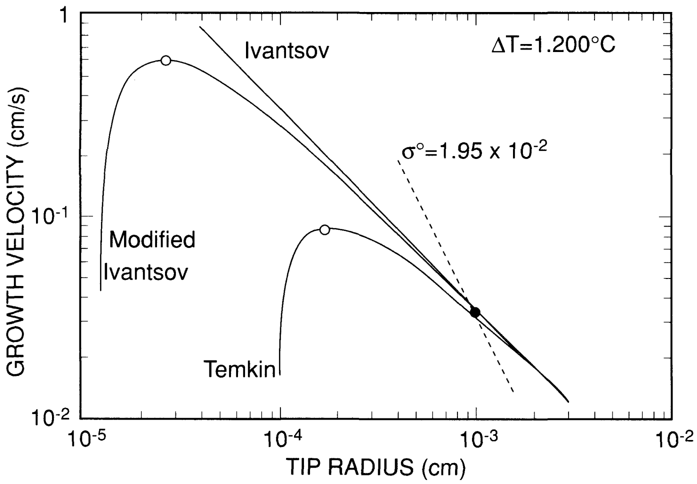

FIG. 3. The variation in dendrite velocity with the dendrite tip radius for a given undercooling in high-purity succinonitrile (Huang and Glicksman, 1981). The dashed line is the marginal-stability criterion for $\sigma^* = 0.0195$.

man *et al.* (1976) confirm that the shape of the dendrite is very close to a parabola, and the Ivantsov relationship, Eq. 6(a), is satisfied when experimental values of D, V, and ρ are used. Thus, the experimental results fall on the Ivantsov curve in Fig. 3, but the Ivantsov model does not predict this specific selection of V and ρ. From a theoretical viewpoint, if only thermal transport process were important for the formation of dendrites in an undercooled melt, then the dendrite tip would be unstable with respect to tip splitting, and no steady-state growth would occur. Thus, another consideration, such as interfacial free energy or interface kinetics that can stabilize the dendrite tip, is essential to define properly the dendrite growth problem. The quantitative characterization of this stabilizing effect is key to the unique solution of the steady-state dendrite growth problem.

Several approximate models were proposed to incorporate the effect of interface energy into the dendrite growth model. The modified Ivantsov model assumed that the dendritic interface is parabolic and isothermal, but the constant temperature corresponds to the tip temperature, which will be different from the melting point because of the curvature effect. This model still gave a continuum of solutions, as shown in Fig. 3, but the velocity–radius relationship exhibited a maximum since the velocity must reduce to zero at the critical radius for nucleation. Subsequently, Temkin (1960) extended the Ivantsov model by assuming the interface to be parabolic, and considered the Gibbs–Thomson effect and the kinetic effect to characterize the variation in temperature along the interface. The nonisothermality of the interface also required the solution of heat flow in the solid. Temkin solved Laplace's equation for the thermal field in the solid and in the liquid, and a solution for the steady-state diffusion equation for the parabolic interface was subsequently obtained by Trivedi (1970), who obtained the result

$$\Delta = [Pe^{P}E_1(P)][1 + (d_0/2P\rho)F_0 + (d_k/\rho)F_k], \tag{7}$$

where $d_0 = T_M c_p \gamma_0 / L^2$ is the capillary length and $d_k = c_p D / L\mu_0$ is the kinetic length in which μ_0 is the linear kinetic coefficient. The functions F are approximately given by $F_0 = (3.8410 + 4P) + (K_s/K_l)[2.06/(1 + P)]$ and $F_k = (1.4050 + 2P) + (K_s/K_l)0.5954/(1 + P)$. K_s and K_l are thermal conductivities in the solid and liquid, respectively. The three terms in the second factor show the undercoolings required for the diffusion process, for the interface energy, and for the interface kinetics, respectively. This model gives a lower growth rate due to the additional heat flux from the sides of dendrite to the tip, in the liquid and in the solid, due to the nonisothermal interface.

The consideration of interface energy in the Ivantsov model gave rise to a continuum of solutions with a maximum in the V–ρ relationship for a given undercooling, as shown in Fig. 3. The tip selection was assumed to correspond to the maximum growth rate. However, all these modifications are not self-consistent since they do not satisfy the shape-preserving condition.

A self-consistent model of dendritic growth was first proposed by Nash and Glicksman (1974), who developed an integral formulation using the Green's function of the diffusion equation in which the interface shape appeared as an unknown. They assumed isotropic interface energy, and solved the equation only approximately, which again gave a continuum of solutions. Thus, the selection of dendrite tip radius and velocity at a given undercooling still remained unexplained. A definitive experimental study by Glicksman *et al.* (1976) in a transparent system in which both V and ρ can be accurately measured showed that, although the Ivantsov equation is satisfied, the dendrite tip selection does not correspond to the maximum growth-rate value, but the selected radius is larger than that corresponding to the maximum growth rate.

1.4 Marginal-Stability Criterion

The problem of dendrite tip selection was addressed by Langer and Müller-Krumbhaar (1977), who carried out a linear stability analysis of the dendrite tip around a parabolic dendrite. They considered isotropic interface energy but neglected the interface kinetics effect. They assumed that a stable steady-state shape exists under isotropic interface energy that departs only slightly from a parabola. They showed that only a narrow band of dendrite tip radii will be stable from the continuum solution of Ivantsov, and the lower limit of stable radius corresponded to the maximum growth-rate condition. They proposed a marginal-stability criterion that assumed that the system selects only the largest stable radius value, as shown by a dashed line in Fig. 3. This marginal-stability criterion, when coupled with the Ivantsov solution, was found to agree remarkably well with the experimental results of Glicksman *et al.* (1976) in pure undercooled succinonitrile (SCN). The model showed that, in addition to the dimensionless parameters Δ and P in the Ivantsov solution, the inclusion of surface energy gives a new dimensionless parameter σ^*, defined as

$$\sigma^* = 2D_l d_0/\rho^2 V \tag{8}$$

in which d_0 is the capillarity length, $d_0 = T_M c_P \gamma_0/L^2$. The marginal-stability condition was found to occur at $\sigma^* = 0.025$. For very small undercoolings, the modification to the Ivantsov equation due to interface energy was found to be negligible. Equations (6a) and (8) thus give the unique values of V and ρ for a given undercooling.

1.5 Microscopic Solvability Theory

Although the marginal-stability criterion gives a good agreement with experimental results, it is based on the erroneous assumption that steady-state growth is possible for a continuum of velocities and tip radii. In the early 1980s, the introduction of simplified models of dendritic growth with local growth laws, such as the geometrical (Kessler *et al.*, 1985) and boundary-layer (Ben-Jacob *et al.*, 1984) models, made it possible to solve the steady-state growth equations without any uncontrolled approximations. These studies lead to two important conclusions:

1. Surface tension ($d_0 \neq 0$) acts as a singular perturbation that breaks the continuous spectrum of steady-state growth solutions. This singular role originates mathematically from the fact that capillary effects enter into the equations as the product of the surface tension length d_0 and the curvature κ that involves the highest-order spatial derivative of the interface shape [e.g. $\kappa \sim d^2z(x)/dx^2$ in two dimensions]. Physically, this singular role of capillarity is already reflected in the stability spectrum of a planar interface. Without capillarity, a sinusoidal perturbation of the interface is always unstable, no matter how small is its wavelength, whereas with capillarity it is only unstable if its wavelength is larger than the stability length $\lambda_s \sim 2\pi(d_0 l)^{1/2}$.
2. Anisotropy has a critical role. For an isotropic surface energy ($\epsilon_4 = 0$), there is *no* possible steady-state solution. In this case dendritic growth becomes replaced by the growth of seaweed-like disordered structures controlled by repeated tip-splitting events. In contrast, with a finite amount of anisotropy ($\epsilon_4 \neq 0$), even small, there is a discrete spectrum of possible steady-state solutions, only the one with the largest velocity being linearly stable against tip splitting.

Numerous studies showed subsequently that these findings extend to the complete diffusive free-boundary problem of dendritic growth described by Eqs. (1)–(5), so that these conclusions are now firmly established.

For growth in two dimensions, the interface is one-dimensional, and the dendrite growth problem can be solved accurately by the Green's function method (Pelcé and Pomeau, 1986; Caroli *et al.*, 1986; Kessler and Levine, 1986; Meiron, 1986; Ben-Amar and Moussallam, 1987). The model predicts that the parameter σ^*, defined in Eq. (8), is not a numerical constant but is a function of the interface energy anisotropy parameter ϵ_4. For vanishing anisotropy value the limiting value of σ^* is obtained as $\sigma^* = \sigma_0 \epsilon_4^{7/4}$, where σ_0 is of the order of unity. Note that the variation in σ^* departs from this result at very small values of ϵ_4. In the absence of anisotropy, i.e., $\epsilon_4 = 0$, the model shows that there are no steady-state solutions.

The basic prediction that anisotropy is necessary for dendrite growth provides a natural explanation for the observed preferred growth direction of dendrites. Previous models, which did not take into account the anisotropy, could only attribute the symmetry to the role played by anisotropy during the initial development of a spherical nucleus.

Rigorous solvability predictions in three dimensions, for arbitrary anisotropy and undercooling values, have been made only for an axisymmetric case in which the interface shape $z(r,\phi)$ is independent of the polar angle ϕ in the x-y plane perpendicular to the growth direction. This axisymmetric approximation reduces the three-dimensional steady-state growth problem to a tractable problem that is effectively two dimensional, and the interface shape $z(r)$ approaches the Ivantsov paraboloid of revolution far from the tip region (Barbieri and Langer, 1989). This paraboloid becomes the exact asymptotic shape in this case. The nonlinear boundary integral equation for this problem was developed by Kessler and Levine (1988) as

$$\Delta - \Delta_m = \int_0^{2\pi} \frac{d\phi'}{2\pi} \times \int_0^{+\infty} \frac{r'dr'}{l} \frac{\exp[z(r') - z(r) - d/l]}{d}, \tag{9}$$

where $l = 2D/V$ is the diffusion length,

$$d = \{r^2 + r'^2 - 2rr' \cos(\phi - \phi') + [z(r') - z(r)]^2\}^{1/2},$$

and

$$\Delta_m = -d_0\left(a_s + \frac{\partial^2 a_s}{\partial \bar{\theta}^2}\right)\left(\frac{z_{rr}}{(1 + z_r^2)^{3/2}}\right) - d_0\left(a_s + \cot\bar{\theta}\,\frac{\partial a_s}{\partial \bar{\theta}}\right)\left(\frac{z_r}{(1 + z_r^2)^{1/2}}\right)$$

represents the Gibbs–Thomson effect for the axisymmetric case in terms of the anisotropy function

$$a_s(\bar{\theta}) = \bar{a}_s[1 + \epsilon_4'(\cos^4\bar{\theta} + \tfrac{3}{4}\sin^4\bar{\theta})] \tag{10}$$

that is averaged in the azimuthal direction and only depends on the angle $\bar{\theta}$ between the normal to the interface and the z axis defined by $\tan\bar{\theta} = -z_r$. $\bar{a}_s$ is defined in Eq. (4).

The nonaxisymmetric three-dimensional model, however, has remained difficult to solve because the two-dimensional interface is harder both to parametrize and to find numerically. In addition, in contrast to the case of two dimensions, the Ivantsov paraboloid needle crystal solution no longer represents the correct asymptotic solution to the steady-state growth equations far behind the tip, which makes it difficult to impose a rigorous boundary condition on the form of the steady-state shape far behind the tip. A solution only in the limit of vanishing anisotropy, $\epsilon_4 \rightarrow 0$, and small undercooling, $\Delta \ll 1$, has been obtained by Ben-Amar and Brenner (1993) by analyzing the behavior of the solution in the tip region separately from the tail. This model yields the classic solvability prediction that at vanishingly small values of ϵ_4, the relationship $\sigma^*(0,\epsilon_4) = B\epsilon_4^{7/4}$ is obtained. This result, which shows the same $\frac{7}{4}$ exponent as in the two-dimensional model, is conceptually important in that it provides a convincing theoretical argument that the structure of the solvability theory does indeed extend from two to three dimensions. The model, however, is only quantitatively valid for very small values of ϵ_4. Thus, for the purpose of testing the solvability theory against experimental results, nonaxisymmetric models are required for arbitrary anisotropy and undercooling values, and such models have recently been developed by Karma and Rappel (1996a, 1996b, 1997) through phase-field simulations.

1.6 Dynamical Models

Several dynamical simulations of dendritic growth have been carried out that establish the critical role of crystalline anisotropy on the growth morphology. Accurate quantitative tests of solvability predictions have also been performed by Ihle and Müller-Krumbhaar (1994) using sharp interface and by Karma and Rappel (1996a, 1996b, 1997) using phase-field models. Kobayashi (1994) first carried out phase-field simulations of dendritic growth in three dimensions with a kinetic anisotropy. More recently, Schmidt (1996) has simulated three-dimensional dendrite morphologies using a finite-element code. Both these studies have yielded dendrite morphologies that resemble those seen in experiment, although they have not compared the results quantitatively with the microscopic solvability model. More detailed phase-field calculations have recently been carried out by Karma and Rappel (1997), and they have compared their results with those of the numerical solvability model and experiments.

The phase-field method is rooted in continuum models of phase transition. It is rapidly emerging as a method of choice for simulating interface pattern-formation phenomena in solidification and other systems. The appeal of this approach is to avoid tracking of macroscopically sharp phase boundaries by introducing a nonconserved order parameter or "phase field," ψ, to distinguish between different phases. The equation of motion for this field is derived variationally from a phenomenological free-energy functional F, and is given by

$$\tau(\mathbf{n})\frac{\partial\psi}{\partial t} = -\frac{\delta F}{\delta t} \qquad (11)$$

in which

$$F = \int d\mathbf{r}\left[\frac{W^2(\mathbf{n})}{2}|\nabla\psi|^2 + f(\psi,u)\right], \qquad (12)$$

$$f = -\frac{\psi^2}{2} + \frac{\psi^4}{4} + \lambda u\psi\left(1 - \frac{2\psi^2}{3} + \frac{\psi^4}{5}\right), \qquad (13)$$

and

$$u = (T - T_M)/(L/c_p). \qquad (14)$$

Equation (13) has minima at $\psi = -1$ and $\psi = +1$ that correspond to the liquid and solid phases, respectively. The anisotropic surface energy defined by Eq. (4) is recovered by choosing

$$W(\mathbf{n}) = W_0\gamma(\mathbf{n})/\gamma_0, \qquad (15)$$

where $\mathbf{n} = -\nabla\psi/|\nabla\psi|$ is the vector field that corresponds to the normal to the boundary and $\gamma(\mathbf{n})$ and γ_0 are defined by Eq. (4). This representation of anisotropy is a direct generalization in three dimensions of the way anisotropy has been previously included in two dimensions. The equation for the phase field is now coupled to that of the diffusion field:

$$\frac{\partial u}{\partial t} = D\nabla^2 u + \frac{1}{2}\frac{\partial\psi}{\partial t}, \qquad (16)$$

in such a way that the equations for the two fields reduce to those of the original free-boundary problem in the limit where the interface width W_0 is small compared to the principal radii of curvature of the boundary. This thin-interface limit can be taken by using the analysis of Karma and Rappel (1996b, 1997). In this approach, the necessary relation for choosing λ and the function $\tau(\mathbf{n})$ is taken such that $1/\mu(\mathbf{n})$ in Eq. (2) vanishes, thereby purposely eliminating the kinetic undercooling at the interface. The equations of the phase-field model, Eqs. (11) and (12), can now be simulated explicitly on large cubic lattices for a fixed undercooling and for different anisotropy values.

A typical three-dimensional dendrite morphology resulting from the simulated growth of a small spherical seed is illustrated in Fig. 4. The results of these runs are summarized in Figs. 5(a) and 5(b), which also shows the result of the numerical and analytical solvability models for an axisymmetric dendrite.

1.7 Comparison between Theory and Experiments

The dependence of P and σ^* on anisotropy predicted by the numerical solvability theory and the phase-field simulations are in good overall agreement (Fig. 5). The Peclet number P is found to agree quantitatively over the entire range of anisotropy, while σ^* values predicted by solvability are systematically lower than the phase-field values. The σ^* value predicted by solvability is about 70% smaller than the one observed in phase-field simulation for $\epsilon_4 = 0.047$, and only about 20% smaller for $\epsilon_4 = 0.0066$. This difference can be attributed to the nonaxisymmetric departure of phase-field dendrites from a shape of revolution that was found to

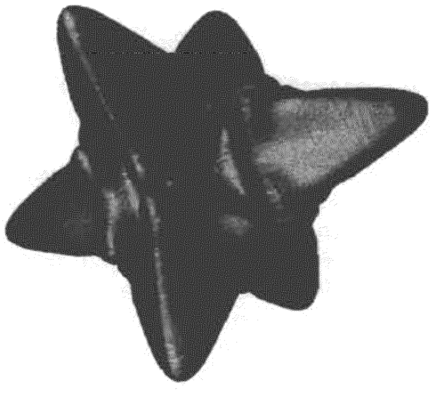

FIG. 4. A three-dimensional nonaxisymmetric dendritic structure predicted by the phase-field method (Karma and Rappel, 1997).

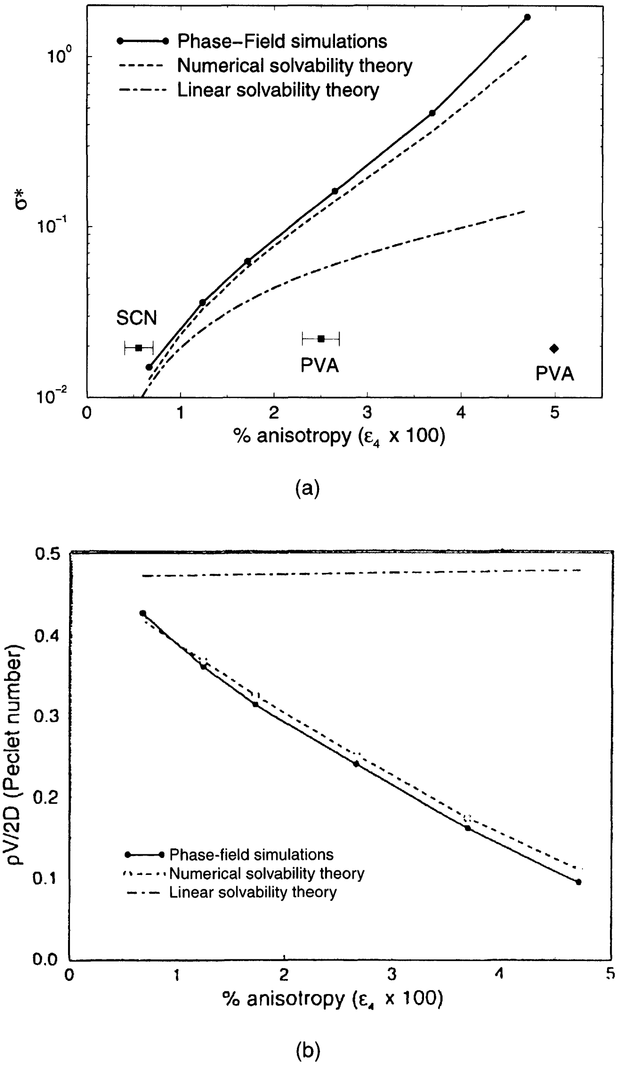

FIG. 5. The relationship between (a) σ^* and anisotropy, and (b) Peclet number and anisotropy, as predicted by the phase-field simulations, numerical solvability, and linear solvability methods. Experimental results for SCN and PVA are also shown for comparison. Two PVA results are plotted: the anisotropy measurements of Glicksman and Singh (1989) shown by a filled diamond, and of Muschol *et al.* (1992) shown by filled squares. (From Karma and Rappel, 1997.)

increase with anisotropy. For the nonaxisymmetric model, the actual tip radius, which is also the value measured experimentally, that is used to calculate σ^* is different from the tip-radius value that corresponds to the asymptotic Ivantsov shape. The results of Fig. 5(b), however, indicate that even at very low anisotropy, these two Peclet numbers still differ in such a way that the choice of definition is quantitatively relevant.

The results of experimental studies in succinonitrile and pivalic acid are also compared in Fig. 5(a). The present comparison is restricted to SCN and PVA, which are the only pure materials with an underlying cubic symmetry for which detailed measurements of both anisotropy and σ^* are available (Huang and Glicksman, 1981; Glicksman and Singh, 1989; Muschol *et al.*, 1992; Rubinstein and Glicksman, 1991). For succinonitrile, the phase-field model predicts $\sigma^* = 0.015$, which is slightly smaller than the experimental value obtained by Glicksman *et al.* (1976), as shown in Fig. 5(a).

The agreement between theory and experiment, however, remains very poor for PVA, both if we use the anisotropy measurement of Mushol *et al.* (1992), or the higher 5% anisotropy value measured previously by Glicksman and Singh (1989). Historically, the proximity of the σ^* values of SCN and PVA appeared as a strong point in favor of marginal stability theory. The departure of σ^* in PVA from the solvability model, however, is significant.

There seem to be at least three possible reasons for this discrepancy. The first is that kinetic effects at the interface, which were purposely excluded from the phase-field computations, could play a significant role at low undercooling in PVA, unlike in SCN where σ^* is measured to be only slightly dependent on undercooling. Kinetic effects have been studied recently by Wang and Sekerka (1996) by two-dimensional phase-field simulations at large Δ, and they found kinetic effects to lead to a decrease in σ^* with increasing Δ that is qualitatively similar to the one observed in experiment in PVA. However, detailed phase-field simulations that take into account the kinetic effects need to be developed to resolve an order-of-magnitude disagreement between theory and experiment.

The second possibility is that experiments, which have intrinsically a finite optical resolution, cannot measure the tip radius ρ sufficiently accurately, and can overestimate its value. The shapes of the dendrite tip region predicted by the axisymmetric numerical model, the nonaxisymmetric phase-field model, and the Ivantsov model are shown in Fig. 6. Thus, it becomes very difficult to measure ρ accurately at large anisotropy because the curvature varies very rapidly in the tip region. Special care needs to be taken to obtain reliable answers. It is possible that only an averaged value of the curvature in the tip region is measured experimentally. This aspect needs to be reexamined carefully for strongly anisotropic materials.

A third and perhaps least likely possibility is that the dendrite tip selects a different dynamical attractor than the underlying steady-state needle crystal at low undercooling. In this case the solvability theory would not be applicable. When the diffusion length becomes much larger than ρ, there is the possibility of a nonlinear feedback mechanism between the side branches and the tip, which could potentially modify the operating state of the tip, although one would not expect an order-of-magnitude shift in σ^*.

1.8 Side-Branch Instability

Everything described so far pertains to the determination of the operating state of the dendrite tip. We conclude this section with a brief description of sidebranching that leads to treelike dendrites. According to current theories, the formation of secondary branches behind the tip should be the result of the selective amplification of some form of noise along the sides of dendrites (Langer, 1989). Current quantitative estimations indicate that thermal noise should, alone, be large enough to account for the experimentally observed sidebranching (Brenner and Temkin, 1995). Although it is not possible experimentally to switch off thermal noise, it is possible to do so in dynamical simulations. Simulations to date do indeed confirm that dendrites do not form secondary branches without noise (Warren and Boettinger, 1995; Karma and Rappel, 1996c). Experimental measurements of sidebranching characteristics also seem consistent with a noise-induced sidebranching mechanism (Dougherty *et al.*, 1987).

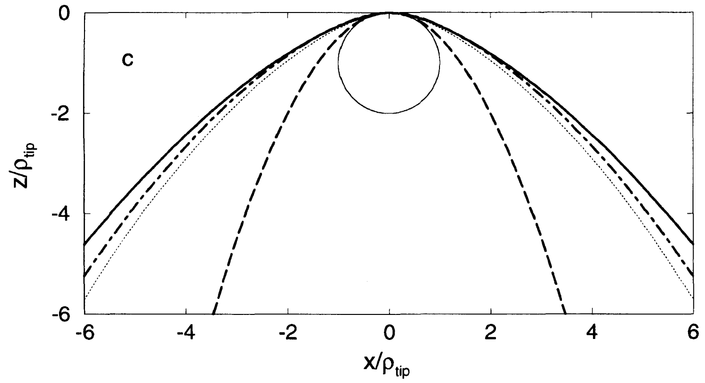

FIG. 6. The shape of the dendrite tip region predicted by the nonaxisymmetric phase-field model, the solid and dash-dotted lines corresponding respectively to $\phi = 0°$ and $\phi = 45°$. The result of axisymmetric numerical calculations (dotted line), Ivantsov parabola (dashed line), and a circle of unit radius that is normalized with tip radius obtained by the phase-field method are shown for comparison. (Karma and Rappel, 1997.)

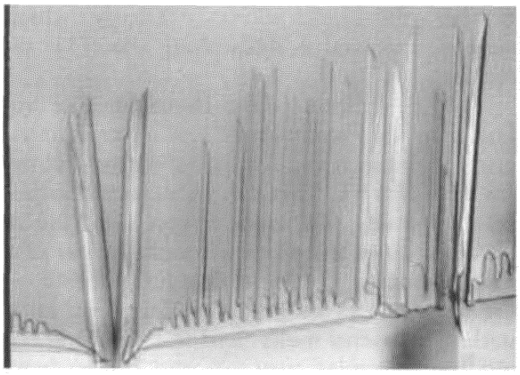

FIG. 7. Fine needle crystals formed during the directional solidification of as-received *tert*-butyl alcohol (Fabietti and Trivedi, 1997).

The fact that thermal noise can produce sidebranching may seem at first surprising. Thermal fluctuations are microscopically small (with an energy scale ~$k_B T_M$, where k_B is the Boltzmann constant) and, as a rule of thumb, do not affect the dynamics of macroscopic objects. Dendrites, however, provide a rather unique exception to this rule. The microscopically small fluctuations become important because their magnitude becomes amplified by several orders of magnitude by the same morphological instability that produces the primary branches in the first place. Some broader questions remain to be understood: how do secondary, tertiary, and higher-order compete dynamically so as to produce an anisotropic fractal structure at the scale of an entire dendritic grain? How can this structure be characterized? Progress on these more complex issues is currently being made (Brenner *et al.*, 1996) but much remains to be understood.

2. WHISKER GROWTH

When crystals are grown from a liquid in a very anisotropic material, very thin and elongated whiskers form. Figure 7 shows an array of such crystals in a directionally solidified transparent material, *tert*-butyl alcohol (TBA) (Fabietti and Trivedi, 1998). The crystal structure plays an important role in the formation of such needlelike crystals (Nabarro and Jackson, 1958). Besides the growth from a liquid, whiskers are commonly grown from the vapor phase. Several theoretical models of whisker growth have been developed. Initial theories by Sears (1953, 1955) were based on the formation of whiskers directly from a vapor phase, i.e., vapor-to-solid transformation, in which the preferential growth leading to a whisker shape was assumed to be due to the presence of an axial screw dislocation that would provide sites for atomic attachment during the crystal growth (Frank, 1949; Burton *et al.*, 1951), as shown in Fig. 8(a).

Several experimental studies have been carried out to test the dislocation model. Axial dislocations in whiskers have been observed only in a few materials that support

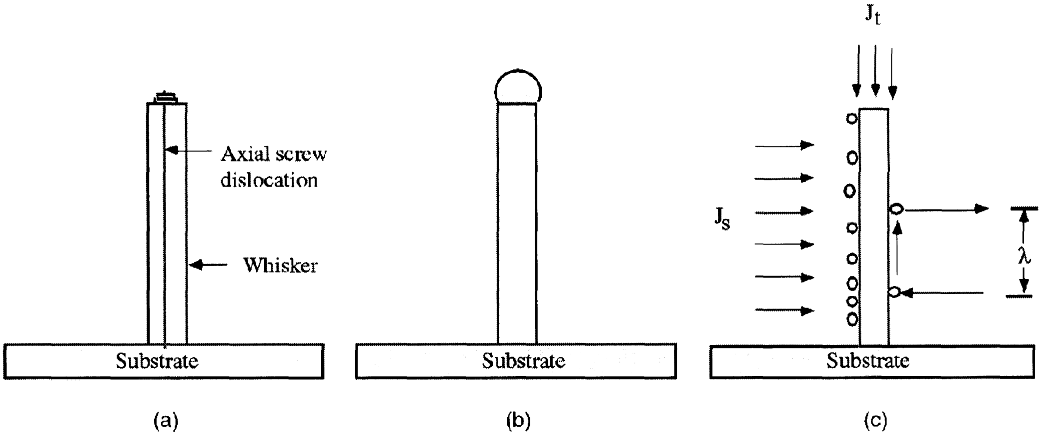

FIG. 8. Schematic illustrations of whisker growth by (a) screw dislocation mechanism, (b) liquid droplet mechanisms, and (c) the diffusion model showing the impingement flux and the desorption of adsorbed atoms.

the formation of whiskers. However, detailed experimental examination of whiskers in several systems found no dislocations in the whisker (Webb, 1958; Wagner *et al.*, 1964; Drum and Mitchell, 1964; Edwards and Huang, 1966; Minagava and Gejyo, 1969; Gabor and Blocher, 1969; Gotoh, 1972; Regis, 1969; Hasiguti *et al.*, 1970; Givargizov and Sheftal, 1972; Koparanova *et al.*, 1994; Hasimoto and Yamaguchi, 1996). In addition, even if screw dislocations were present in the substrate, the growth of steps leading to a spiral growth would be preferred over the formation of a whisker during the early stages of growth. Typically, whiskers have been found to form only under high supersaturation conditions, whereas the screw-dislocation mechanism is dominant only under very low supersaturations. Finally, experimental studies showed the need for impurities to form whiskers. When high-purity materials were used, no whisker formation occurred (Wagner, 1970). Thus another mechanism may also be operative for the whisker growth.

Wagner and Ellis (1964, 1965), in their experimental studies on Si whisker growth, observed that a droplet of liquid was present on the growing front of each whisker, as illustrated schematically in Fig. 8(b). They proposed an alternative mechanism in which the growth occurs through the transport of matter from vapor to liquid to solid, a process called the vapor–liquid–solid (VLS) growth. The presence of the liquid droplet has now been observed in several whisker-growth studies, and the droplet forms as a result of the presence of impurity, which alloys with the substrate or deposits, causing the alloy region to melt at the substrate temperature. Wagner and Ellis (1964, 1965) and Wagner (1967) proposed a model for the growth of silicon whiskers with gold as an impurity element. When the substrate is heated above the eutectic temperature, a gold-silicon liquid alloy is formed, and the liquid takes the shape of a droplet. A vapor in the form of a mixture of $SiCl_4$ and H_2 is introduced, which react at the liquid droplet surface to produce silicon. Silicon then transports to the solid–liquid interface where it gets deposited and causes the whisker to grow. The whiskers were found to grow along the ⟨111⟩ directions, and the unidirectional growth was a result of the anisotropy in the solid–liquid interface energy, which gave preferential growth along the ⟨111⟩ direction.

The recognition of the importance of impurity in the formation of a whisker enabled one to obtain a regular two-dimensional array of whiskers. This can be achieved either by depositing gold on a silicon substrate at predetermined locations through the use of a mask or by depositing a thin film of gold on the substrate. This gold film forms an alloy with silicon and melts, and the resulting liquid film becomes unstable and forms droplets in two dimensions with a characteristic wavelength.

2.1 Diffusion Model

A theoretical model of whisker growth was first proposed by Sears (1953, 1955) in which the diffusion of adsorbed atoms was considered to control the growth of whiskers. The axial velocity of the whisker due to the diffusive flux of adsorbed atoms at the advancing front can be calculated by considering the number of atoms impinging on the advancing surface less the number of atoms evaporating from the advancing surface, and assuming that the net impinged atoms get attached to the solid and increase the length L of the whisker. This gives

$$V_0 = \frac{dL}{dt} = \frac{(p - p_0)\Omega}{(2\pi mkT)^{1/2}}, \tag{17}$$

where Ω is the atomic volume in the solid, m is the mass of an atom, and p_0 is the equilibrium vapor pressure at temperature T. When this result was compared with the experimental data for mercury whisker growth, Sears observed that the experimental growth rate was more than three orders of magnitude larger. He thus postulated that the whisker growth occurs by the adsorption of atoms on the substrate and on the sides of the whiskers, and these adsorbed atoms move by surface diffusion toward the advancing front of the whisker, as shown in Fig. 8(c). This is known as the diffusion model for the whisker growth.

Besides the direct impingement of atoms on the advancing front, the flux J_t in Fig. 8(c), the whisker growth model considers the following ideas:

1. impingement of atoms on the lateral sides of the whisker, J_s, and temporary adsorption of the atoms,
2. diffusion of adsorbed atoms to the tip of the whisker, and
3. evaporation of adsorbed atoms that do not reach the tip before lifetime τ_s, or when they reach the mean free surface diffusion length, λ_s, with $\lambda_s = (D_s\tau_s)^{1/2}$, as shown in Fig. 8(c).

Based on these ideas, the surface diffusion equation was developed by Dittmer and Neumann (1960) as

$$\frac{\partial n}{\partial t} = J_s + D_s\left(\frac{\partial^2 n}{\partial z^2}\right) - \left(\frac{1}{\tau_s}\right)n, \tag{18}$$

where $n(z,t)$ is the concentration of atoms along the whisker length, z the axial growth direction, and J_s the impingement flux. Solutions of this diffusion equation have been developed by several investigators: Dittmer and Neumann (1958, 1960), Blakely and Jackson (1962), Ruth and Hirth (1964), and Simmons *et al.* (1964, 1967). The diffusion model is valid only when the adsorbed layer is only a fraction of a monolayer.

2.2 Steady-State Solution

Since diffusion occurs much faster than whisker growth, a steady-state condition can be assumed, i.e., $\partial n/\partial t = 0$, and a quasi-stationary surface diffusion profile can be calculated. This steady-state solution is obtained as

$$V = \frac{dL}{dt} = V_0 + \left[\frac{4V_0\lambda_s}{d}\right]\tanh\left(\frac{L}{\lambda_s}\right). \tag{19}$$

Equation (19) was developed in a fixed frame of reference. Ruth and Hirth (1964) have obtained the steady-state solution in a moving frame of reference attached to the whisker front, and under most whisker-growth conditions, the solution was found to approach that for the fixed frame of reference.

When whiskers are grown by chemical vapor deposition in the VLS technique, the first term in Eq. (19) can be dominant for larger-diameter whiskers, so that $V \approx V_0$. On the other hand, for a whisker grown from its own vapor, or when the deposition process is physical vapor deposition, the first term, i.e., V_0, is negligible. The general behavior of the result in this case can be visualized by examining the limiting cases. For short whiskers, or during the early stages of growth, i.e., for $L \ll \lambda_s$, the second term gives for the growth rate

$$V = 2V_0L/d. \tag{20}$$

Substituting $V = dL/dt$ and integrating gives

$$L = L_0e^{(2V_0/d)t}, \tag{21}$$

where L_0 is the whisker length at $t = 0$. Thus, an exponential growth law is predicted initially.

For long whiskers, when $L \gg \lambda_s$, the whisker growth rate reduces to

$$V = \frac{4V_0\lambda_s}{d} \tag{22}$$

which gives

$$L = \left[\frac{4V_0\lambda_s}{d}\right]t, \tag{23}$$

so that a linear growth law is predicted. For intermediate lengths, a smooth transition from an exponential to linear growth is observed. The whisker-growth model does not predict a unique velocity or whisker diameter at a given undercooling. Rather, a continuum of solutions is shown to exist that relates velocity to the diameter.

2.3 Time-Dependent Model

A rigorous non-steady-state solution of Eq. (18) was obtained by Simmons *et al.* (1964, 1967) to determine the conditions under which steady-state approximation is valid, and to present a complete solution of the time-dependent whisker-growth problem. They rewrote Eq. (18) in terms of a parameter $U = n - n_e$, in which n_e is the equilibrium concentration of adatoms on a stationary whisker of radius r that is in equilibrium with the vapor phase. For the origin of the coordinate system at the base of the whisker, the diffusion equation was obtained as

$$\frac{\partial U}{\partial t} = D_s \frac{\partial^2 U}{\partial z^2} - \frac{U}{\tau} + J, \tag{24}$$

where $J = J_s - J_0$. The boundary conditions at $z = 0$ and $z = \mathrm{L}$ are given by

$$\left[\frac{\partial U}{\partial z}\right]_{z=0} = 0, \tag{25}$$

$$U(L(t),t) = 0. \tag{26}$$

The flux balance at the whisker tip gives the growth rate as

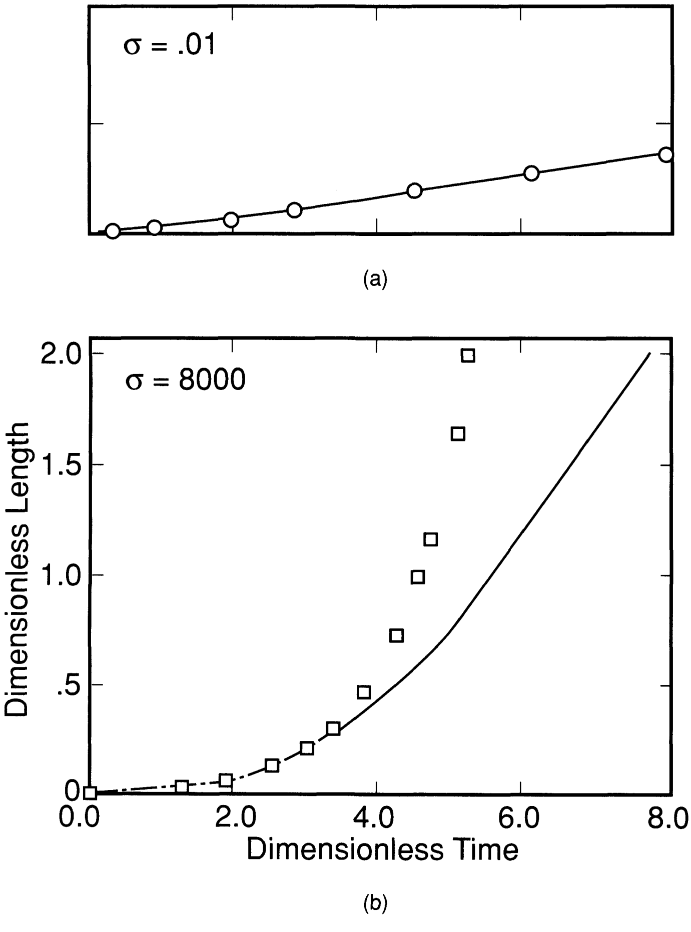
$$\left[\frac{\partial L}{\partial t}\right]\alpha = -D_s\left[\frac{\partial U}{\partial z}\right]_{z=\mathrm{L}}, \tag{27}$$

where $\alpha = v/p$, in which p is the perimeter of the whisker and v is the number of atoms in 1 cm length of the whisker including the equilibrium number of adsorbed atoms on the surface. Since experimental studies show that the number of atoms along the radius is larger than 20, the value of α for a cylindrical whisker of effective diameter d is given by $\alpha = d/4\Omega$.

An exact analytical solution of the above problem was obtained by Simmons *et al.* (1967). Except for a short transient period, the solutions in terms of dimensionless length and dimensionless time were found to depend only on one dimensional parameter, σ, defined as

$$\sigma = (J/\alpha)\tau \approx 4V_0\tau/d. \tag{28}$$

The results of the model for two different values of σ are shown in Fig. 9, in which the predictions of the steady-state model of Dittmer and Neumann (1960) are also shown for comparison.



(a)

(b)

FIG. 9. The variation in the dimensionless length, $L\ (J/4D_s\alpha)^{1/2}$, with the dimensionless time, $t' = (J/\alpha)t$, after Simmons *et al.* (1967). The square points are for the steady-state model of Dittmer and Neumann (1958).

The limiting values of velocities for the time-dependent model were also obtained. For $L \ll \lambda_s$, the result can be written in terms of dimensional parameters as

$$V = 2V_0L/d. \tag{29}$$

This limiting case gives an identical result to that obtained by Dittmer and Neuman (1960); i.e., an exponential growth law is predicted for the initial whisker length. Thus, the results of the time-dependent and the steady-state models, shown in Fig. 9(b), match quite precisely for the initial time.

For long whiskers, when $L \gg \lambda_s$, the whisker growth rate was obtained as

$$V = \left(\frac{4V_0D_s}{d}\right)^{1/2}\left(\frac{\sigma}{1 + \sigma}\right)^{1/2}, \tag{30}$$

which gives a linear growth law for the whisker length. The slope of the line, however, depends upon the value of σ. For $\sigma \gg 1$, the above result gives

$$V = \left(\frac{4V_0D_s}{d}\right)^{1/2}, \tag{31}$$

whereas for $\sigma \ll 1$, it predicts

$$V = \left(\frac{4V_0\lambda_s}{d}\right)^{1/2}. \tag{32}$$

The result for $\sigma \ll 1$ is identical to the result of the steady-state model of Dittmer and Neumann, and an excellent agreement between the steady-state and time-dependent models is seen in Fig. 9(a) for $\sigma = 0.01$. For very large values of σ, the slopes of the lines for the two models in the linear regime are different. The steady-state model overestimates the whisker length in the linear region, as seen in Fig. 9(b).

2.4 Kinetic Model

The above surface-diffusion–controlled models are valid for whisker growth with a screw dislocation or for the VLS mechanism when the growth of whisker is by the physical vapor deposition. The screw dislocation or the liquid droplet serves as an active sink for the atoms to join at the advancing front. If both the screw dislocation and the liquid droplet are present, the whisker growth will be faster. For VLS growth, when the diameter is large, i.e., $d > 1$ μm, the capillarity effects are negligible, and the velocity does not vary significantly with diameter. In this case, the second term in Eq. (19) is negligible so that the growth is controlled by the direct impingement of atoms at the droplet surface, i.e., $V = V_0$.

When the whisker is grown by the chemical vapor deposition technique, the kinetics of the reaction can also be a rate-limiting factor. For example, for the silicon whisker growth in the chloride process, the following chemical reaction produces silicon:

$$SiCl_4 + 2H_2 \rightarrow Si + 4HCl. \tag{33}$$

The reaction is believed to occur at the interface. Since the vapor–liquid interface is rough, the reaction rate will be greater at the vapor–liquid interface than at the vapor–solid interface. Consequently, most silicon atoms are supplied by the liquid droplet, and the contribution of surface diffusion is negligible. The whisker growth, in this case, will be governed by the following processes:

1. chemical reaction at the vapor–liquid interface,
2. diffusion of silicon in the liquid phase, and
3. incorporation of atoms into the crystal at the liquid–solid interface.

The transport of atoms through the liquid would be quite rapid compared to the diffusion of adsorbed atoms on the surface of the whisker. This is due to the fact that the diffusion in the liquid is faster, and the diffusion distances in the droplet are very small. In case of compounds, it is also possible to have transport by surface diffusion (Wang and Fischman, 1994). Thus, if the diffusion in the liquid and the decomposition reaction are rapid, then the whisker growth will be controlled by the atomic attachment kinetics.

The growth rate of whiskers, controlled by the interface kinetics, is given by

$$V = A(\Delta\mu/kT)^n \tag{34}$$

in which A is the kinetic coefficient and n is an exponent whose value depends upon the attachment mechanism. $\Delta\mu$ is the effective difference in chemical potential between the Si atom in the nutrient phase (vapor or liquid) and in the solid, which, for very small whisker diameters, is given by the Gibbs–Thomson effect as

$$\Delta\mu = \Delta\mu_0 - 4\Omega\gamma_{vs}/d, \qquad (35)$$

where $\Delta\mu_0$ is the chemical potential difference at a plane interface, or for $d \to \infty$, and γ_{vs} is the vapor–solid interface energy. Substituting this value in the whisker-growth equation gives

$$V^{1/n} = A^{1/n}\frac{\Delta\mu_0}{kT} - A^{1/n}\frac{4\Omega\gamma_{vs}}{kT}\frac{1}{d}. \qquad (36)$$

This equation predicts a linear relationship between $V^{1/n}$ and $1/d$. A critical diameter, d^*, is thus obtained at which the whisker velocity goes to zero, and this is given by

$$d^* = 4\Omega\gamma_{vs}/\Delta\mu_0. \qquad (37)$$

Thus, if the value of d^* is measured experimentally, then the whisker velocity can be obtained as

$$V^{1/n} = A^{1/n}(\Delta\mu_0/kT)(1 - d^*/d). \qquad (38)$$

Experimental studies on silicon whisker growth show that the whisker growth-rate dependence on d appears to be close to $n = 2$, which is for the dislocation mechanism of crystal growth. However, no dislocations have been observed in the experiments on Si growth by the chemical vapor deposition method. Thus, a mechanism of two-dimensional nucleation is proposed by Mutaftschiev *et al.* (1965) and by Chernov and Lyubov (1968), which gives

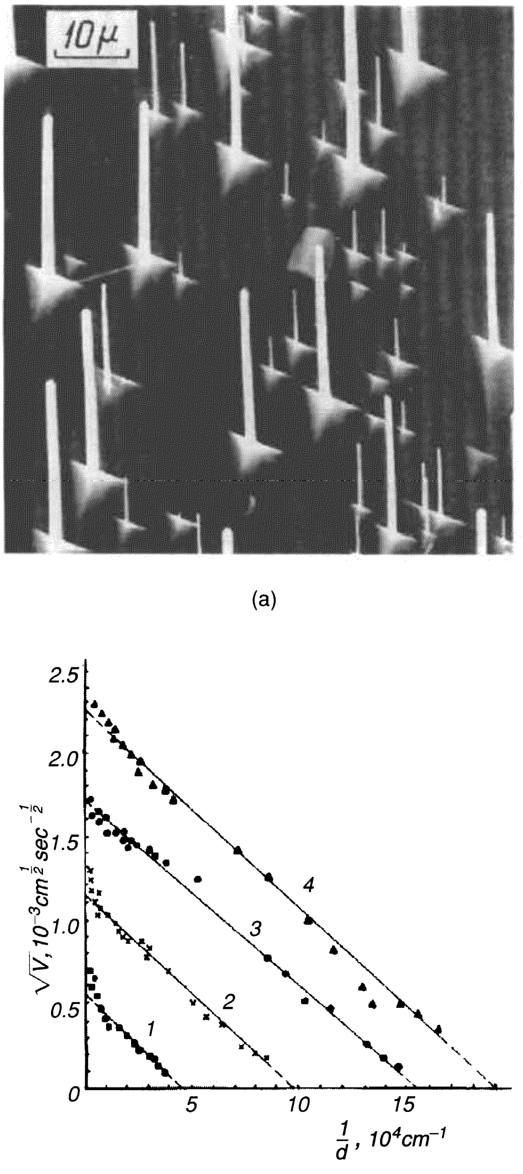
$$V = B\exp\left(-\frac{\pi\Omega\gamma_e}{3kTh\Delta\mu}\right), \qquad (39)$$

where γ_e is the specific free energy of the edge of the nucleus, h is the height of the critical nucleus (see Sec. 2.5), and B is a constant.

2.5 Whisker-Growth Experiments

Several experimental studies have been carried out to examine the growth characteristics of whiskers (Dittmer and Neumann, 1960; Price, 1960; Parker *et al.*, 1963; Parker and Hardy, 1964; Budurov *et al.*, 1972). The main driving force for the whisker growth is the supersaturation, which controls the growth rate and diameter of whiskers. Controlled studies by physical vapor deposition have been carried out for different supersaturations to obtain quantitative information on whisker-growth velocity and diameter by using the field-emission microscope and by the direct observation of whisker growth. For small whiskers, examined in the field-ion microscope, an exponential growth law is observed (Gomer, 1958; Melmed and Gomer, 1961). For large whiskers a linear law is found by Dittmer and Neumann (1960). Thus, an exponential growth rate is observed initially, which becomes linear with time or length of the whisker, as predicted by the diffusion theory.

Whisker-growth experiments have also been carried out by using the VLS technique in which whiskers can be formed at a predetermined site and their growth kinetics can be quantitatively characterized. The basic characteristics of whiskers can be seen by examining the results of the Si whiskers grown from the vapor of different supersaturations by the VLS process. The supersaturation is controlled by the ratio of $SiCl_4/H_2$ in the vapor phase. A typical picture of the Si whiskers is shown in Fig. 10(a), which illustrates the relationship between the growth rate and the diameter of the whisker; i.e., thin whiskers grow more slowly than thick whiskers. This observation shows that capillarity effects, given by the Gibbs–Thomson effect, play a crucial role in the development of whiskers since a finer whisker consumes a larger fraction of driving force to form the surfaces. The quantitative measurements of the growth rate of whiskers are shown in Fig. 10(b), which shows a linear relationship between $V^{1/2}$ and $1/d$, where d is the diameter of the whisker. Different curves are for different supersaturations, with supersaturation increasing from line (1) to line (4). The extrapolation of the lines to $V = 0$ gives the critical diameter of a hemispherical nucleus for a given supersaturation, which is given



(a)

(b)

by $4\gamma/\Delta G_V$, in which γ is the solid–vapor interface energy and ΔG_V is the Gibbs free-energy change per unit volume. These results are in agreement with Eq. (36) for $n = 2$, although they could also be fitted by the exponential growth law predicted for the two-dimensional nucleation process.

An unambiguous test of the whisker-growth theories has not been possible since many of the parameters are not known accurately. In fact, experimental results are generally compared to the theory to determine the growth law and then obtain the values of the parameters from the model.

ACKNOWLEDGMENTS

This work was carried out in part (RT) at the Ames Laboratory, which is operated for the U.S. Department of Energy by Iowa State University, under Contract No. W-7405-Eng-82, supported by the director of Energy Research, Office of Basis Energy Sciences. This work was supported (AK) by DOE Grant DE-FG02-92ER45471.

GLOSSARY

Anisotropy: Orientation dependence of interface energy and interface kinetic coefficient.

Anisotropy Parameter: Half of the percentage difference between the surface energy measured along the (100) direction and the (110) direction for a material with an underlying cubic symmetry.

Capillary Length: A characteristic length of the surface-energy effect.

Directional Solidification: Solidification under a positive temperature gradient in the liquid. The latent heat of fusion is dissipated through the solid.

Phase Field: A scalar field used to distinguish between the solid and liquid phases within a phenomenological mathematical description of first-order phase transformation.

Undercooling: A difference in temperature between the equilibrium freezing temperature and the bath temperature. The equilibrium temperature for a pure melt is given by the melting point, and that for an alloy is given by the liquidus temperature of the alloy.

INTRODUCTION

Wind-turbine technology has developed from a crude science in the 1970s to sophisticated economic devices utilizing the latest in power electronics, aerodynamics, and mechanical drive-train designs. Wind turbines now available in the market place offer renewable energy at 5 cents per kilowatt-hour economics (Smith and Ilyin, 1991). The design of wind turbines involves using low-speed aerodynamics, complex mechanical system design, and power conversion to provide low-cost and reliable power. This article covers a brief history of recent wind-energy technology, the wind resource, mechanical design principles, power conversion, and the economics of wind energy from a design and commercialization perspective.

1. HISTORY

Interest in renewable sources of energy, including the contemporary wind turbine, as commercial power sources erupted in the mid 1970s when concerns about the environmental effects of conventional energy sources gained momentum simultaneously with the OPEC oil embargoes. The U.S. federal and California state renewable-energy tax credits together with the Public Utilities Regulatory Policy Act of 1987 (PURPA) requiring public utilities to purchase power from independent power producers at the avoided cost created the necessary economic climate. Investors joined with innovative technologists to form several small enterprises dedicated to the development of wind-turbine designs capable of competing with

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

more conventional power sources in the utility market. Lessons learned during the early years of utility-grade wind-turbine development have led to understanding of the resource and technology sufficient for the evolution of successful economic wind turbines. Governmental assistance, in the form of basic research at national institutions and some forms of federal subsidies, also contributed to necessary understanding of the technology and eventual success of the industry. After the tax credits expired in 1986, a number of wind-turbine manufacturers and developers remained in business, and California dominated the world in wind-energy production.

Today, wind-power plants are going on line in different sites around the world. Given the advanced state of the wind-turbine technology, the available worldwide wind resource, and an expected increase in demand for energy sources not damaging to the environment, it is sensible to expect that wind energy will become a significant component of energy supplies in the near-term future. In this article, some of the basics on how a wind turbine operates as well as some of the issues in wind-turbine utility applications are discussed.

2. THE WIND

Wind is the movement of the air. This movement can be consistent or inconsistent; can occur all the time, only at night, or only during the day. There can be a seasonal variation with the strongest winds occurring during the summer or during the winter. Understanding the wind and integrating that understanding with technology that can harvest the electrical energy is the goal of wind-resource assessment.

2.1 The Wind Resource

The wind resource is a general term used to describe the wind energy at a location (EPRI, 1995). The characteristics of the wind resource include wind speed, wind direction, wind turbulence, wind shear, and air density. To describe a wind resource means to describe quantitatively the primary features of each of these parameters. Since wind power is directly related to the cube of the wind speed, it is obvious that wind speed is the most important parameter in resource assessment.

To identify promising sites for wind-energy development, areas with annual average wind speeds of 6.5 m/s at typical hub heights of wind turbines (25 to 40 m) should be considered. Annual wind speed is the first of several important indicators that can be used to characterize a wind resource. However, average wind speed alone is not a reliable indicator of the power in the wind. Sites having the same annual average wind speed may not have the same wind-power density as a result of differences in the wind-speed frequency distribution. The wind-speed frequency distribution gives the number of hours that the wind occurs at any given wind speed. Table 1 (Elliott, 1987) is a comparison of the average wind speeds and wind-power densities at 10 m for three sites—Culebra, Puerto Rico; Tiana Beach, New York; and San Gorgonio, California. The wind-speed frequency distributions are substantially different at the three locations, resulting in different wind-power densities.

Wind direction is another important parameter. Individual wind turbines, used for producing electrical energy, are usually sited in large parks or arrays. Understanding the wind direction is critical for siting the individual wind turbines on account of the possible wake effects between turbines and for proper placement of turbines on terrain features. An area with a single prevailing wind direction will have a different array design than an area with multidirectional winds, which requires more spacing between turbines.

Turbulence in the wind can influence operations and maintenance costs associated with a wind park and can influence the fatigue life of wind-turbine components. Turbulence is the result of rapid changes in the

Table 1. Comparison of annual average wind-power density at three sites.

Site	Wind speed (m/s)	Wind-power density (W/m^2)
Culebra, Puerto Rico	6.3	220
Tiana Beach, New York	6.3	285
San Gorgonio, California	6.3	365

wind speed or the wind direction. A commonly used indicator of wind-speed turbulence is the term *turbulence intensity* (TI), which is defined as the standard deviation of the wind speed divided by the average wind speed for the period.

Wind shear is the change in wind speed with increasing elevation. Depending upon the topography, flow structure, and surface roughness, the wind shear can be positive (wind speed increasing with increasing height), neutral (wind speed unchanged with increasing height), or negative (wind speed decreasing with increasing height). Wind-energy researchers have found that wind measurements at hub height are critical to the success of any project. Extrapolation techniques exist for estimating the wind speed at other levels in the atmosphere. The first is the standard wind-speed power law, and the second is the logarithmic power law. The only adjustment is a height adjustment from the published measurement level to a standardized height of 30 m. Several formulas exist for adjustment of wind speed from one height to a second height. The first formula is the logarithmic wind profile:

$$V(z) = (V_*/\kappa)\ln(Z/z_0), \tag{1}$$

where $V(z)$, in meters per second, is the wind speed at height Z, Z is the elevation above the ground, V_* is the friction velocity (m/s), κ is the von Karman constant (0.4), and z_0 is the roughness length. The second formula is the wind-speed power law:

$$V_2 = V_1(Z_2/Z_1)^{\beta}, \tag{2}$$

where V_2, in meters per second, is the calculated wind speed at height 2; V_1 is the observed wind speed at height 1; Z_1 is the elevation of the observed wind speed, in meters, above the ground; Z_2 is the elevation of the calculated wind speed, in meters, above the ground; and β is the wind-speed power-law exponent. The value $\beta = \frac{1}{7}$ is the most common value used in the wind industry.

Air density will also influence the production of wind energy. Air density is calculated from daily, monthly, seasonal, or annual temperature and pressure information for the site. Basic formulas for calculating air density are found in Rohatgi and Nelson (1994).

2.2 Statistical Variation and Turbulence

2.2.1 Wind-Speed Frequency Distribution The most critical information concerning the wind resource is the wind-speed frequency distribution. Several statistical relationships are available that are commonly used to develop these frequency distributions—the Weibull function and a special case of the Weibull function, the Rayleigh function.

The Weibull function is a two-parameter function that is used to estimate wind-speed frequency distribution. It is defined as follows:

$$f(V) = (k/c)(V/c)^{k-1}\exp(-V/c)^{k}, \tag{3}$$

where $f(V)$ is the Weibull probability density function for V in (m/s), and c, expressed in meters per second, is the Weibull scale factor. k is the Weibull shape factor, which describes the distribution of the wind speeds. The Weibull function is commonly used because it has been found to give a good fit to the observed wind-speed data at the surface (Wentink, 1976; Justus *et al.*, 1976) and in the upper air (Barnes *et al.*, 1975).

A special form of the Weibull probability density function, known as the Rayleigh distribution, has been found typically to represent the wind-speed frequency distributions at most sites. In the Rayleigh distribution, the shape factor (k) is assumed to have a value of 2.0. The Rayleigh distribution is expressed as

$$R(V) = (\pi V/2\mathcal{V}^2)\exp(-\pi V^2/4\mathcal{V}^2). \tag{4}$$

In this equation, $\mathcal{V}$ is the long-term average wind speed in meters per second. Corotis (1977) and Cliff (1977) found that the Rayleigh distribution provided a very good fit between the theoretical and actual wind-speed distributions.

If actual wind-speed data are available, a widely used procedure in wind-energy analysis is to assemble the wind-speed data into a histogram that shows the number of hours or observations of wind speed in discrete 1-m/s bins (Rohatgi and Nelson, 1994). A wind-speed frequency histogram is then obtained by dividing the number of observations in each bin by the total number of observations in the data set.

2.2.2 Turbulence Wind turbulence causes random load and output power fluctuations, which stress the entire wind-turbine structure—rotor, gearbox, generator, tower, and foundation. As wind-speed variations are highly irregular and cannot be described in a deterministic manner, these variations are best described by TI and other, more sophisticated methods, which include aspects of frequency, amplitude, and time. An excellent discussion on the aspects of wind turbulence is included in Rohatgi and Nelson (1994).

While TI is commonly used as a gross measure of turbulence, Barnard *et al.* (1995) and Wendell *et al.* (1993) have pointed out that there may be better indices to classify wind turbulence. On the basis of the turbulence characterization studies undertaken by Battelle, Wendell *et al.* (1993) proposed two other terms to characterize more adequately the turbulence characteristics of a site, specific to wind-turbine technologies. These two terms are turbulence engulfing gust (TEG), which refers to those eddies that affect the entire rotor disk at once, and turbulence fluctuating shear (TFS), which refers to those eddies that only affect a portion of the rotor area through shear flow. Recently, Barnard *et al.* (1995) proposed a model relating conventional wind-speed measurements and wind-turbine blade fatigue. Based on case studies obtained from the National Renewable Energy Laboratory, this model is shown to be a much better predictor between low-turbulence and high-turbulence cases than the TI index.

3. TURBINES

3.1 Power in the Wind

Before any mechanical aspects of wind turbines can be discussed, the driving force of the machines must be considered. For a given wind speed V, the power in the wind depends on the area presented through the equation

$$P_T = \tfrac{1}{2}\rho A V^3, \tag{5}$$

where the subscript T of P refers to the total power existing in the wind, ρ is the air density, and A is the presented area, or swept area as it is commonly referred to by wind engineers. There is a theoretical limit, called the Betz limit, of approximately 59% to the efficiency a wind turbine can extract power from the wind. The Betz limit can be derived by an actuator disc model as in Eggleston and Stoddard (1987). Any wind turbine will have an intrinsic efficiency, called the power coefficient C_P, which varies with wind speed. It is customary to give the power coefficient as a function of the ratio of linear blade-tip speed to wind speed or simply the tip-speed ratio, λ, the dimensionless quantity

$$\lambda = r\Omega/V, \tag{6}$$

where r is the radius of the rotor and Ω is the angular velocity of the wind turbine in radians per second. The numerator in this equation is the tip speed of the blade. The aerodynamic performance of a wind turbine is specified when the power coefficient is given as a function of the tip-speed ratio over the range of wind speeds in which the wind turbine operates. C_P is determined experimentally, or through a detailed aerodynamic calculation as described below. Figure 1 is a typical C_P curve. C_P has a theoretical maximum dictated by the Betz limit, but most wind turbines have a maximum C_P of 50% to 52%. This formulation allows the power extracted by a wind turbine to be given by the closed-form equation

$$P = \tfrac{1}{2}\rho A V^3 C_P. \tag{7}$$

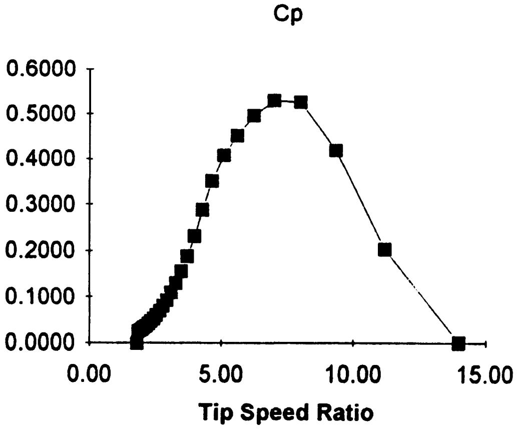

FIG. 1. Hypothetical curve of C_P.

The aerodynamics of the blades determines the power coefficient. If the lift and drag coefficients of the blades are known, then the power coefficient can be calculated using an iterative approach such as the one derived in Wilson *et al.* (1976), or in Eggleston and Stoddard (1987). Many computer programs are available that perform this calculation. Once the power coefficients are known, a power curve as a function of wind speed can be calculated. Figure 2 is a typical curve of power versus wind speed. There are three critical wind speeds for any wind turbine. The first is the cut-in wind speed, v_{cutin}, that at which the wind turbine can first produce power. The second critical point, v_{rated}, is the lowest wind speed at which the turbine reaches its rated power. The last critical point, v_{cutout}, is the high-wind cutout speed above which the wind turbine is shut down. These three points identify four distinct regions of the power curve. In the first region, left of v_{cutin}, the wind speed is too low to generate positive power. In the second region, between v_{cutin} and v_{rated}, power increases from zero to rated power. In the third region between v_{rated} and v_{cutout}, the power is constant at the wind turbine's rated level. This is idealized, and most wind turbines vary in output power somewhat after rated power. In the last region, above v_{cutout}, the wind turbine is shut down to prevent excessive winds from damaging the equipment.

The power of a wind turbine is regulated in one of two ways. The first method, called pitch regulation, depends on a mechanism to pivot the blades to higher angles of attack, making the blades operate less efficiently aerodynamically and shedding excess power in the wind. This approach requires that the blade pitch angle be controlled on a continuous basis when the wind speed is greater than v_{rated}, to track the changing wind speed. The second method used to regulate wind-turbine power, called stall regulation, depends on the blades being designed to go into aerodynamic stall above v_{rated}. In this passive approach, no blade-pitching mechanisms are required, although some stall-regulated wind turbines use some sort of aerodynamic spoiling mechanism to stop the turbine.

A useful quantity used in comparing the performance of wind turbines is the annual energy capture per square meter of swept area. This quantity depends on the wind resource. If the wind speed is partitioned into uniform intervals, with V_i being the center of interval i, then annual energy per square meter of swept area for a wind turbine is given by the equation

$$e = \tfrac{1}{2}\rho \sum_{i=1}^{V_{\max}} [F(V_i + 0.5) - F(V_i - 0.5)]V_i^3 C_{P,i}, \tag{8}$$

where $F(V_i)$ is the wind-speed distribution function for the site. When the wind-speed distribution is not known, the Rayleigh distribution is normally used. The standard air density at sea level is $\rho = 1.2$ kg/m^3. Using an annual average wind speed of 8 m/s, and Betz limit for C_P, the annual energy captured per square meter of swept area is 3038 kW · hr/yr · m^2. This represents the theoretical limit for energy capture for a wind turbine. The power coefficient can be as high as 0.53

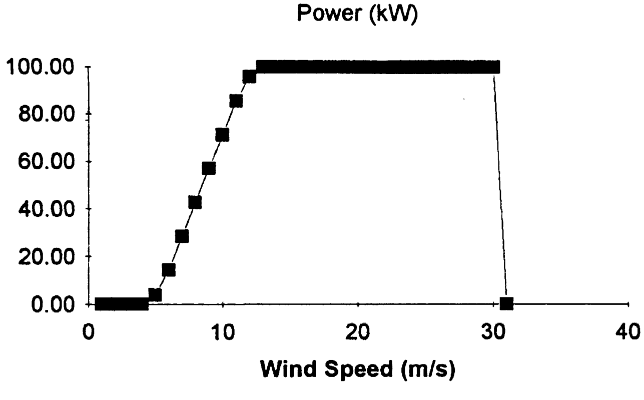

FIG. 2. Hypothetical power curve for 100-kW wind turbine.

for the optimum wind speed but is much less than that value for other operating wind speeds. The annual energy per square meter for the hypothetical 100-kW wind turbine of Figures 1 and 2 is 1700 kW·h/yr·m^2, which is a more realistic value. Variable-speed operation of a wind turbine is an advantage in terms of energy capture, because the rotor changes speed allowing the blade tips to follow the maximum power coefficient over a wide range of operating speeds, thereby capturing more energy. Constant-speed wind turbines are often designed so that the maximum power coefficient is aligned with the design wind-speed distribution to give the maximum energy capture.

3.2 Mechanical Aspects of Wind Turbines

Wind turbines can be broadly categorized into two types: horizontal-axis wind turbines (HAWTs) in which the rotating axis is horizontal, parallel to the wind direction, and supports the blades in a plane perpendicular to the ground, and vertical-axis wind turbines (VAWTs) in which the rotating axis is vertical and the wind turbine has the appearance of an egg beater. HAWTs are by far the more common type of wind turbine and are commercially available in any size ranging from a couple of hundred watts to more than 1 MW. VAWTs are commercially available through a small number of manufacturers but appear to have a number of advantages that may make them cost competitive in the near future. HAWTs and VAWTs are each discussed in separate sections below so that the fundamental properties of each system can be considered.

One property that all wind-turbine types have in common, referred to as the "square-cubed law," illustrates how the cost effectiveness of a wind-turbine architecture is governed by the size of the wind turbine. The square-cubed law states that the loads on the components of a wind turbine are proportional to the cube of the diameter of the rotor, while the energy capture is proportional to the square of the diameter of the rotor. The consequence of this law is that the cost of the wind turbine will increase faster than the benefit for large wind turbines, and for any design type, an optimum design size will exist at the point at which the increasing variable costs overtake the fixed costs of the system. Holley *et al.* (1987) reported this law for particular wind-turbine designs. The optimum square-cube rotor diameter varies widely with the design. Typical optimum values fall in the diameter range corresponding to between 300 and 600 kW for HAWTs. The square-cubed law optimum size is not as easy to define for VAWTs, because the height of a VAWT can vary independently from the diameter, but the optimum sizes of VAWTs on a cost-of-energy (COE) basis are thought to be somewhat larger than those of HAWTs.

3.3 Horizontal-Axis Wind-Turbine Trade-offs

Figure 3 is an illustration of a typical two-bladed HAWT, in which the basic components have been identified. HAWTs have the following design options and trade-offs:

1. 2 or 3 blades. Two blades cost less than three blades, but two-bladed systems require a more complicated teetered hub.
2. Free yaw or active yaw control. Free-yaw systems risk higher yaw rates, which induce large gyroscopic loads, but effective yaw-control systems are notoriously difficult to design.
3. Upwind or downwind orientation. Upwind wind turbines are quieter and capture more energy but usually require an active yaw-control system.
4. Power regulation by aerodynamic stall or by blade pitch. Stall offers mechanical simplicity but very difficult aerodynamics for limiting power. Blade pitch offers good control of the average aerodynamic power, but it requires complicated mechanical control mechanisms and has large load fluctuations.
5. Constant-speed or variable-speed operation. Variable-speed operation allows the rotor to operate at the maximum aerodynamic efficiency in below-rated winds, and offers potentially better power quality, but it requires costly and complicated electronics and has higher losses.

3.4 Horizontal-Axis Wind-Turbine Input Loads

Most loads entering a wind turbine originate from aerodynamic forces at the blades. Figure 4 shows a blade section. Figure 4(a)

is an illustration of the wind input on the blade section, and 4(b) is an illustration of the resulting loads. The forces on an airfoil are normally resolved into lift force F_L, and drag force F_D. F_L and F_D can be combined to form the resultant aerodynamic force, F_A. For the purposes of wind-turbine load analysis, it is more convenient to resolve F_A into the lead-lag force F_{LL}, in the direction of the blade chord, and the flatwise force F_{FW}, perpendicular to the blade chord. In addition to the aerodynamic forces, there is an aerodynamic moment M_A, which tends to pitch the blade; i.e., the moment vector points in the direction of the blade length. If the blade element is twisted, pitched, or coned, if the rotor is tilted, if the rotor is yawed out of the wind, or if blade vibration has translated or changed the orientation of the blade element, then appropriate coordinate systems

need to be invoked. At any time increment, the loads F_{LL}, F_{FW}, and M_{A} can be calculated for each blade section and summed over the entire blade to find the forces and moments at the blade root–hub intersection. When the loads are combined at the hub from the two or three blades, the lead-lag forces combine to form the productive torque on the main shaft, and the flatwise forces combine to form the thrust load on the system. The aerodynamic moments affect the blade root loads, and the blade pitch link mechanism if one exists, but normally do not combine to form global loads. As mentioned above, any changes from the simple orientation of the blade elements result in off-axis loads, which combine to form the yaw forces, among others. Yaw forces cause the rotor to turn into or out of the prevailing wind direction. The yaw rate combines with the rotor angular velocity and the rotor inertia to form gyroscopic bending moments on the main shaft. These loads are transmitted to the bearings, transmission, frame, yaw bearing, tower, and foundations.

It is significant to note that for horizontal-axis wind turbines, the wind loading is highly stochastic. The inertial subrange of the wind, at which most energy is created, has a strong random component. The blades rotate through turbulent eddies, ground boundary-layer–induced wind shear, and tower shadow, which all contribute to the varying nature of the loads. Because of the highly varying nature of the loads, several HAWT components will be designed primarily by random loads. The design driver can be either fatigue considerations or extreme limits. Components will be designed by high-wind survival loads or by dynamic operating load cases. International standards now exist that specify which load cases must be satisfied to obtain certification of wind turbines. The International Electrotechnical Commission (IEC) (1994) establishes four wind-speed classes to be used in establishing loads, with annual average wind speeds of 10, 8.5, 7.5, and 6 m/s, respectively, and an average turbulence intensity of 0.17 for all four classes. Standard IEC 1400-1 should be consulted for international design standards.

3.5 Horizontal-Axis Wind-Turbine Dynamics

To obtain a complete picture of the loads on a wind turbine, the dynamics of the system must be addressed. Blade vibrations have a considerable effect on loads both at the blade-hub connection and on the blade itself. Drive-train dynamics affect how the loads at the hub are transmitted to the rest of the system, influencing the power generated as well as the loads that affect design of the transmission, frame, bolts, yaw bearing, tower, and foundation.

The blades can best be modeled dynamically either by a finite-element approach or by assigning modal coordinates in a generalized coordinate system. The drive train can be modeled as a two–degree-of-freedom lumped-mass system as shown in Fig. 5.

Using Fig. 5 as a guide, the following two equations of motion may be written down:

$$I_R\alpha_R + d(\Omega_R - \Omega_G) + k(\theta_R - \theta_G) = Q_R, \tag{9}$$

and

$$I_G\alpha_G - d(\Omega_R - \Omega_G) - k(\theta_R - \theta_G) = D(\Omega_G - \Omega_0) = Q_G. \tag{10}$$

Given the input torque Q_R, the rotor and generator inertias I_R and I_G, the torsional

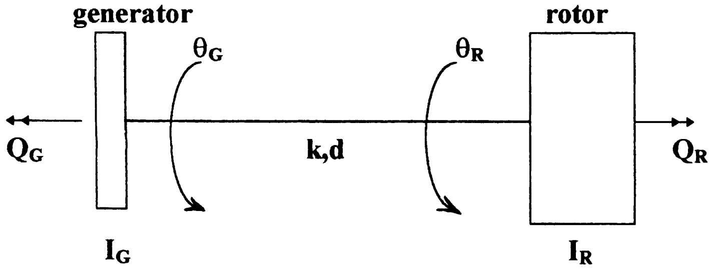

FIG. 5. Drive-train free-body diagram.

stiffness k, the structural damping d, the generator synchronous speed Ω_0, and the generator slip constant D, the two equations may be solved numerically to determine the rotor and generator speeds, Ω_R and Ω_G. This simple model will predict the dynamic motion of the drive train. Notice that in the equations, the absolute angles θ_R and θ_G are never needed. Since the model includes the transmission, transmission losses may be added. Also, care needs to be taken to insure that the inertias I_R and I_G are referred to the same speed. If a more detailed model is needed to predict, for example, the behavior of the yaw system, then the equations above need to be expanded to include additional variables and constants.

3.6 Vertical-Axis Wind Turbines

Vertical-axis wind turbines have historically played a less significant role in the commercial wind-energy industry. The reasons for this range from the lower aerodynamic efficiency of VAWTs compared to HAWTs, to the tendency of markets to accept the more familiar technology. Since the VAWT blade does not require twist, uniform blades are satisfactory. This allows the potential cost of the blades to be significantly lower per foot than for HAWTs, thus offsetting the requirement of significantly more blade length than for HAWTs.

The concept for the modern vertical-axis wind turbine was introduced by the French engineer Darrius, who observed that if the blades are formed into the shape that a spinning rope would assume if it were constrained on the ends, then the operating stresses in the blades would be mostly in tension, the load direction in which blades offer the most strength. In addition, constraining the blades at the top allows guy cables to be utilized to stiffen the tower top. This concept was put into practice in the 1970s and 1980s by industries and government laboratories in the United States and Canada. The early VAWTs showed potentially excellent longevity but were not cost competitive with many HAWTs. However, improved aerodynamics and reduced blade manufacturing costs now provide the technology to make VAWTs potentially as cost effective as HAWTs, particularly with larger sizes.

Vertical-axis wind turbines present the designer a different type of problem than HAWTs. The primary design loads for HAWTs are likely to result from the random fluctuations in the wind. For VAWTs, the primary consideration is the stiffness of the system. The fundamental frequency of the central tube decreases with increasing rotational speed and must be kept above zero. This requires the central tube to have a large inertia and the guy cables to provide considerable stiffness. Once the stiffness requirements are satisfied, then the system will most likely be able to withstand whatever operating and high-wind–survival loads are generated. The blades have a similar problem. Rotation causes centrifugal softening of the blades, which must maintain enough stiffness to resist divergence. Larger VAWTs are also subject to blade flutter problems, requiring the blades to have added stiffness.

VAWTs are subject to large periodic loads that are generated during operation. VAWT blades move through a wide range of angles of attack during each rotation, causing large fluctuations in aerodynamic loads with frequencies that are multiples of the rotational frequency. One tool that is useful for identifying potential resonance problems is a Campbell diagram, which displays how the excitation frequencies cross the structure's natural frequencies as a function of rotor speed. Figure 6 shows a Campbell diagram for the Sandia 34-m VAWT in Bushland, Texas (Ashwell, 1992). The abscissa of Fig. 6 is the operating speed of the wind turbine, and the ordinate is the frequency. The horizontal lines represent the different natural frequencies of the system, which vary with operating speed. The diagonal lines emanating from the origin are the 1 per revolution or 1P, 2P, 3P, 4P, and 5P frequencies at which structural members can be excited by aerodynamic forces as they rotate in and out of the wind. Crossings of any natural frequency with any per revolution excitation at a rotational speed will result in system resonances at that rotational speed and must be avoided. The abbreviations represent the different natural frequencies; for example, 1F, 2F, and 3F represent the first, second, and third blade flatwise motion of the blade flapping perpendicular to the direction of rotation. The tower in-plane and out-of-plane (of the blades) vibrations are denoted by TI and

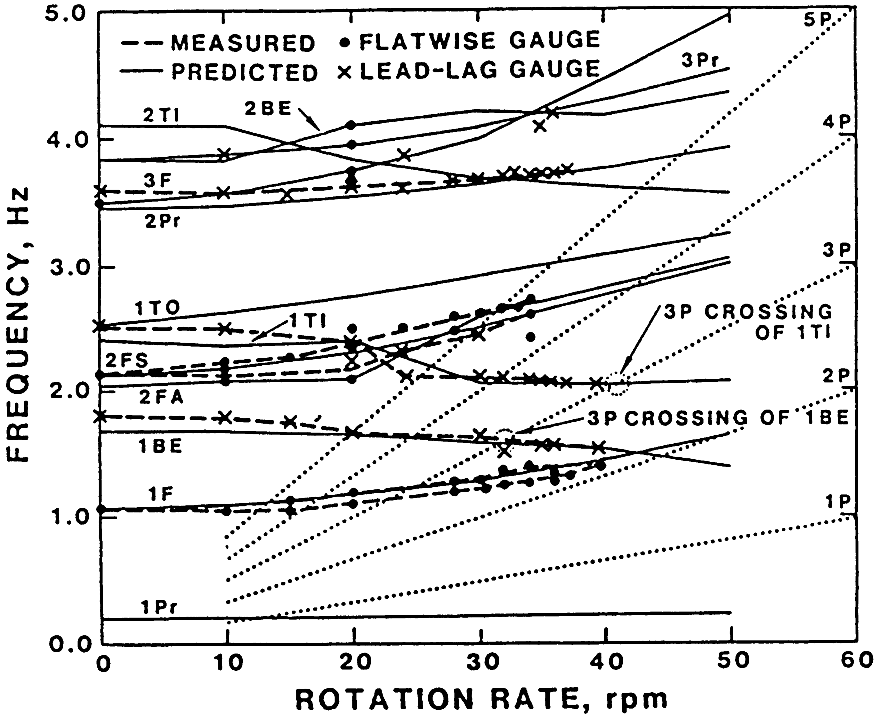

FIG. 6. Campbell diagram for the Sandia 34-m VAWT.

TO, respectively. This type of resonance is avoided in three-bladed vertical-axis wind turbines.

The rotor of a VAWT can also be modeled by a simple system, such as that given for the HAWT.

4. AIRFOILS

Development of suitable airfoils is a crucial element of modern wind-turbine design. The airfoil's function is to exert an influence on the free-stream flow so that lift is produced in such a manner as to enable the rotor system of the turbine to produce power. Successful wind-turbine airfoil design combines three main factors, which are

1. an understanding of the more important aspects of two-dimensional airfoil theory,
2. an analysis of the aerodynamic environment in which the airfoil will operated, and
3. a determination of the airfoil characteristics that are most desirable for the wind-turbine operational applications.

4.1 Aspects of Two-Dimensional Flow about an Airfoil

4.1.1. Forces on the Airfoil Basic airfoil data are set forth in the form of nondimensional force and moment coefficients as shown in Fig. 7. Of principal interest are the lift, drag, and moment coefficients, expressed for two-dimensional airfoils as c_l, c_d, and c_m, respectively. They are usually expressed in terms of angle of attack α, or with respect to each other, the most common being $c_l(\alpha)$, $c_d(\alpha)$, $c_m(\alpha, c_l)$. From c_l and c_d, the normal (c_n) and chordwise (c_c) force coefficients can be calculated. While the difference between c_l and c_n is usually small, the relationship between c_c and c_d can be very significant. When the c_c component is directed forward, a driving force results, thus enabling the rotor to produce power.

The pitching moment and aerodynamic center (designated by the subscript ac) are of significance in turbine design because of structural considerations. Following the generally accepted NACA (National Advisory Committee on Aeronautics) practice, the

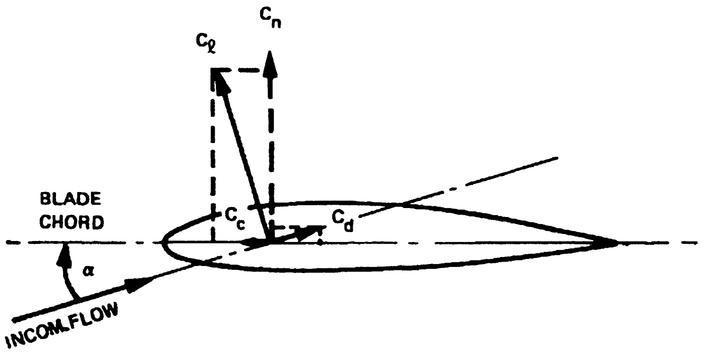

FIG. 7. Basic airfoil data.

pitching moment in reference to an axis passing through the aerodynamic center, designated by $c_{m,ac}$, remains constant with respect to c_l until stall is reached. The aerodynamic center is usually considered to be close to the $\frac{1}{4}$-chord point of the airfoil. The chordwise component of aerodynamic force does not contribute significantly to the moment about the ac, as the major contributor is the normal component, approximately equal to lift. Given this assumption, the location of the center of pressure (designated by the subscript cp) can be expressed as $x_{cp}/c = c_{m,ac}$, where c is the blade chord and x_{cp} is the chordwise distance from the point of application of the normal force to the aerodynamic center. The value of x_{cp} is positive when measured ahead of the aerodynamic center and negative when aft of the aerodynamic center. The value of $c_{m,ac}$ has a very significant effect on blade aeroelastic phenomena. When $c_{m,ac}$ is greater than zero, center-of-pressure movement resulting from increased angle of attack generates a force that resists torsional deflection of the blade. When $c_{m,ac}$ is less than zero, additional torsional loads can result. For this reason, early successful helicopters used symmetrical sections where $c_{m,ac} = 0$. Further developments in the understanding of aeroelastic phenomena have allowed designers to use cambered airfoils, which can produce higher lift coefficients in spite of $c_{m,ac}$ values of less than zero.

The primary purpose of the airfoil shape is to produce lift. The simplest way to visualize the lift generation is shown in Fig. 8 where an infinite mass of an ideal fluid flows with a velocity V around a cylinder of infinite length about which exists a circulation of strength Γ. By applying the Kutta–Jukowski law (Abbot and Von Doenhoff, 1959), an important element in the application of classic vortex theory, the relationship between the lift on the unit length of the cylinder and the strength Γ of the circulation about the cylinder can be expressed as $l = \rho U_\perp \Gamma$, where Γ is the strength of circulation

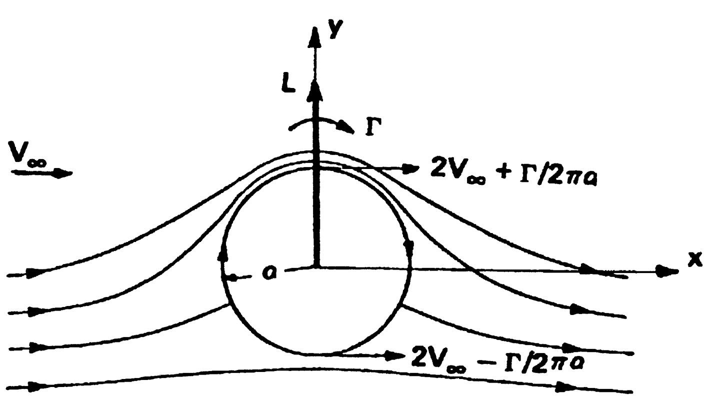

FIG. 8. Circulation around a cylinder.

around the airfoil, ρ is the air density, and $U_\perp$ is the air velocity component perpendicular to the vortex filament at that section.

The flow pattern can be described through the so-called complex potential $w = \theta + i\psi$, where θ is the velocity potential, ψ is the stream function, and i is the square root of negative 1. This equation can be represented as a function of the complex variable $z = x + iy$, $w = f(z)$. From this relationship, the velocity of the flow at a given point z can be obtained from the following differentiation: $dw/dz = u + iv$, where u is the velocity component in the x direction and v in the y direction.

The complex potential of uniform flow around a cylinder with circulation is

$$w(z) = V_{\text{freestream}}[z + (a^2/z)] + i(\Gamma/2\pi) \ln z,$$

where a is the cylinder radius.

By performing the previous differentiation, the classic flow patterns shown in the illustration can be obtained from this equation. The illustration shows that the streamlines at the top of the cylinder are closer together at the top of the cylinder than at the bottom, indicating that the velocity of local flow in the upper region is higher than the lower. From Bernoulli, the pressure on the top of the cylinder will be lower and the pressure on the bottom higher than the freestream. Thus, an upwards lift force is generated. Note that because of the symmetry of flow with respect to the y axis, no drag is present in this model. The stagnation points should also be noted, being those areas where the incoming flow has only a radial velocity component with respect to the surface of the cylinder.

From this model, much of the work of the development of the theory of finite-thickness airfoil sections began. In the early part of the century, Jukowski (Stepniewski and Keys, 1984), by using conformal transformations, developed a way of transforming a cylinder into an airfoil shape, while the flow about the cylinder with circulation was transformed into a corresponding flow about the airfoil. The conformal transformation as described by Durand (1943) consists of a method in which a geometrical field 1, characterized by an assemblage of points and lines, may be transformed into another field 2, point by point and line by line, in such a manner that the infinitely small element of area in field 1 shall transform, in field 2, into an element of similar geometrical form and proportions, while at the same time, the aggregate in field 2 may be quite different from that in field 1. While this approach produced fair approximations with practical tests, its lack of consideration of viscous effects did not permit the definition of a pressure gradient to produce desired boundary-layer conditions, which is the basis of much modern airfoil design.

4.1.2 Viscous Effects and Boundary Layer The simple visualization previously discussed considers air as an ideal incompressible, nonviscous fluid and ignores the tangential shearing forces resulting from viscosity. It should be noted that all aerodynamic forces acting on the airfoil are influenced by viscosity, the magnitude of these influences being dependent on Reynolds number. The dependence of aerodynamic forces on Reynolds number is sometimes called the "scale effect."

Of principal interest to the airfoil designer is the condition of the boundary layer. Here, viscosity is of great significance to the boundary-layer mechanics. The air flowing next to the surface has no velocity with respect to the surface, whereas at some distance from the airfoil, the velocity is that of the freestream. This layer of air is called the boundary layer. The flow of air over an airfoil is laminar near the leading edge, with the boundary layer being relatively thin. The flow then passes through a transition zone and becomes turbulent, but still attached to the airfoil. The boundary layer is much thicker in the turbulent zone.

Under certain conditions the boundary layer will separate entirely. The flow over the upper surface will experience an initial reduction in pressure with the resultant increase in velocity and then recover against an area of increasing, or adverse, pressure gradient. Against an adverse pressure gradient, both laminar and turbulent boundary layers will eventually separate. At the point of separation, the surface friction is zero. Ahead of this point, the flow in the boundary layer is downstream, and after the point of separation, it is upstream. It will be appreciated that the skin friction drag for laminar flow is significantly lower than for turbulent flow, while the turbulent boundary layer is more stable than the laminar flow because of the greater mixing in the turbulent boundary layer. Faster moving air particles from the outer edge of the boundary layer with more inertia mix within the boundary layer contributing to the total momentum of the boundary layer. This enhances the boundary layer's ability to move against an adverse pressure gradient. It must be noted that the condition of the boundary layer is significantly influenced by roughness and will strongly influence the selection of an airfoil for wind-turbine application. A pressure distribution curve for a typical nonlaminar airfoil is shown in Fig. 9.

Separation is commonly associated with stall, in which the boundary layer separates such that it influences the circulation about the airfoil, with a rapid decrease in lift with increasing angle of attack and a large increase in drag. The type of stall encountered is greatly influenced by the geometry of the leading edge and by the pressure distribution. While the airfoil designer has considerable leeway on the sharpness of stall, there is comparatively little understanding of deep stall conditions. Such conditions exist especially in wind turbines that use aerodynamic stall to regulate rotor power.

4.1.3 Definition of the Airfoil Shape

It is evident that the design of an airfoil can best be accomplished by establishing the desired boundary-layer condition with a pressure distribution that effectively defines the shape of the airfoil. While Jukowsi's approach gave fair correlation with practical tests, it was not until the 1930s that the path to modern airfoil design was started. Theodorsen (1932) developed a theory of wing sections of arbitrary shape. Jacobs (1939) subsequently inverted this method in order to determine an airfoil shape that would produce a desired pressure distribution. Thus the way was open to the modern methods of defining a boundary layer that would produce the desired airfoil characteristics and the shape of the airfoil itself.

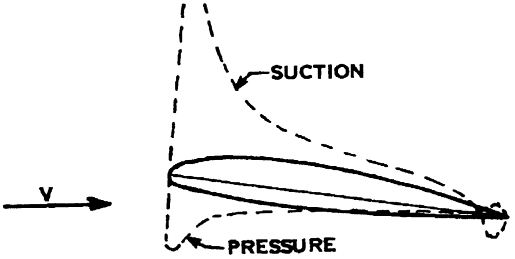

FIG. 9. Pressure-distribution curve for a typical nonlaminar airfoil.

One major environmental influence is the accumulation of dirt and insects on the leading edge of the airfoil. Sufficient debris can accumulate to degrade seriously the performance of the airfoil. Significant decreases in maximum lift coefficient and large increases in drag can result from dirt accumulation, and these factors must be taken into account in the airfoil specifications. Early wind turbines suffered catastrophic power losses well in excess of 50% because of environmental degradation of the blades.

4.2 Determination of Airfoil Characteristics

The airfoil design objectives and specifications will be selected to produce the most effective rotor system for a given wind resource, environmental conditions, and turbine generator capacity. The airfoil specification will be tailored to a particular type of rotor system and the location of the airfoil section on the blade. For instance, the requirements for the root-section airfoil of a horizontal-axis wind turbine are significantly different from the tip region because of the great difference in speed and angle of attack. A stall-regulated machine will have an airfoil where the boundary layer is designed to separate and the airfoil stall at a given windspeed, thus preventing the rotor from overpowering the turbine. In this case, the stall regulation is achieved by having the airflow separate at a designed angle of attack and lift coefficient. The maximum lift coefficient may also be suppressed to avoid overpowering the turbine in high winds, thus allowing a larger rotor and greater energy capture in lower winds. The airfoil designer will also look at the constraints on the airfoil. For instance, a designer may specify a minimum airfoil thickness for structural reasons. Another example is the requirement for vertical-axis wind turbines to produce lift on both the upwind and downwind passes of the blade, which further restricts the airfoil design options. The requirements may also specify a limit on the amount of laminar flow on the upper section, especially where manufacturing techniques might restrict the achievement of reduced drag by maximizing laminar flow. The airfoil design objectives can also specify defined stall characteristics, susceptibility to roughness, and numerous other less significant characteristics.

Once the wind turbine designer has specified the airfoil requirements, a modern design and analysis program such as the Eppler Airfoil Design and Analysis Program can be used (Eppler and Somers, 1980). This program consists of a conformal-mapping method for prescribing velocity-distribution characteristics and producing the physical airfoil shape required to achieve them, a panel method for analysis of existing airfoil shapes, and a boundary-layer method. From the design objectives, a drag polar can be produced from which the program can specify the necessary velocity distribution. Given the capabilities of such programs, the designer can directly determine the velocity distributions that will produce the desired boundary-layer conditions.

Thus, with correct definition of the airfoil requirements and skilled use of tools such as the Eppler program, the profile of the wind-turbine blade can be accurately defined. These results can then be used with a variety of methods to determine the actual rotor performance. Many of these methods are adapted from propeller and helicopter rotor design, such as momentum theory, vortex theory, and blade element theory. These methods give reasonably accurate predictions of wind-turbine performance. The main area of development still remains the achievement of a better understanding of the airfoil requirements of the wind turbine in service conditions.

5. ELECTRICAL-POWER GENERATION

The airfoils and mechanical drive train of the wind turbine harness the energy of the wind and make it available for use as mechanical power. This power can be used, as in earlier times, for turning mill stones or pumping water. However, the use of wind energy for these purposes is most efficient when the point of collection and the point of use are coincident. Converting the mechanical motion of the wind to electrical energy provides the means to collect the energy at the point of the greatest wind resource, transport it to points of use, and convert it back to mechanical or other forms for use in other activities. This energy conversion and transportation requires an electrical generator, possibly a power electronic converter, and an electrical network or "balance of plant."

5.1 Generators

Many generation technologies have been proposed and studied for this application, but the most commonly used generators are the induction and synchronous generators. Of these, the induction generator is by far the most widely used generator for grid-connected applications. Induction generators require reactive power for excitation and are generally not well suited for stand-alone application because of this need for reactive power.

Constant-speed wind turbines have traditionally used induction generators directly connected to the synchronous utility network. The reactive demand of the induction generators is then supplied by the network but can be compensated at the generators with a series of switched capacitor banks so that the power factor of the turbines will be 1.0 at full power output. The reactive demand of the substation and collection system is then corrected at the substation by additional banks of switched capacitors. Using this method, the wind-power plant can generate power at near-unity power factor at any power level. During periods of light winds, when the wind turbines are not operating, this capacitance is available to be switched to aid in voltage stability by the utility.

The mechanical power delivered by the turbine to the generator shaft is given by the product of the rotor shaft speed and the torque on the mechanical shaft:

$$P_m = \omega_m T_m. \tag{11}$$

The mechanical power is converted to electrical power in an induction generator according to the relationship

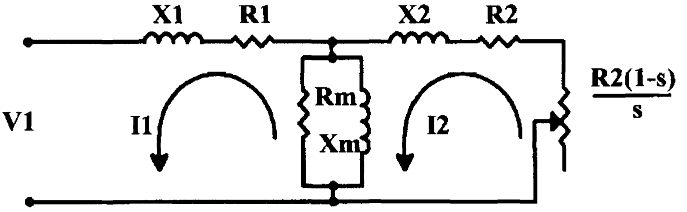

FIG. 10. Induction generator schematic.

$$P_m = 3I_2^2R_2(1 - s)/s, \tag{12}$$

where I_2 is the rotor current, R_2 is the rotor resistance, and s is the slip speed given by $s = (\omega_0 - \omega_m)/\omega_0$. ω_0 is the electrical synchronous speed, $3600/(p/2)$ rpm where p is the number of magnetic poles of the generator, always an even number, usually 2 or 4. Figure 10 is a schematic diagram of one phase of a three-phase induction generator connected to a utility, represented by V_1. Knowing the generator parameters and using Kirchhoff's laws to solve for the stator phase current I_1 will give the real and reactive power delivered to the utility as $S = V_1I_1^*$.

A constant-speed wind turbine using directly connected induction generators will generate no appreciable harmonics and have no synchronization problems. With power-factor correction capacitors connected at the wind turbines and at the wind-power plant substation, the power factor can be controlled to be near unity at any power level. A wind-power plant using constant-speed wind turbines with induction generators can be made to generate power with no power-quality issues at any power level.

Synchronous generators (Fig. 11) are capable of supplying both real and reactive power to the network but require synchronization to the network before direct connection, are more expensive than induction generators, and are less tolerant of transient overtorques that may occur from wind gusts. Small- to medium-sized wind turbines will commonly use induction generators and larger wind turbines will sometimes use stall-regulated air foils and synchronous generators.

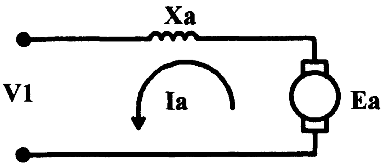

FIG. 11. Synchronous generator schematic.

The mechanical power is converted to electrical power in a synchronous generator according to the relationship

$$P_m = 3V_1|E_a| \sin\delta/X_a, \tag{13}$$

where V_1 is the terminal voltage, X_a is the synchronous reactance, E_a is the excitation voltage, and δ is the excitation phase angle.

A constant-speed wind turbine using directly connected synchronous generators will generate no appreciable harmonics and be able to control reactive power and the terminal voltage by varying the excitation phase angle δ. A wind-power plant using constant-speed wind turbines with synchronous generators can be made to generate power with no power-quality issues at any power level.

5.2 Power Electronic Converters

Variable-speed wind turbines use an electronic power converter to convert the variable frequency of the wind turbine to the synchronous frequency of the utility network. Power electronic converters typically used in wind-turbine application include both line-commutated and force-commutated topologies. Line-commutated converters using thyristor technology are less expensive but require reactive power and are used with synchronous generators only. These line-commutated converters are highly efficient, but because of their switching control, which allows for control of device turnon but requires that the line current go through a zero crossing for device turnoff, generate a high level of current harmonics.

State-of-the-art force-commutated converters using solid-state devices such as isolated-gate bipolar-transistor (IGBT) power-electronic devices can operate to control both the real and reactive power of the wind turbine. The converter can operate to control the amplitude of the line-current wave form by determining the power generation from the wind turbine, and the frequency and phase angle of the line-current wave form by monitoring the utility voltage. This method ensures that the wind turbine is always synchronized with the utility voltage regardless of the utility frequency, either 50 or 60 Hz. This method also controls the power factor of the wind turbine by controlling the current displacement angle.

Power electronic converters will typically generate some level of harmonics due to the switching, with higher switching frequencies generating cleaner wave forms with lower harmonics. The high switching frequencies that are possible using IGBT devices produce a current wave form of very good fidelity and low harmonic components. The step-up transformers and transmission lines that connect the wind turbines to the utility further reduce the already low harmonics so that at the point of common coupling, there is very little harmonic distortion due to the wind-turbine converters.

Recent release of recommended practices such as IEEE-519 have specified current-harmonic limits at the point of common coupling with the utility for power converters or other electrical equipment. This recommended practice calls for a maximum total harmonic distortion of the current and a maximum distortion due to any single harmonic at the point of common coupling to the high-voltage utility system. A wind-power plant using variable-speed wind turbines with power electronic converters can be made to generate power within these harmonic-power quality limits at any power level.

The capability to control reactive power can provide transmission efficiencies and voltage stability. This capability is available during high winds when generating real power and also during light winds when no real power is being generated. This feature is particularly valuable on weak grids to enhance voltage stability.

6. ECONOMICS

The method described below is the one recommended by the National Renewable Energy Laboratory (NREL) of Boulder, Colorado, for most applications (Cohen *et al.*, 1989.) Other methods, including yearly cash-flow analyses or the utility revenue requirements method (EPRI, 1986), may be more appropriate, depending on the developer and customer.

The primary economic figure of merit for wind turbines is the cost of energy (COE). This number should be provided in constant dollars and calculated for a standard size installation, a 50-MW (rated) wind farm with an expected life of 30 years. The COE depends on several economic factors to bring the long-term costs and revenues in relation to the initial capital cost. The NREL approach reduces the year-by-year analysis into a simple formula by introducing a fixed charge rate (FCR), which incorporates the effects of the present value discount rate and interest rates into a single number. Using this formulation, the COE is calculated by the equation

$$\mathrm{COE} = \frac{\mathrm{FCR} \times \mathrm{ICC}}{\mathrm{AEP}_{\mathrm{net}}} + \mathrm{LRC} + \mathrm{O\&M}, \qquad (14)$$

where COE = levelized cost of energy ($/kW·h), FCR = fixed charge rate (1/yr) = 0.109, ICC = initial capital cost ($), O&M = annual operating and maintenance cost ($/kW·h), LRC = levelized replacement cost ($/kW·h), typically 0.2 cents/kW·h, $\mathrm{AEP}_{\mathrm{net}}$ = net annual energy production (kW·h/yr). The $\mathrm{AEP}_{\mathrm{gross}}$ of a single turbine can be expanded into the output of a larger wind facility using the following formula:

$$\mathrm{AEP}_{\mathrm{net}} = \mathrm{AEP}_{\mathrm{gross}} \times (1 - \mathrm{EL}) \times \text{availability}, \qquad (15)$$

where EL is the product of individual energy losses calculated as below, and availability is the percentage of calendar time that the turbines are functional and ready to deliver power to the grid. EL is calculated as follows:

$$\begin{aligned}\mathrm{EL} = 1 &- (1 - L_{\mathrm{array}}) \times (1 - L_{\mathrm{soiling}}) \\ &\times (1 - L_{\mathrm{collect}}) \times (1 - L_{\mathrm{control}}) \\ &\times (1 - L_{\mathrm{icing}}),\end{aligned} \qquad (16)$$

where L_{array} are array losses (2%–8%), L_{soiling} are blade soiling losses (1%–3%), L_{collect} are collection system losses from turbine to grid

(1%–3%), L_{control} are control, grid, and miscellaneous losses (2%–4%), and L_{icing} are blade icing losses (2%–8%). The typical ranges of losses are indicated in the parentheses.

COE values typically fall in the range of 4–7 cents/kW·h. Wind energy requires a good wind resource to be economic and requires a utility customer or other readily available load to be practical. An average annual average wind speed of about 6 m/s is the minimum needed to obtain a COE of below 6–7 cents/kW·h. Some countries, particularly in Europe and North America, require utilities to buy power at the avoided cost of the utility, which is the dollar amount of fuel saved by operating the wind turbines. Many local situations may lead to power purchase contracts that are more favorable than the avoided cost. If a wind-power plant can displace the need to install a conventional power plant, capacity credit may be available, which can result in a large increase over the avoided cost of energy. Government incentives are also frequently available to developers and owners of renewable-energy generation, which can make otherwise marginal economic installations very attractive.

GLOSSARY

Apparent Power: The complex phasor sum of real and reactive power.

Balance of Plant: The electrical infrastructure to collect and transport the energy from the wind turbines to the point of use.

Betz Limit: Theoretical limit of wind turbine energy capture = 59% of wind-power density.

Campbell Diagram: A modal plot for VAWTs used to identify potential resonant conditions.

Pitch Regulation: A method of wind-turbine power regulation in which the blades are pivoted to larger angles of attack in high winds, making the blades operate less efficiently aerodynamically.

Power Factor: The cosine of the phase angle between the voltage and current wave forms of the same phase.

Reactive Power: Electrical energy stored in inductance or capacitance during one part of an alternating-current cycle and released during another part of the cycle without doing work.

Real Power: Electrical energy generated or consumed from doing work.

Square-Cubed Law: Law stating that the loads of a wind turbine increase as the cube of the diameter while the power increases as the square, thus implying a practical limit for the size of a cost-effective wind turbine.

Stall Regulation: A passive approach to wind-turbine power regulation in which the blades are designed to go into aerodynamic stall above the rated speed and no blade-pitching mechanisms are required.

Turbulence Intensity: The standard deviation of the wind speed divided by the average wind speed for the period.

Wind Power Density: Fluid power in the wind per unit of cross-sectional or swept area, measured in units of watts per square meter.

Wind Shear: The change in wind speed with increasing elevation.

INTRODUCTION

The intensity of x rays and neutrons reflected from an interface at near-grazing incidence depends sensitively on the refractive-index profile normal to the interface. As the refractive index depends on the density, the measured reflectivity vs incidence angle can be used to determine the interfacial density profile with sub-ångstrom resolution. The density sampled is, however, different for the two probes. As neutrons interact with the atomic nuclei, they probe the scattering amplitude density profile of the nuclei. This amounts effectively to probing the average mass density profile, where the contribution of each atomic species is weighted by its nucleus–neutron interaction strength, which varies irregularly throughout the periodic table. X rays, however, interact with the electronic charge and thus probe the total electronic density profile of the interface. The two probes provide, therefore, slightly different, though related, information on the interface structure. Since modern synchrotron x-ray sources are 5–6 orders of magnitude brighter than the best neutron sources, x-ray reflectivity measurements routinely achieve much higher resolutions and accuracies than their neutron counterparts. However, the magnetic interaction and the large variation of the neutron scattering length upon isotopic substitution renders neutron reflectivity a method of choice in special cases such as studies of surface magnetism and the adsorption of polymers at liquid and solid surfaces.

The use of x-ray reflectivity to measure the index of refraction of matter was originally suggested by Compton (1923). Parratt (1954) revived this method and used it in his seminal study of glass-deposited thin metal films. Marra *et al.* (1979) first applied the very small penetration depth for low angles of incidence to study the surface structure of crystals, opening up a new and very active field of research, which has provided a wealth of new knowledge about surface reconstruction and quasi-2D phase transitions. The x-ray reflectivity studies of the free surfaces of liquid metals (Lu and Rice, 1978) and of liquid crystals (Als-Nielsen *et al.*, 1982; Pershan and Als-Nielsen, 1984) laid the foundations for the fast-growing field of surface studies of liquids and soft condensed matter. These methods provided true *microscopic* information on important phenomena

like surface freezing and melting and the structure of the various phases of monomolecular Langmuir films. These techniques were later extended to solid–solid crystalline, liquid–solid, and even liquid–liquid interfaces.

The first detailed theoretical treatment of x-ray reflectivity was given by Picht (1929). Abeles (1950) and Parratt (1954) provided the first dynamical treatments, based on ideas drawn from classical optics of multilayers. The distorted-wave Born-approximation theory of Vineyard (1982) was an important step beyond the kinematical theory (Born approximation). Since then a large number of theoretical studies of both specular reflection and the accompanying diffuse scattering have been published, taking into account an increasing number of real effects like surface roughness, capillary surface waves in liquids, static and dynamic disorder in solid surfaces, and the stepped nature of crystalline surfaces.

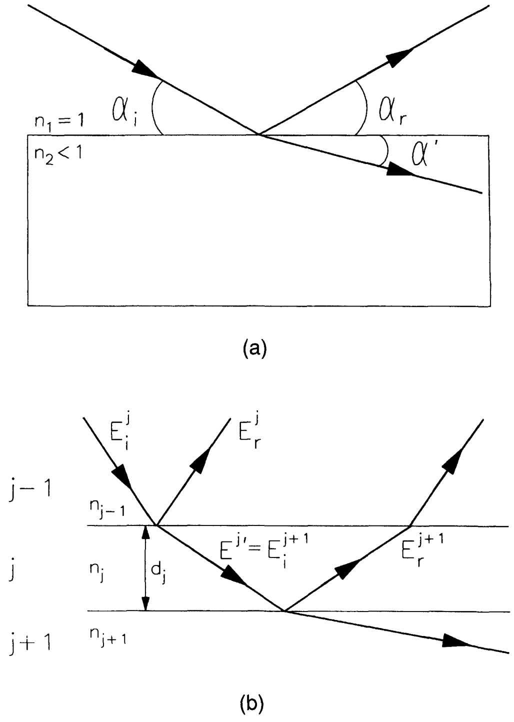
Neutron reflectivity was first employed by Fermi and Zinn (1946) to measure the scattering length and phase shift of the neutron upon reflection. Hughes and Burgy (1951) pioneered the use of neutron reflectivity to study surface magnetism, a method further developed by Felcher (1981) and co-workers. More recently, Penfold and Thomas (1990) studied polymer adsorption at, and surfactant monolayers on, the free surface of mixtures of D_2O and H_2O by ingeniously using the isotope variation of the scattering length to eliminate the signal originating from the water. Surfaces of solid polymers and interfaces between polymeric bulks were also studied extensively by Russell (1990) and others.

The fast and wide dissemination of x-ray reflectivity and related surface methods since the 1980s is mainly due to two important factors. The first is the advent of powerful synchrotron radiation sources, dedicated to the production of x rays. They provide intense, highly collimated x-ray beams, which are prerequisites for these grazing-angle surface studies. The second is the explosive growth in computer power since the 1970s, which put powerful computer fitting, modeling, and simulation methods within easy reach of small groups and individual researchers. A similar growth rate was enjoyed by neutron reflectivity. This growth was largely due to the construction of high-power research reactors and spallation sources in the United States, United Kingdom, and France. With the development of brighter thermal-neutron sources, a faster increase is expected in the use of neutron reflectivity for surface studies.

1. THEORY OF REFLECTIVITY

1.1 General Features

Standard electromagnetic theory (Born and Wolf, 1975) predicts the splitting of a plane wave incident on an interface between two media of refractive indices $n_1 \neq n_2$ into reflected and refracted waves, as shown in Fig. 1(a). While $\alpha_i = \alpha_r$ regardless of n_1 and



(a)

(b)

FIG. 1. (a) Reflection and refraction diagram at a free surface. Note that for x rays the refractive index of matter is less than unity. Hence, the refraction angle α' is smaller than the incidence or reflection ones, α_i and α_r. (b) The various waves reflected and refracted at the lower and upper surfaces of one layer, j, in a multilayer structure. n_j and d_j are the layer's refractive index and thickness, respectively.

n_2, the angle of refraction α' is determined by Snell's law:

$$n_1 \cos\alpha_i = n_2 \cos\alpha'. \tag{1}$$

For both x rays and neutrons, the complex refractive index n is given by

$$n = 1 - \delta + i\beta. \tag{2}$$

For x rays,

$$\delta = r_0\rho_e\lambda^2/2\pi, \quad \beta = \mu\lambda/4\pi, \tag{3}$$

where r_0 is the classical electron radius, λ is the wavelength, ρ_e is the electron density, and μ is the mass absorption coefficient. For neutrons, $r_0\rho_e$ is replaced by the neutron scattering-length density, $\Sigma_i N_i b_i$, where b_i is the empirically determined scattering length of nucleus i and N_i is its number density. The weak interactions render δ in Eq. (2) small, of order 10^{-5}–10^{-6} for most materials. The absorption term $\beta \ll \delta$ in most cases and, for simplicity, will be neglected from now on.

Free surfaces of solids and liquids are by far the most studied interfaces. Here $n_1 = 1$, and since for x rays $\delta > 0$, $n = n_2 < 1$. Snell's law yields $\alpha' < \alpha_i$, and thus, upon decreasing α_i, a finite angle $\alpha_c = \sqrt{2\delta}$ is reached where $\alpha' = 0$. For an angle of incidence smaller than this critical angle, total external reflection of the incident wave occurs; i.e., the reflectance, defined as the complex quantity $r = E_r/E_i$, has a modulus that is unity for $\alpha_i < \alpha_c$, and so is, of course, the reflectivity $R = |r|^2$.

For angles $\alpha_i > \alpha_c$, $|r|$ and R are no longer unity and for an infinitely sharp and flat surface are given by Fresnel's law:

$$r = \frac{q - q'}{q + q'} \quad \text{and} \quad R_F(q) = \left|\frac{q - q'}{q + q'}\right|^2, \tag{4}$$

where $q = (4\pi/\lambda)\sin\alpha_i$ is the momentum transfer perpendicular to the surface, $q' = \sqrt{q^2 - q_c^2}$, and the absorption is assumed to be negligible. The reflectivity R is a fast decreasing function, and for $q \gg q_c$ is very closely approximated by $R_F(q) \approx (q_c/2q)^4$. In the field of small-angle bulk scattering, this is long known as Porod's law. In practice, critical angles are a few tenths of a degree, and reflectivities at $\sim 20q_c$, just a few degrees, are of order $\sim 10^{-7}$. Thus, the well-collimated and very intense x-ray beams available at synchrotron sources are often the tools of choice for reflectivity measurements. Note that because of the low angles of incidence the reflectivity is practically polarization independent.

Real interfaces are neither abrupt nor ideally flat. On an atomic scale the transition between adjacent media is of a finite width. For example, thermally induced capillary waves in liquids, and structural defects or crystalline surface steps in solids, modify the density profile. The reflectivity off a real surface will therefore deviate from Fresnel's law. Two main approaches exist for calculating the reflectivity in these cases. The first is the dynamical approach originally proposed by Parratt (1954). The second is the kinematical approach, based on the first Born approximation. While the first of these is more rigorous, the second is much easier to use in practice and yields in most cases accurate and reliable density profiles. We now discuss each of these methods separately.

1.2 Dynamical Theory of Reflectivity

The density variation perpendicular to the interface can be approximated by a piecewise-constant function, thus replacing the actual interface by a series of N slabs having each a constant refractive index $n_j = 1 - \delta_j$ and a width d_j. By increasing the number and decreasing the width of the slabs, the approximation can be made arbitrarily close to the actual density profile. The first slab, $j = 1$, denotes the medium above the free surface (e.g., the vacuum), and the last, Nth, slab is the bulk where $d_N = \infty$. Consider now the jth slab, depicted in Fig. 1(b). The continuity requirements of the field at each interface yield for the reflectance r_j of slab j (Born and Wolf, 1975)

$$r_j = a_{j-1}^4(r_{j+1} + F_j)/(r_{j+1}F_j + 1), \tag{5}$$

where $a_j = \exp(-iq_jd_j/4)$, $F_j = (q'_{j-1} - q'_j)/(q'_{j-1} + q'_j)$, and $q'_j = \sqrt{q^2 - q_{c,j}^2}$, with $q_{c,j}$ denoting the critical angle for slab j. Equation (5) is solved iteratively, by noting that since $d_N = \infty$, the reflectance off the bottom of the Nth slab is zero, and the sole contribution of that slab is from the upper interface. This yields $r_N = a^4_{N-1}F_N$, which is then used to calculate r_{N-1} and so on until the free-surface reflectance r_2 is obtained, whence $R(q) = |r_2|^2$. This method properly accounts for the effects of refraction and is therefore exact. Absorption can also be conveniently included by using a complex momentum transfer $q'_j = \sqrt{q^2 - q^2_{c,j} + i\mu_j/2}$. An additional advantage of the dynamical theory is that it gives a natural description of the many important cases involving layered interfaces such as ordered diblock polymers, thin films on a solid substrate, or monomolecular Langmuir films on water. For more than a few layers, however, its use becomes very tedious analytically, although the iterative algorithm is very easy to program for computer calculations. By contrast, the approximate kinematical theory, given below, has the advantage of yielding a closed-form expression for the reflectivity that is sufficiently accurate for most cases.

1.3 Kinematical Theory of Reflectivity

Consider again the multislab approximation discussed above. This time, however, we assume small reflectivities and neglect refraction effects so that each slab reflects the incident wave independently. The amplitude ratio of the reflected to incident wave for a single slab j at depth z below the nominal surface is given by (Als-Nielsen and Kjær, 1989; Schlossman and Pershan, 1990)

$$E^j_r/E_i = 4\pi i r_0 \langle \rho_e(z) \rangle d_j/q, \tag{6}$$

where $\langle \cdots \rangle$ denotes averaging in the x-y plane, parallel to the surface. Making the slabs of equal infinitesimal thickness dz, and summing the contributions over z, multiplying each by the appropriate phase factor $\exp(iqz)$, one obtains the so-called "master equation":

$$R(q) = R_F(q) \left| \frac{1}{\rho_\infty} \int_{-\infty}^{\infty} \frac{d\langle \rho_e(z) \rangle}{dz} \exp(iqz) dz \right|^2, \tag{7}$$

where ρ_∞ is the bulk electron density. Thus, the Fresnel reflectivity is modified by the absolute value of the Fourier transform of the density gradient, which is, within a constant, the standard crystallographic structure factor of the interface. Strictly speaking, the master equation applies in the weak-reflectivity limit, i.e., where $R \ll 1$. For many cases, however, it is sufficiently accurate at all q. It has the advantage of being easily applicable to analytic models of the density profile and is therefore widely used. It should be noted, however, that since Eq. (7) employs the square of the structure factor, the phase information is lost just as in standard crystallography, and a unique inversion of the measured $R(q)$ to obtain $\rho_e(z)$ is not possible in the general case. However, through judicious use of additional information and general physical constraints, it is possible in almost all cases to obtain a well-defined and accurate description of the density profile.

1.4 Unique Features of Neutron Reflectivity

Neutrons have several unique properties that can be used to advantage in particular cases. For some materials (e.g., silicon) the scattering and absorption cross sections are extremely small; thus neutrons can travel through these materials with little attenuation. This feature can be used to advantage when studying thin organic films in contact with liquid interfaces. Also, for x rays the scattering-length density always has the same sign, whereas for neutrons δ can assume both negative and positive values for different atoms and isotopes. In particular, H and D have b values of opposite signs. Hence an appropriate mixture of D_2O and H_2O can be prepared (molar ratio of 0.088:1) such that its average scattering length is equal to that of air. The free surface of such a mixture will not reflect or refract an incident neutron beam, and the general concept is referred to as contrast matching. The cancellation of the bulk signal greatly improves the signal/noise ratio in experiments involving monolayers on water, surface adsorption of polymers in solution, and solute concentration near a free surface of water. Furthermore, by deuterating a specific part of an organic molecule or biomolecule, one can study by neutron reflection the behavior of that part only near the surface. Although anomalous dispersion of x rays near an absorption edge was also employed for similar measurements, neutrons are superior to x rays in this respect.

Another advantage of neutrons is their

magnetic interaction with matter. For magnetic materials the total scattering length is $b \pm C\mu$, where μ is the magnetic moment and C is a constant (Felcher, 1981). The sign depends on whether the neutron polarization is parallel (+) or antiparallel (−) to the magnetization. Thus, polarized-neutron reflectivity permits studies of magnetic structures near the surface. The measurement of the so-called flipping ratio, the ratio of the parallel to antiparallel reflectivities, is particularly advantageous since the interference from many nonmagnetic variables cancels out.

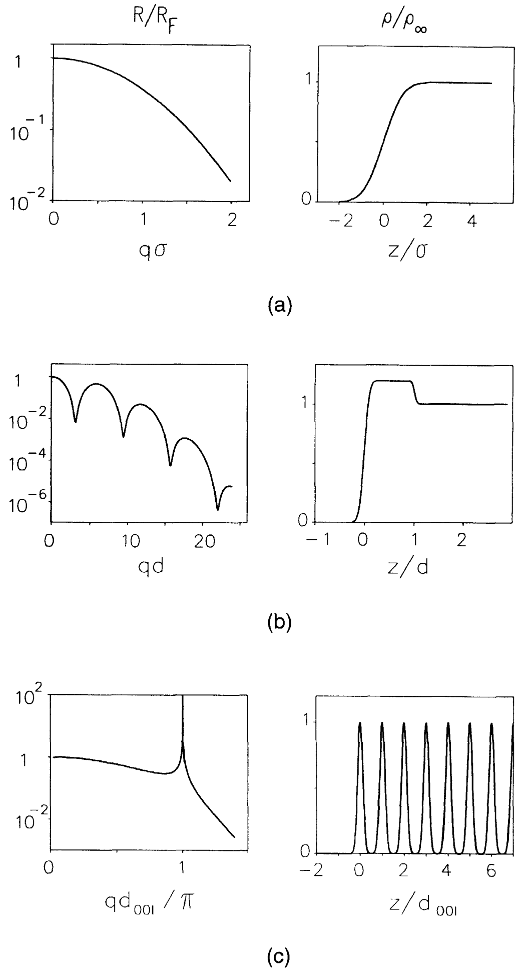


FIG. 2. Prototypical reflectivity curves R divided by the Fresnel-law R_F (left) and their corresponding surface-density profiles (right). The curves are discussed in Sec. 1.5.

1.5 Examples

Figure 2 shows a few typical examples of surface profiles and the resulting reflectivity curves. We now discuss each separately.

1.5.1 Rough Surfaces An important case, shown in Fig. 2(a), is the "rough" surface, where the density profile perpendicular to the surface has a finite width. This may be the free surface of a liquid, broadened by thermally excited capillary waves; an amorphous solid surface with a random height distribution; or a crystal surface with extra unit cells missing or piled up at random positions on the crystallographic plane constituting the nominal "surface." Averaged over the x-y plane, the perpendicular density profile of such a diffuse interface is well represented in many important cases by an error function. The master equation yields in this case

$$R(q)/R_F(q) = \exp(-q^2\sigma^2), \tag{8}$$

where σ is the width parameter of the height distribution. This Debye–Waller type term is used to represent diffuseness or roughness in profiles of more complicated structure. It is easily recognized by plotting R/R_F vs q^2 on a semilog scale, yielding a straight line, where the slope is $-\sigma^2$. An example of this is shown in the inset in Fig. 3.

1.5.2 A Thin Film on a Substrate The reflectivity from a thin film of thickness d and a uniform electron density ρ_e on a substrate with $\rho_e' \neq \rho_e$ and an equal roughness σ at the upper and lower interfaces is shown in Fig. 2(b). The master equation yields

$$R(q)/R_F(q) = [a^2 + b^2 + 2ab\cos(qd)] \times \exp(-q^2\sigma^2), \tag{9}$$

where $b = \rho_e/\rho_e'$ and $a = 1 - b$. The typical oscillatory reflectivity curve, often called Kiessig fringes, is the signature of such a film. The film thickness d can be determined immediately from the curve by $d \approx 2\pi/(q_i - q_{i+1})$, where q_i, q_{i+1} are the positions of two consecutive extrema.

1.5.3 Crystal Surface Assume a cubic crystal, having an abrupt surface parallel to a set of lattice planes $00l$ of spacing d_{00l}. Summation of the contributions from all

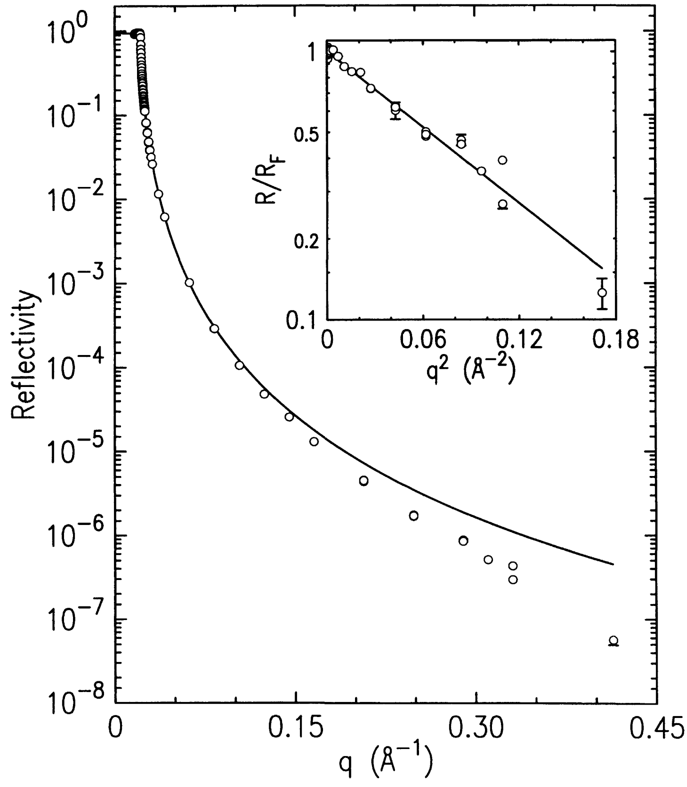

FIG. 3. X-ray reflectivity from the water–vapor interface (solid dots). The deviation between the data and the Fresnel law (solid line) is due to capillary-wave–dominated surface roughness. The inset shows that the Gaussian roughness model in Eq. (8) fits the measured reflectivity well with a roughness width parameter σ = 3.3 ± 0.1 Å. Adapted from Braslau *et al.* (1988). For further details see Sec. 3.1.

planes in the kinematical approximation yields

$$R(q) \sim [q \sin(qd_{00l}/2)]^{-2} \exp(-q^2\sigma_b^2), \qquad (10)$$

where σ_b is the bulk Debye–Waller factor. For small q, $\sin(qd_{00l}/2) \sim qd_{00l}/2$ and Eq. (10) assumes the right q^{-4} form of Fresnel's law. For $q = q_{00l} = 2\pi l/d_{00l}$, however, Bragg peaks are obtained, as shown in Fig. 2(c). The "wings" of these peaks fall off as $\sim|q - q_{00l}|^{-2}$. This shape is, of course, modified in real crystals by the molecular form factor, surface roughness, faceting, reconstruction, and adsorption of foreign molecules at the surface.

2. INSTRUMENTATION

The spatial resolution in reflectivity measurements is inversely proportional to the angular range measured. High resolution entails, therefore, measuring out to large angles of incidence and consequently very low reflectivities. The use of high-intensity x-ray beams available at synchrotron sources is thus very beneficial for many of these measurements. Present-day second-generation synchrotron sources and the associated beam-line optics are capable of producing monochromatic fluxes of the order of 10^{11} photons per second in a $\leq$1-mm^2 spot. This represents a flux increase of $\sim10^4$ over conventional rotating-anode laboratory-based sources.

For solid samples, a conventional two-circle diffractometer can be used to measure the reflectivity. The sample is oriented in this case perpendicular to the rotation plane of the circles (usually the horizontal) and the reflectivity is measured in a θ-2θ scan as in a single-crystal Bragg-reflection measurement. Because of the small angle of incidence, the illuminated area ("footprint") on the sample is magnified greatly as compared to the beam width. For sufficiently large samples a narrow slit is positioned close to the sample to keep the footprint smaller than the size of the sample at all angles of incidence. For samples that cannot be made larger than the footprint, an angle-dependent illuminated-area correction (e.g., $\sin\theta$) is required.

Reflectivity measurements are often accompanied by complementary surface-scattering measurements including grazing-incidence diffraction, truncation rod, and diffuse scattering. This requires exploring a large volume in reciprocal space, and thus four- or six-circle diffractometers are often employed for these measurements, sometimes in conjunction with ultrahigh-vacuum environmental chambers to keep the surface of the samples atomically clean (Feidenhans'l, 1989; Robinson and Tweet, 1992).

Liquid samples dictate a different geometry. By virtue of their horizontal surfaces, the plane of reflection is always vertical. The incident beam must be, therefore, bent down to impinge on the surface at the required angle of incidence. As the beams generated at synchrotron sources are highly collimated and horizontal, the beam is reflected downward by a tilted crystal. At laboratory-based rotating-anode sources, which produce a highly divergent beam, the incident beam is selected by a collimator looking back at the source at the required downgoing angle. In both cases, the sample is translated in the up–down direction as the angle of incidence is varied, to intercept the downgoing beam. Finally, the reflected beam is detected by a scintillator–phototube combination, an ion chamber, a diode, or a one- or two-dimensional detector.

Neutron-reflectivity measurements are carried out at both steady-state thermal-neutron reactors and pulsed spallation sources. At the former, the reflectometers function similarly to x-ray reflectometers since Bragg optics can be used for neutrons as well as x rays. Such reflectometers have been built in either the standard or liquid configurations. Reflectometers at spallation sources have been developed to take advantage of the relationship between the neutron wavelength and velocity (Felcher *et al.*, 1987). The sample and detector are fixed to provide the desired incident and exit angles α to satisfy the specular condition. The incident beam contains a spread of wavelengths with a known spectrum. The reflected beam is analyzed by a neutron time-of-flight technique to provide the reflected intensity for each wavelength. Through the relation $q = 4\pi/\lambda\sin\alpha$, this provides the required $R(q)$ curve. An important advantage of this energy-dispersive mode of measurement is that the reflectivity is acquired for a range of q values simultaneously without moving the sample or the incidence and exit slits and with a fixed area illuminated on the sample. Although similar energy-dispersive x-ray reflectivity measurements have been done, they are more complicated experimentally and seldom used in practice.

Several current reflectometers are described in detail by Russell (1990).

3. APPLICATIONS

3.1 Simple Liquids: Water

The liquid–vapor interface is intrinsically very sharp and flat. Its reflectivity should therefore closely follow the Fresnel-law $R_F(q)$. The water–vapor interface is perhaps the most common interface in nature and one of the first studied with x-ray reflectivity. The measured reflectivity (Braslau *et al.*, 1988) is reproduced in Fig. 3 along with the Fresnel law. Below $q_c = (4\pi/\lambda)\sin\alpha_c = 0.0217$ Å^{-1}, the reflectivity is nearly unity as expected. In the range $q_c \leq q \leq 0.4$ Å^{-1}, the reflectivity decreases by over seven orders of magnitude. While at low q values the measured curve is seen to follow closely Fresnel's law (solid line), as expected, above $q = 0.15$ Å^{-1} the data deviate increasingly from Fresnel's law. This deviation is exceptionally well described by the Gaussian function given in Eq. (8) as is apparent from the inset to Fig. 3. The best fit to the data yields an interfacial profile width of $\sigma = 3.3 \pm 0.1$ Å. This was shown to be predominantly due to thermally induced capillary waves in addition to a small intrinsic interfacial width. The dominant capillary contribution is predicted to have a width ~2.8 Å, in excellent agreement with the measurements. The capillary-wave model also predicts the dependence of the width upon the spectrometer resolution, surface tension, and temperature. All of these effects have been confirmed experimentally. Measurements of the diffuse scattering close to the specular direction also support the capillary-wave model. For liquid metals, the surface tensions of which are up to tenfold higher than that of water, recent measurements (Magnussen *et al.*, 1995; Regan *et al.*, 1995) reveal a surface roughness of ≤1 Å.

3.2 Thin Films: Water on Glass

For thin films on a substrate, the waves reflected from the upper and lower interfaces of the film interfere and yield a modulated reflectivity curve. The x-ray reflectivity curve of a thin water layer on a smooth borosilicate float-glass substrate is shown in Fig. 4 (Garoff *et al.*, 1989). Periodic oscillations in the curve are apparent. The monotonic decrease of their amplitude with q is due to the effects of roughness. The period of $\Delta q = 0.069\ \text{Å}^{-1}$ corresponds to a water-layer thickness of $d = 2\pi/\Delta q = 91$ Å. The solid line shows a model reflectivity curve where the density profile incorporates a water–vapor interfacial width of 4.2 Å, an average water-layer thickness of 91 Å, and a water–substrate interface width of 3 Å.

In addition to their scientific interest, thin films also have important industrial applications in the fields of coatings, electronics, biotechnology, and medicine. X-ray reflectivity has become a powerful probe of the structure of these films, and many films and multilayers have been studied including semiconductors, metals and alloys, polymers, Langmuir–Blodgett films, Langmuir films on water, liquid crystals, and liquid helium.

3.3 Polymer Films: Combined X-Ray and Neutron Reflectivity

The study of block copolymer films on solid substrates, using both x-ray and neutron reflectivity, demonstrates the complementary nature of these two techniques. In Fig. 5, x-ray and neutron reflectivity data (Mayes *et al.*, 1994) are shown for a diblock copolymer film, cast onto a flat polished silicon substrate and annealed for 24 hours. The polymer consists of a deuterated polystyrene block (d-PS) and a protonated polymethyl methacrylate block (PMMA). The PS, having a lower surface energy, aggregates upon annealing at the surface, while the PMMA resides at the silicon surface. As the electron densities of the two components are similar, the internal layered structure of the film does not give rise to optical-density variations for x rays. Thus only the fringes due to the total thickness of the film are observed in the x-ray data. A constant-density model fit to the x-ray data, shown in Fig. 5 as a solid line, shows very good agreement and yields a uniform film thickness of ~1120 Å, which corresponds to $3\frac{1}{2}$ bilayers. By contrast, the different neutron scattering lengths of hydrogen and deuterium, the first being positive and the other negative, result in very different optical densities for the internal layers for neutrons. This gives rise to additional interference beyond that reflecting the film's total thickness, as can be seen in the neutron data in Fig. 5. A model fit to the data, shown as the solid line, yields a thickness of ~320 Å for each of the PM and PMMA bilayers, with a diffuse transition layer of 50 Å between them and a surface roughness of 6 Å. As can be seen, the agreement between the model and data is excellent.

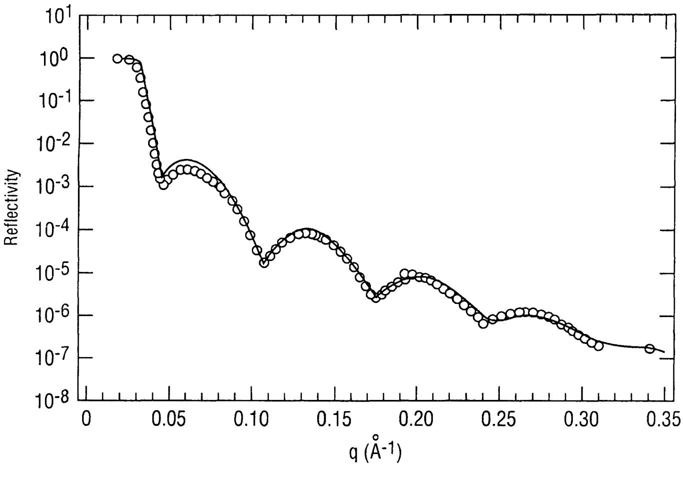

FIG. 4. X-ray reflectivity from a 91-Å-thick water layer on a glass substrate. The oscillations in the reflectivity curve originate from the interference between rays reflected from the water–vapor and the glass–water interfaces. Adapted from Garoff *et al.* (1989). For further details see Sec. 3.2.

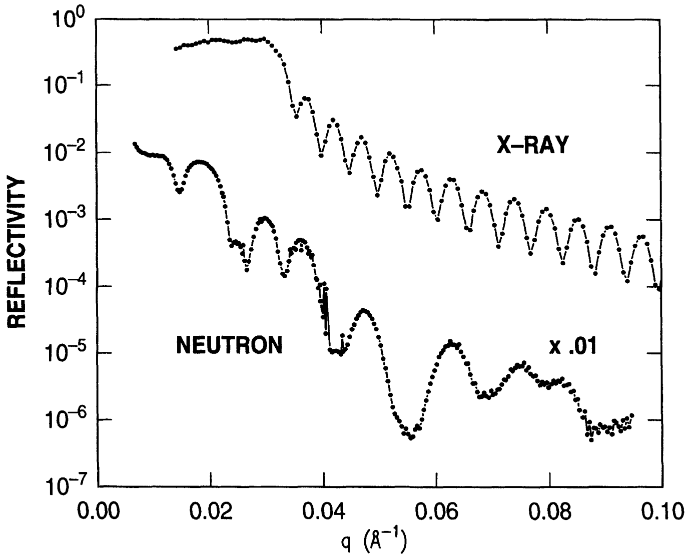

FIG. 5. X-ray and neutron reflectivities from an annealed deuterated-protonated di-block copolymer film cast onto a silicon surface. The irregular oscillations in the neutron reflectivity result from interference due to the alternating deuterated-protonated internal layered structure of the film, and the large variation of the neutron scattering length upon isotopic substitution. By contrast, since the charge density is equal for both types of layers, no internal structure is observed in the x-ray reflectivity, and only the regular fringes due to the total thickness of the film, ~1120 Å, are observed. Adapted from Mayes *et al.* (1994). Further details are given in Sec. 3.3.

A large number of similar studies on different polymers have been carried out, providing a wealth of information about the statics and kinetics of phase separation in polymer blends and block copolymers.

3.4 Polarized-Neutron Reflectivity: Ultrathin Fe Films

Theoretical studies indicate that magnetic moments of atoms at the surface of metals should be greater than those of bulk atoms. The same should hold for atoms in ultrathin metallic films. Polarized-neutron reflectivity has been successfully implemented to study this and related issues in a number of metallic films.

One such study (Huang *et al.*, 1993) addressed ultrathin Fe films, ranging in thickness from 4 to 16 Å. The reflectivity from a 16-Å film in a 200-Oe magnetic field at room temperature is shown in Fig. 6. As discussed earlier (Sec. 1.4), for neutron polarization parallel to the field, the usual nuclear scattering length of the Fe atom is enhanced by a magnetization term generated by an assembly of aligned atomic magnetic moments μ. For the other polarization, the scattering amplitude is *decreased* by the same amount. The difference between the parallel (filled circles) and antiparallel (open circles) polarizations is apparent in the figure. By fitting the reflectivities for both polarizations with a simple model, the effective iron layer thickness, 14 Å, and the iron scattering density, 7.0×10^{-6} Å^{-2}, have been obtained. These values indicate a (not unreasonable) 13% decrease in the density of Fe in the film as compared to the bulk. Contrary to theoretical predictions, the magnetic moment per atom is determined to be $(2 \pm 0.2)\mu_B$, the same as that of bulk Fe, regardless of thickness. However, temperature-dependent measurements show that the thinnest films exhibit a lower Curie temperature than that of the bulk and a magnetization axis tilted out of the film surface.

3.5 Crystalline Surfaces: Clean Au(001) in Vacuum

For crystalline surfaces, x-ray reflectivity provides information on the atomic arrangement of the topmost layers. As an example, the reflectivity from the Au(001) surface in ultrahigh vacuum is shown in Fig. 7 (Gibbs *et al.*, 1988). Note that the maximum q measured, ~5 Å^{-1}, is nearly an order of magnitude greater than what is typically achieved for simple liquids or thin films. For Au(001), the sample size limits the q range to values greater than q_c. The Bragg peak at $q = 3.08$ Å^{-1} corresponds to the bulk (002) reflection. The calculated reflectivity for an ideally ter-

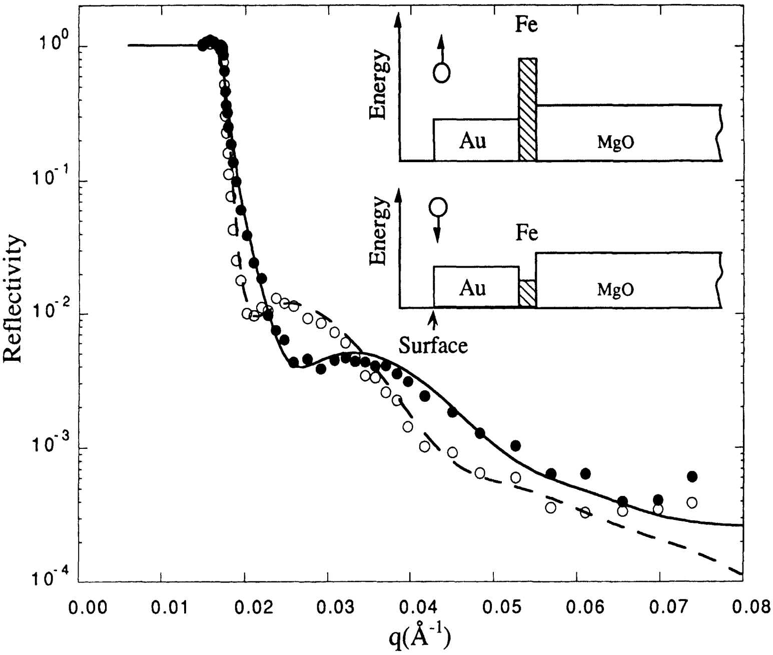

FIG. 6. Spin-dependent neutron reflectivity from a 16-Å-thick Fe film. A 200-Oe magnetic field aligns the spins parallel to the surface and transverse to the beam. Filled and open circles indicate data for neutron spin parallel (+) and antiparallel (−) to the applied field, respectively. Note the strong dependence of the measured curves on polarization. The inset describes the different potentials for neutron spin parallel (top) and antiparallel (bottom) to the magnetic field. Reproduced from Huang *et al.* (1993) with permission of The American Physical Society. See Sec. 3.4 for further details.

minated gold surface (dashed curve) deviates from the measured reflectivity, especially where the reflectivity is weak. This deviation results from the top gold layer, which does not have the same symmetry and gold density as the underlying gold layers. Rather, the top gold layer is "reconstructed" such that these top-layer atoms are arranged in a hexagonal pattern with a density 25% greater than the underlying layers and the topmost interlayer spacing is 20% larger than the bulk (001) layer spacing of 2.04 Å. The predicted reflectivity for this model (solid line) describes the essential features of the data. The prominent asymmetry around the (002) peak results from the 20% lattice expansion. Above 1170 K the reconstruction vanishes. A similar reconstruction was observed by x-ray reflectivity under electrochemical conditions (Ocko *et al.,* 1990). Studies have been carried out on other crystalline facets, different metals, and semiconductor surfaces, and at the electrode–electrolyte interface.

4. RELATED TECHNIQUES

There are several important techniques, related to reflectivity, whence additional information on the structure of the surface can be derived. For example, the surface "roughness" reduces the specularly reflected intensity by scattering intensity out of the specular direction. This diffuse scattering is dominated by, and can be analyzed to yield information on, the nature of the in-plane correlations of the "roughness," and their range and spatial dependence (Sinha *et al.,* 1988).

A few techniques take advantage of the refracted beam, which, for angles of incidence smaller than the critical angle, becomes evanescent. It travels along the surface and has an amplitude that decays exponentially with depth below the surface. As the penetration depth is of order ~50 Å, the diffraction of this wave by the surface layer provides information on the structure of the surface layer, free from any obscuring signal from the

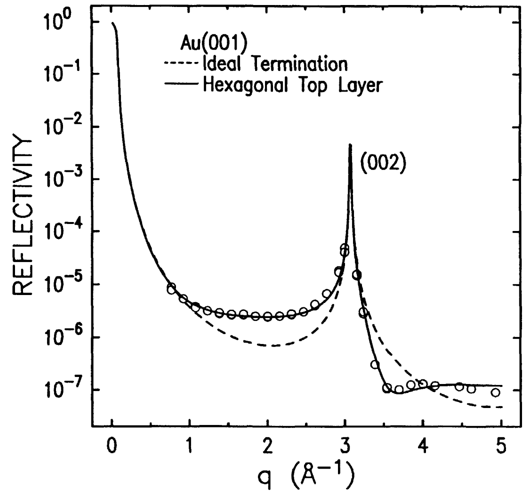

FIG. 7. X-ray reflectivity from the (001) surface of a single crystal of gold in ultrahigh vacuum. The Bragg peak at $q = 3.08$ Å^{-1} is the bulk (002) reflection. The measured reflectivity (open circles) deviates from the one calculated for an ideally terminated gold surface (dashed curve) but is well described by a surface model (see Sec. 3.5 for details) where the top gold layer is reconstructed in a hexagonal structure different from that of the bulk (solid curve). Adapted from Gibbs *et al.* (1988).

bulk. This effect is the basis for the grazing-incidence diffraction (GID) technique, a powerful tool for surface structure determination. Although it has been used to determine the liquid-surface structure factor of liquid metals and alloys, it is used most extensively for studying ordered surfaces and monolayers. Here the order in the surface translates into Bragg peaks, often unique to the surface and nonexistent for the bulk. However, perpendicular to the surface the order is restricted: a single molecular layer for Langmuir films or a crystalline half-space for the free surface of a crystal. Thus, the intensity distribution in the GID peaks is not pointlike as in a bulk Bragg peak; rather it is elongated perpendicular to the surface. These surface-normal scattering distributions, often called Bragg rods, are the two-dimensional equivalents of the Laue spots obtained in diffraction from bulk crystals, where the order is three dimensional. The intensity distribution along the rod can be analyzed to yield information mostly on the structure of the scattering medium perpendicular to the surface. Note that unlike specular reflectivity, which yields similar information but averaged over all of the surface, the Bragg rods originate in the ordered regions and hence yield information on these regions only. This is particularly useful for studies of partially ordered surfaces and monolayers.

The variation of the penetration depth of the refracted beam with the angle of incidence has also been used to investigate the concentration dependence of a specific atom on depth below the surface. This is done by using radiation of a fixed wavelength above the absorption edge of the atom and measuring the intensity variation with the *angle* of incidence of the fluorescence from that atom. A related technique, called SEXAFS for Surface Extended Absorption Fine Structure, uses the intensity variation with incident *wavelength* of the fluorescence at wavelengths close to, and above, an absorption edge. Since the angle of incidence is kept below the critical for all wavelengths, the fluorescence originates in the surface layer only, on account of the short penetration depth. This technique is useful for investigating the local structure near the given atom up to its second or third coordination sphere.

INTRODUCTION: X RAYS AND VISIBLE LIGHT

Light is scattered by matter because its electromagnetic field drives electrons into oscillatory motion, which causes them to radiate some of the incident flux. This fundamental phenomenon is valid for visible as well as x-ray light, but the competition with other types of interaction can depend strongly on the energy (frequency) of the light. For this treatment we will consider x-ray interactions as elastic events (no energy loss) in which many centers collectively and coherently contribute to the scattering process.

Visible light and x rays behave similarly in this type of geometric scattering, the important parameter being the relative value of the wavelength (λ) to some characteristic length (d) in the scatterer. For comparable values of λ/d, diffraction is basically independent of λ.

Diffraction with visible light is usually from one- or two-dimensional structures such as slits, edges, or arrays of slits (gratings), where λ/d basically defines the problem. On a more limited front, optical diffraction from a three-dimensional object can be usefully pursued. With x rays of wavelengths the order of 1 Å (10^{-8} cm), the atomic granularity of the basic structure determines the characteristic length of the diffraction.

X rays, because of their high penetrating power compared to visible light, diffract from three-dimensional structures. The conditions for strong diffraction from three-dimensional periodic structures are much more restrictive than from lower-dimensional systems, making strong interferences a much rarer event. This is discussed in more detail in Sec. 2.

1. THE STRUCTURE OF THE ATOM

The diffraction pattern observed from an object illuminated by a plane wave is the summation of the amplitudes of scattered waves from each component of the object taking into account the path-length–induced phase differences. The amplitude of scattering E from an arrangement of matter defined

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

by the vectors **r**, with scattering amplitude per unit of volume $f(\mathbf{r})$, is*

$$E = \int_{\text{object}} f(\mathbf{r}) e^{i(\mathbf{k}-\mathbf{k}_0)\cdot\mathbf{r}} dv, \tag{1}$$

where $\mathbf{k}_0$ and **k** are the incident and diffracted wave vectors with magnitude $|\mathbf{k}| = 2\pi/\lambda$. $i(\mathbf{k} - \mathbf{k}_0)\cdot\mathbf{r}$ is the phase angle of a scatterer at position **r** with respect to some reference scatterer at an arbitrary origin and is merely 2π times the optical path-length difference in units of λ. $\mathbf{k} - \mathbf{k}_0$ is called the scattering vector (Fig. 1).

X rays are scattered by electrons with an amplitude given by $f_e = e^2/mc^2$, the Thompson scattering length, so that (1) becomes

$$E = f_e \int \rho(\mathbf{r}) e^{i(\mathbf{k}-\mathbf{k}_0)\cdot\mathbf{r}} dv, \tag{2}$$

where $\rho(r) = \Psi\Psi^*$ is the density of electrons of wave function Ψ. (e is the charge of an electron, m its mass, and c the velocity of light; $e^2/mc^2 = 1.38 \times 10^{-13}$ cm.) If the object is an atom, then the quantity

$$f = \int \rho(\mathbf{r}) e^{i(\mathbf{k}-\mathbf{k}_0)\cdot\mathbf{r}} dv \tag{3}$$

is called the *atomic scattering factor,* or simply the *form factor.* [Note that if all the electrons are treated as point scatterers at the atom center, then $f = \int \rho(r) dv = Z$, the number of electrons in the atom.] If an atom (or a dilute gas of atoms) is illuminated by a plane wave of x rays, the scattered intensity I, as a function of the scattering vector $\mathbf{k} - \mathbf{k}_0$, will be proportional to the quantity $|f|^2$. From a complete intensity data set, Fourier inversion of $\sqrt{I}$ will give $\rho(r)$, the radial distribution of electron density in the atom.

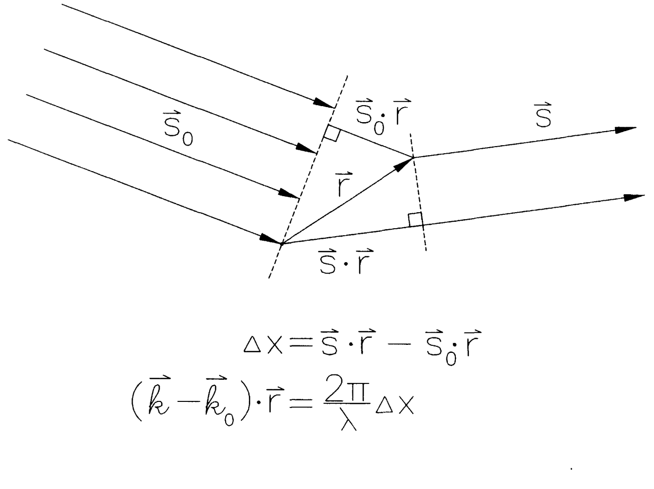
Figure 2 shows the form factor for neon gas derived from the experimental scattering intensities. 2θ is the total scattering angle. The theory curves are from theoretical calculations of the electron wave functions for neon (Compton and Allison, 1935).

2. PERIODIC STRUCTURES

Structures that are periodic, where each structural element is precisely repeated on a grid determined by translational vectors $\mathbf{a}_1$, $\mathbf{a}_2$, $\mathbf{a}_3$, have scattering patterns with sharp maxima in certain directions. For example, in one dimension, a set of scattering centers spaced $\mathbf{a}_1$ apart along a straight line will produce maxima when the following condition with integer h is met [see Fig. 3(a)]:

$$(\mathbf{k} - \mathbf{k}_0)\cdot\mathbf{a}_1 = 2\pi h. \tag{4}$$

This condition shows that maxima exist in directions **k** when the path difference between the incident $\mathbf{k}_0$ and scattered waves **k** from each element is a multiple h of the wavelength of the x rays. The diffraction pattern in this case is a series of cones of scat-



$\vec{S}_0$
$\vec{S}_0 \cdot \vec{r}$
$\vec{S}$
$\vec{r}$
$\vec{S} \cdot \vec{r}$
$\Delta x = \vec{S}\cdot\vec{r} - \vec{S}_0\cdot\vec{r}$
$(\vec{k} - \vec{k}_0)\cdot\vec{r} = \frac{2\pi}{\lambda}\Delta x$

FIG. 1. The scattering vectors showing the path-length phase of a scatterer at vector position **r**. **S** and $\mathbf{S}_0$ are unit vectors in the diffracted and incident directions, respectively. Δx is the path-length difference with respect to a scatterer at position 0.

---

*We use complex notation $e^{i\mathbf{k}\cdot\mathbf{r}} = \cos\mathbf{k}\cdot\mathbf{r} + i \times \sin\mathbf{k}\cdot\mathbf{r}$ to represent a plane wave traveling in the **k** direction. $\mathbf{k}\cdot\mathbf{r} = 2\pi x/\lambda$, where x is distance along the **k** direction.

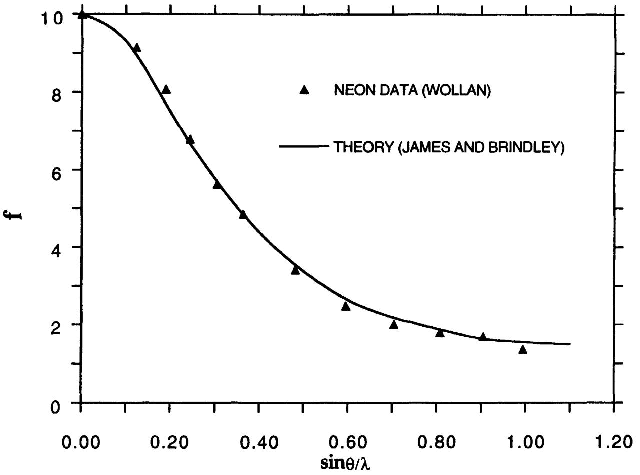


FIG. 2. The atomic x-ray scattering factor for neon as determined by Wollan (Compton and Allison, 1935). The total scattering angle is 2θ.

tering centered about $\mathbf{a}_1$ with the cone angle depending on the incident direction with respect to the line of scatterers.

For two-dimensional scattering, an additional similar condition must be satisfied for a periodicity defined by the translation vector $\mathbf{a}_2$, viz:

$$(\mathbf{k} - \mathbf{k}_0)\cdot\mathbf{a}_2 = 2\pi k \quad (k \text{ integer}). \tag{5}$$

Scattering from a two-dimensional array (such as a mesh screen) will take place when conditions (4) and (5) are simultaneously satisfied, and this is shown geometrically in Fig. 3(b) as the intersections of two cones centered around the respective axes $\mathbf{a}_1$ and $\mathbf{a}_2$.

If we now go to three-dimensional (3-D) periodic structures and consider the problem geometrically, we see that a third equation similar to (4) and (5) must be satisfied (involving the vector $\mathbf{a}_3$ and a third integer l), which requires the mutual intersection of three cones in space. Such a common intersection is clearly a rare occurrence. In two dimensions, two cones will, in general, intersect producing strong diffracted rays. With 3-D gratings, conditions must be carefully set to obtain a strong diffracted beam. Shooting a well-collimated monochromatic x-ray beam at a crystal will produce a diffracted beam with vanishingly small probability. However, as we show later, certain experimental conditions make 3-D diffraction a more likely event.

Equations (4) and (5) with the additional one for a third translational vector $\mathbf{a}_3$ are

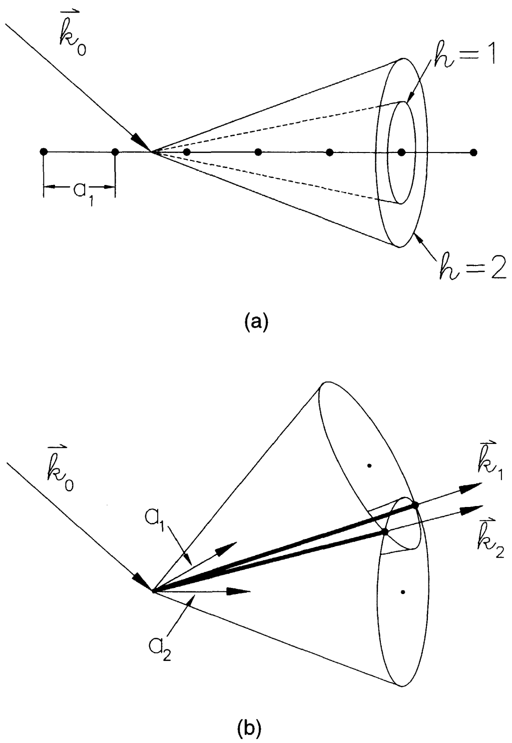

FIG. 3. Diffraction from one- and two-dimensional gratings. (a) The diffraction pattern from a one-dimensional array of scatterers consists of a series of concentric cones centered on the line of scatterers. The indices h represent different orders. (b) Diffraction from a 2-D grating will, in general, produce a pair of diffracted rays for each order pair (h,k). The diffracted rays are the intersection of the cones about $\mathbf{a}_1$ and $\mathbf{a}_2$.

known as the *Laue equations,* which we consolidate in terms of unit vectors $\mathbf{s}$ and $\mathbf{s}_0$ in the diffracted and incident beam directions respectively:

$$
\begin{aligned}
(\mathbf{s} - \mathbf{s}_0)\cdot\mathbf{a}_1 &= \lambda h,\\
(\mathbf{s} - \mathbf{s}_0)\cdot\mathbf{a}_2 &= \lambda k,\\
(\mathbf{s} - \mathbf{s}_0)\cdot\mathbf{a}_3 &= \lambda l.
\end{aligned} \tag{6}
$$

In a remarkable simplification, Bragg (Ewald, 1962) showed that these three equations are equivalent to mirror reflection from planes of atoms. For planes spaced d apart, strong reflections will occur when the incident beam of wavelength λ makes an angle θ with respect to the planes such that

$$\lambda = 2d \sin\theta. \tag{7}$$

This is known as *Bragg's law* and is the fundamental equation in x-ray scattering (see Fig. 4). When (7) is satisfied, the path-length difference between successive planes d equals one wavelength.

For crystalline materials, Bragg's law determines the condition for strong diffraction from an arbitrarily large number of parallel planes (Miller planes) defined by the integers h, k, l. We show in a later section that the intensities of Bragg reflections from the Miller plane (hkl) can be related to structure (i.e., the actual distribution of atoms).

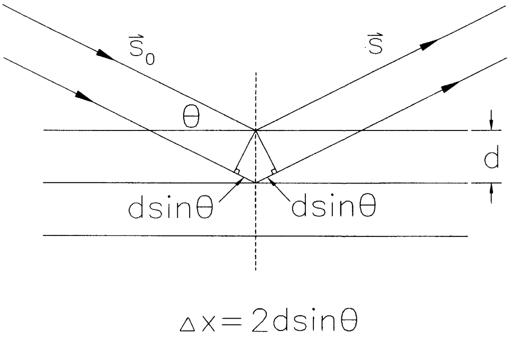

FIG. 4. A simple schematic showing how Bragg's law can be derived by requiring that the scattering path-length difference between two successive planes of scatterers be a multiple of a wavelength.

3. KINEMATIC VERSUS DYNAMICAL DIFFRACTION

3.1 Kinematic Diffraction

In the usual simplified treatment of the scattering of x rays, it is assumed that when an atom scatters an x-ray beam, the scattered wave has a negligible interaction with the atoms on its way out of the crystal. This approximation is known as the *kinematic theory of diffraction.* It predicts an experimentally observable Bragg intensity of scattering by a small crystal of volume Δv as

$$I_{hkl} = I_0(e^2/mc^2)^2 D|F_{hkl}|^2\Delta v, \tag{8}$$

where F_{hkl}, the structure factor for the Bragg (Miller) planes h, k, l, is related to the atomic scattering factors f_i of Eq. (3) with phase factors determined by the positions $(xyz)_i$ of the ith atom in the basic repeating unit cell of the crystal:

$$
\begin{aligned}
F_{hkl} &= \sum_{\text{atoms}} f_i[\cos 2\pi(hx_i + ky_i + lz_i)\\
&\quad + i \sin 2\pi(hx_i + ky_i + lz_i)]\\
&= |F_{hkl}|e^{i\Phi_{hkl}}.
\end{aligned} \tag{9}
$$

The structure factor F_{hkl} contains the positional coordinates of all the atoms and is in essence the crystal structure. The quantity D in (8) contains geometric and extrinsic parameters such as detector sizes, distances, and angular speeds of crystal rotation, which depend on the particular diffraction technique used.

If one could measure F_{hkl} for a large number of reflections, the coordinates of each atom could be computed. However, the quantity F_{hkl} has both amplitude $|F|$ and phase Φ as represented in Eq. (9). The amplitude is

$$
\begin{aligned}
F = \Bigg\{&\left[\sum_i f_i \cos 2\pi(hx_i + ky_i + lz_i)\right]^2\\
&+ \left[\sum_i f_i \sin 2\pi(hx_i + ky_i + lz_i)\right]^2\Bigg\}^{1/2}.
\end{aligned} \tag{10}
$$

The phase angle is

$$\Phi_{hkl} = \tan^{-1}\left[\frac{\sum_i f_i \sin 2\pi(hx_i + ky_i + lz_i)}{\sum_i f_i \cos 2\pi(hx_i + ky_i + lz_i)}\right]. \tag{11}$$

Experimentally one measures the intensity [Eq. (8)], which only gives the magnitude $|F_{hkl}|$ and not the phase information intrinsic in Eq. (9). It is for this reason that a careful measurement of large numbers of Miller reflections from a crystal will *not* provide sufficient information to extract the positional coordinates $(xyz)_i$ of each atom.

In x-ray crystallography, the art of deriving the atomic structure of a crystal, the crystallographer must use other means to arrive at the phases of the structure factor F. The need to derive, or guess at, the phases has spawned a variety of innovative procedures (too arcane to discuss in this treatment), some of which have led to Nobel prizes for their creators (Karle and Hauptman, 1953).

Another way of formulating the diffraction pattern from crystalline materials is to treat the crystal as a periodic, continuous distribution of matter $\rho(\mathbf{r})$. $\rho(\mathbf{r})$ is the electron density at point $\mathbf{r}$. Using very basic applications of Fourier series, it can be straightforwardly shown that $\rho(\mathbf{r})$ can be expressed as a 3-D Fourier series whose coefficients are F_{hkl}, the x-ray structure factors,

$$\rho(xyz) = \sum_h \sum_k \sum_l F_{hkl} e^{2\pi i(hx+ky+lz)}. \qquad (12)$$

With complete knowledge of F_{hkl}, the crystal structure $\rho(x,y,z)$ can be calculated. This somewhat different approach requires that both the magnitude and phase of the structure factor F_{hkl} be known and demonstrates again that intensity data alone, which gives only the amplitude $|F_{hkl}|$ and not the phase ϕ, is *not* sufficient to solve the structure.

In those cases (perfect crystals and strong reflection) where one cannot neglect multiple scattering, the quantitative description of intensities discussed earlier is no longer valid, and we enter the regime commonly described as dynamical diffraction.

3.2 Dynamical Diffraction

Multiple diffraction strongly affects the strength and phase of the propagating primary wave in the crystal. The intensity is no longer proportional to Δv, the volume of the crystal illuminated, and in the ideal case the intensity in a Bragg peak is proportional to F, not F^2.

It is not possible in this limited treatment of diffraction to delve deeply into the intricacies of dynamical diffraction, but a few points are worth mentioning. Bragg reflection curves from the face planes of a perfect crystal are predicted to have a particular top-hat shape with an angular range of total reflection and a finite width. This is called the Darwin curve and represents accurately the reflectivity curve from monochromator crystals used with synchrotron radiation sources.

In certain cases, standing waves are generated in the crystal that dramatically affect the diffracted intensities. In one case, called the Borrmann effect, the effective absorption of x rays from a crystalline material can be reduced by several orders of magnitude when these standing waves are created. See Batterman and Cole (1964).

4. RELATIONSHIP BETWEEN X-RAY CRYSTALLOGRAPHY AND MICROSCOPY

Why does the crystallographer have to go through the agony of measuring a million or so x-ray reflections while the microscopist (optical or electron) puts the sample in an instrument and literally looks at the magnified object? Why, in those cases, is the phase problem not a problem?

The main difficulty in doing x-ray microscopy is that there are no lenses that will refract and collect x rays to an image plane. X rays emanating from a point on the object cannot be focused to a corresponding point on an image plane.

When light interacts with matter, it scatters, creating a diffraction pattern. The eye, or lens in a microscope, collects the multibeamed diffraction pattern and simultaneously combines the beams together at an image point such that the relative amplitudes and phases of all scattered wavelets are coherently combined.

It is not necessary to identify the diffraction pattern as a part of the imaging process. Since all the diffracted beams occur and are collected at the same time from the initial incident plane wave, there is no phase problem because the diffraction pattern is not measured separately. The waves continue on to an objective lens, which combines all the diffracted rays keeping track of all the relative phases and amplitudes to illuminate the image plane.

In x-ray diffraction, because of the technical problems of simultaneously creating and recombining diffracted beams, each beam must be separately recorded, thereby losing the phase. The intensities of the diffracted beams are proportional to $F \cdot F^* = |F|e^{i\phi} \cdot |F|e^{-i\phi} = |F|^2$ and therefore do not give up phase information.

5. CRYSTALLOGRAPHY AND THE PHASE PROBLEM

The human rhinovirus-14 contains about 10^6 atoms. The actual virus unit is a soccer ball–shaped structure whose outer coat (the leather in the ball analogy) contains about 0.75×10^6 atoms. The outer coat is the sensitive part that attaches itself to the human cell. Knowing its precise topological structure is an essential step in the key to understanding how the virus infects the cell and, more to the point, provides certain essential information to design an antiviral drug.

The virus can be crystallized with about four virus units in the spatially repeating unit cell. The solving of the structure requires the coupling of knowledge of the biology of the system with sophisticated experimental techniques for crystal growth and a subtle intuitive understanding of the mathematical and computational techniques.

This *tour de force* in structure determination was performed by Michael Rossmann (Rossmann *et al.*, 1985) of Purdue University. The measurement involved determining the intensities of 2.5×10^6 Bragg reflections in order to establish the positions of about 10^6 atoms.

The experimental setup was quite straightforward by modern standards. A monochromatic beam of synchrotron-radiation x rays of energy about 8 keV (1.5 Å) was incident on a crystal of the virus, which was rotated through a fraction of a degree while exposing an x-ray film to the diffracted beams. Crystals of the rhinovirus are shown in the photograph of Fig. 5. A typical x-ray exposure is shown in Fig. 6. The relative intensities of the spots were determined from the films, and the $|F_{hkl}|^2$ were determined using Eq. (8).

As a help in determining the phases, a crystal of the virus was grown that was "doped" with gold atoms in such a way that these heavy atoms resided on specific sites in

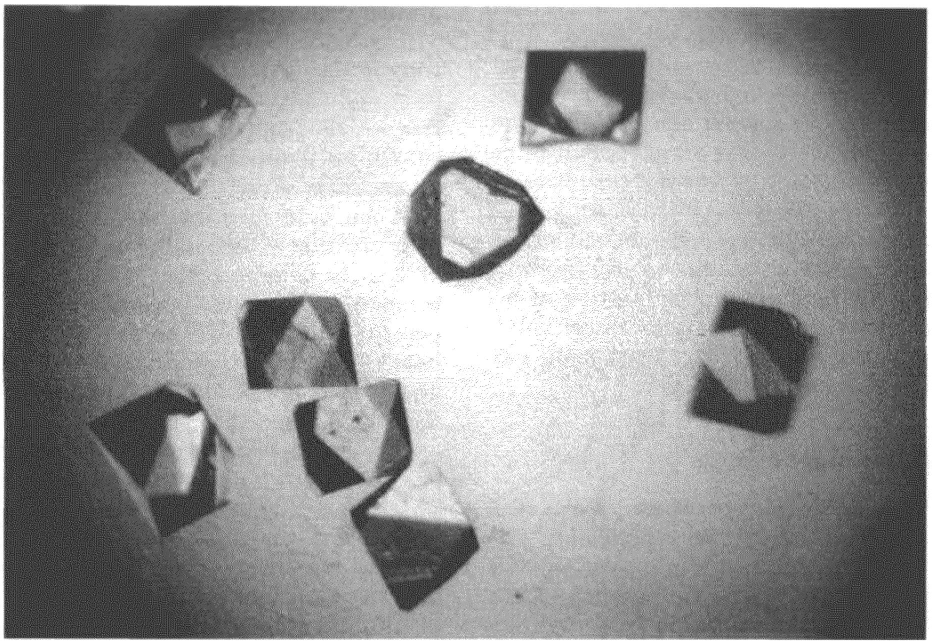

FIG. 5. Crystals of the rhinovirus-14 grown by Michael Rossmann. Typical crystal sizes are about 0.5 mm.

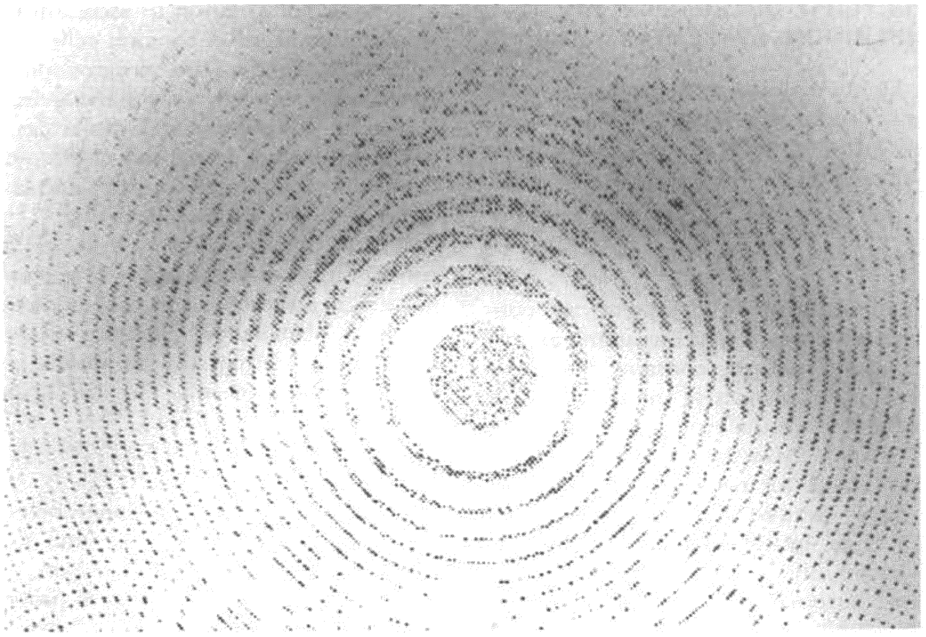

FIG. 6. Diffraction photographs of the HRV14 virus taken at the Cornell High Energy Synchrotron Source (CHESS). The crystal was oscillated through 0.3°, using x rays of 1.56-Å wavelength. Typical modern exposure times for a diffraction pattern of this quality would be considerably less than 1 min.

the structure. The gold atoms contain many electrons and therefore scatter more strongly than the typical atoms making up the virus and position themselves in the structure so as not to strongly perturb the native structure. Comparing the intensities of the peaks (see Fig. 6) between the native and the gold-doped "isomorphous replacement" structure gives important phase information. In this instance, the gold atoms act as a reference phase in a similar way that a reference beam in light holography allows the hologram to record phase information on a film. From the rough phases obtained in this comparison, and the F_{hkl} derived experimentally, an electron density map is computed using Eq. (12). This first map has poor resolution primarily because of noise (errors) in the data, which limit the resolution to about 6 Å.

This first try at the electron density uses roughly estimated phases because of errors in the data and experimental values of $|F_{hkl}|$. The resulting map has poor resolution and does not display the known symmetry of the structure very precisely. Here, the first trick in a boot-strapping iterative procedure is initiated. The computed electron density is averaged and made to comply with the known symmetry of the virus. Using this averaged density $\rho(r)$, the structure factors are calculated using Eq. (3), which is the same as F_{hkl} in Eq. (9) but for a continuous distribution of matter. New phases are calculated from F_{hkl} using Eq. (11). Now, these new phases and the *old* $|F_{hkl}|$, experimentally determined (the latter are the only things known for sure), are used in Eq. (12) to recalculate $\rho(r)$, which is the improved estimate of the structure. This process is repeated, each time providing new phases and incrementally adding higher-order terms in the Fourier series of Eq. (12), thus improving the resolution until a discernible high-resolution map is determined.

This simplified explanation is merely to give the reader a feeling for the complexities of getting around the phase problem through innovative experimental and computational techniques. In this manner, Rossman *et al.* (1985) obtained the first mammalian structure determined by x-ray crystallography.

6. STRUCTURAL DETERMINATION OF NONPERIODIC SYSTEMS

In a highly ordered and periodic system such as a crystal, the x-ray diffraction patterns consist of a sharp periodic distribution of x-ray beams as we have seen in Fig. 6.

6.1 Gases

In the most disordered system, we consider a gas of random noninteracting atoms. The diffraction pattern contains no sharp peaks, but one could derive the radial distribution of charge in the atom from the intensity data. In Fig. 2 we show the experimental scattering curves for neon gas with a theoretical curve derived from Thomas–Fermi wave functions. In this case, each atom scatters independently of all the others, and the diffraction pattern is simply the sum of the intensities from each atom illuminated by the beam. For a crystalline material, on the other hand, all atoms contribute to each diffraction spot in a highly complex manner, precisely determinable from their known positions in the crystal.

The order present in real materials continuously covers the range between these two extremes; and, not surprisingly, the complexity of the diffraction patterns ranges from trivial to intriguingly subtle. In the simplest cases, such as scattering from a gas, structural information such as the radial distribution of electrons in the atom can be obtained from intensity data alone. In the more complex structures we must have intensity and phase information to ascertain the positions of the atom in the unit cells.

Let us follow the progression toward more complex structures starting from scattering by gas atoms and molecules. If our gas sample were composed of diatomic molecules of O_2 instead of the simple single-atom rare gas discussed in Fig. 2, we can still treat the scattering of N molecules as N times that obtained from a single molecule, since the molecules are noninteracting and randomly distributed. Then the structure factor, Eq. (9), defines the amplitude scattered from a single molecule. For the O_2 molecule

$$F = \sum f_i e^{i(\mathbf{k}-\mathbf{k}_0)\cdot\mathbf{r}} = f_0(1 + e^{i(\mathbf{k}-\mathbf{k}_0)\cdot\mathbf{r}_{ab}}),$$

where $\mathbf{r}_{ab}$ is the vector distance between the two atoms of the molecule and f_0 is the atomic scattering factor for oxygen.

The intensity of scattering is proportional to $|F|^2$, which, averaged over all orientations of the O_2 dumbbells, can be shown to be

$$I \approx |F|^2 = 2f_0^2\left(1 + \frac{\sin kR}{kR}\right), \qquad (13)$$

where R is the distance between two oxygen atoms.

The intensity of scattering is simply the sum of the scattering from two random oxygen atoms [the first term in Eq. (13)] plus a sinusoidal modulation with a period determined by the separation R of the two atoms in the molecule. Figure 7 shows the experimental curve and theoretical prediction for the O_2 molecule (Compton and Allison,

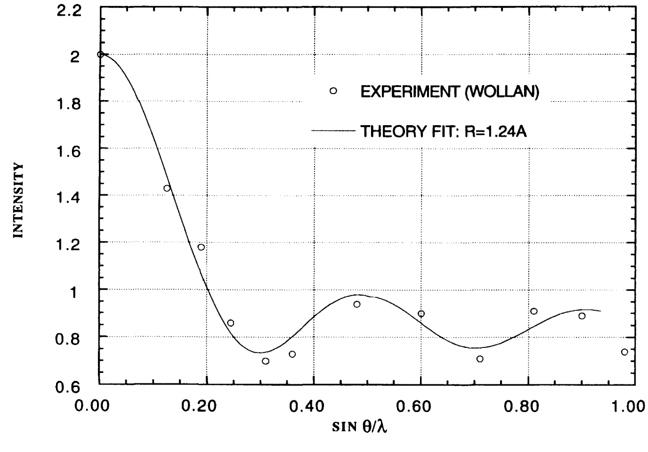

FIG. 7. X-ray scattering from diatomic oxygen. The solid curve is the fit of Eq. (13) with a value of R = 1.24 for the separation of the two atoms in the O_2 molecule.

1935). From a fit of the intensity vs scattering angle according to Eq. (13), the value of R can be readily obtained. The data in Fig. 7 give a value of $R = 1.24$ Å for the separation of the oxygen atoms in the O_2 molecule.

For more complex molecules, more sinusoidal periods will be present in the intensity function—in fact, one for each interatomic distance. The general expression for the intensity from an N-atom molecule will be

$$I = I_e \sum_{i=1}^{N} \sum_{j=1}^{N} f_i f_j \frac{\sin kr_{ij}}{kr_{ij}}, \tag{14}$$

where r_{ij} is the interatomic distance between atoms i and j and I_e is the Thompson scattering from a single electron. It can be readily seen that Eq. (14) reduces to the result for O_2 [Eq. (13)] when only two atoms are present.

Note that the structural information derived from the intensity of x-ray scattering gives interatomic distances r_{ij}, but not the spatial orientation of the vector distances between atoms. However, in many instances this limited structural information can be the key to deriving the complete structure.

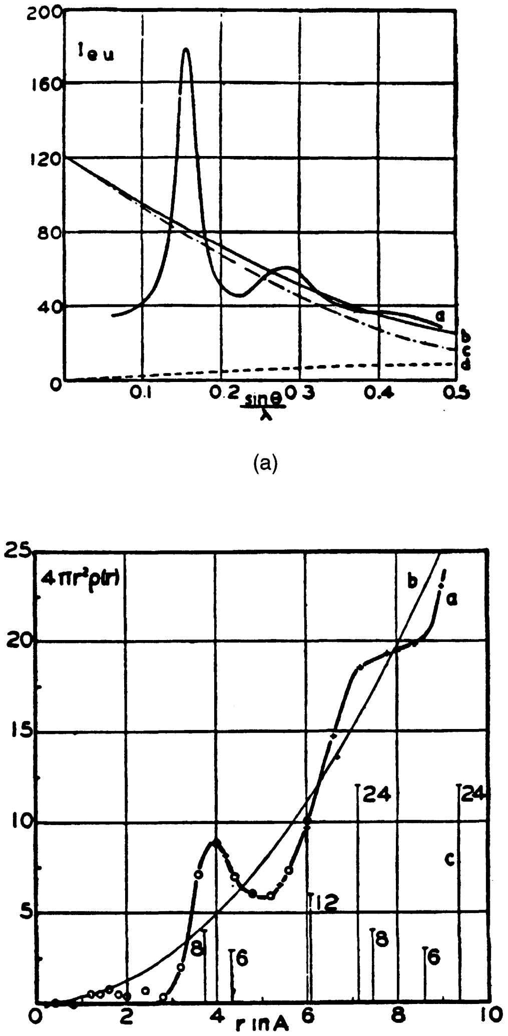
6.2 Liquids

Liquids and amorphous materials have complex structures where atoms interact strongly but do not produce a periodic crystalline structure. Nevertheless, there can be strong local ordering between neighboring atoms that strongly affects the macroscopic properties of the liquid.

In a manner similar to the scattering from dilute gases, x rays can give important information about the near-neighbor environment of the individual constituents. An analysis expanding on the concepts discussed earlier for gases leads to an expression for the intensity of x rays scattered from a monatomic liquid as

$$I = I_e \int_{\text{specimen}} 4\pi r^2 [\rho_0 - \rho(r)] \frac{\sin kr}{kr}\, dr, \tag{15}$$

where $4\pi r^2 \rho(r) dr$ is the number of atoms in a spatial shell dr of radius r about a given atom at the origin. This is the so-called radial distribution function of the material.



(a)

(b)

FIG. 8. (a) The experimental intensity curve for liquid sodium as a function of $\sin\theta/\lambda$ where 2θ is the total scattering angle and λ is the wavelength. (b) The radial distribution functions $4\pi r^2 \rho(r)$ derived from the data in (a). The curve b is the distribution in a homogeneous specimen. The bar graph c shows the distribution of neighbors in crystalline sodium (Tarasov and Warren, 1936).

We show in Fig. 8 the intensity curve (James, 1950) from liquid sodium together with the derived radial distribution function. Liquid sodium has a structure similar to that of a hard-sphere liquid, which can be modeled by the radial distribution function of a container randomly filled with ball bearings. For more complex liquids—for example, H_2O

(Morgan and Warren, 1938)—the effect of the molecular basis of the structure is apparent in the diffraction pattern of Fig. 9 compared to Fig. 8.

7. INTENSITY- VERSUS AMPLITUDE-DERIVED STRUCTURAL INFORMATION

Section 6 on scattering from nonperiodic structures shows that intensity information without phases can give important parameters of the structure of a material. One can generalize these results as follows: The intensity of scattering of x rays, without the phase information, gives only information on the interatomic distances present in a structure. This is valid irrespective of whether the structure is crystalline or amorphous. If one needs further information about how the interatomic distances are vectorially related to one another, then additional information about scattering phases is necessary.

Even for highly complicated structures such as the cold virus HR14 (see Sec. 5), one can, from intensity data alone, get the crystalline analog of the radial distribution function in liquid scattering. If the density of matter in a crystal is defined by $\rho(\mathbf{r})$, then this quantity gives the electron density at the point $\mathbf{r}$ in the crystal. If an atom is at that point, then the density is high. If the vector $\mathbf{r}$ lies between atoms, the density is low. If we now take the product of that density with the one a vector distance $\mathbf{X}$ away,

$$P_r(\mathbf{X}) = \rho(\mathbf{r})\rho(\mathbf{r} + \mathbf{X}),$$

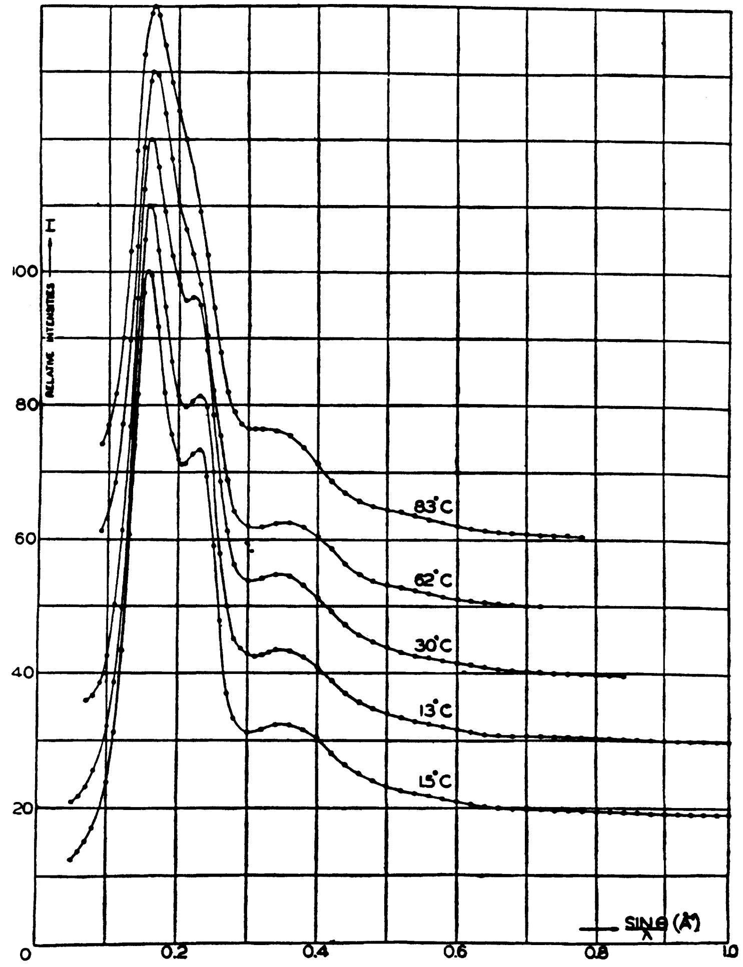


FIG. 9. The diffraction pattern of liquid H_2O at various temperatures (Morgan and Warren, 1938).

then $P_r(\mathbf{X})$ is the correlation function of the distribution of matter at a point $\mathbf{r}$ in the unit cell with a similar quantity for a point at vector distance $\mathbf{X}$ away. The average of this quantity over the repeat unit cell of the structure,

$$P(\mathbf{X}) = \iiint_{\text{cell volume}} \rho(r)\rho(\mathbf{r} + \mathbf{X})dv,$$

is a quantity called the autocorrelation function of the structure. Using methods similar to those leading to Eq. (12), we can show that the function $P(\mathbf{X})$ can be expressed as a Fourier series whose coefficients are not F_{hkl} as in Eq. (12) but F_{hkl}^2, which does not include the phase of the structure factor:

$$P(\mathbf{X}) = \sum_h \sum_k \sum_l F_{hkl}^2 e^{2\pi i(hX_x + kX_y + lX_z)}. \tag{16}$$

$P(\mathbf{X})$ is called the Patterson function of the crystal. F_{hkl}^2 is directly determined from the intensities of the x-ray diffraction Bragg peaks. The vector $\mathbf{X}$ is a vector in the real crystal. So, measuring a set of Bragg peak intensities, deriving F^2 from Eq. (8), and plugging them into (16) gives, without phase information, the self-correlation function of the structure. This is precisely what was done to get the radial distribution function of a liquid in Eq. (15) from the intensity of scattering. For a crystal, this function does not produce the structure, but it gives unambiguous information about relative atomic positions in the unit cell. This can be a significant clue to crack the structure.

In Fig. 10 we show a projection of the Patterson function of FeS_2 together with corresponding actual structure. Note that the Patterson function is more complicated than the actual crystal. This is because every vector distance between atoms is represented as a peak with respect to the origin of the Patterson function ($X = 0$). Thus the relative position of the atoms is lost.

Since the general rule that you get nothing for nothing applies, the Patterson function, easily obtainable, gives a very complicated semblance of the real crystal. However, in many cases, important clues about the structure can be quickly obtained.

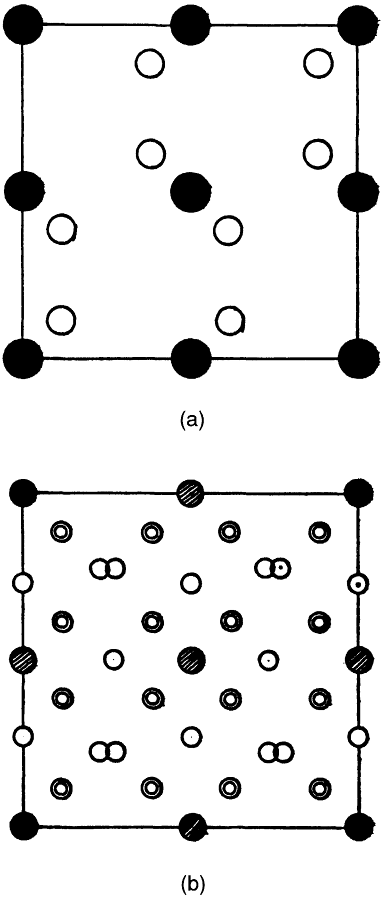

FIG. 10. (a) The atoms in a unit cell of FeS_2 as viewed from a cube face of the structure. (b) The Patterson function, derived solely from intensity data in the same projection.

8. X-RAY INSTRUMENTATION

8.1 Detectors

In recent years, x-ray diffraction techniques have undergone a major technological revolution due to remarkable advances in source and detector development. The development of synchrotron radiation sources has provided unprecedented new possibilities in the field of x-ray diffraction. It is analogous to the impact that the invention of the laser has had in the field of optics. Synchrotron radiation makes available fluxes up to six or more orders of magnitude greater than conventional x-ray tube sources with added ability to tune the photon energy continuously.

This source is also stroboscopically pulsed so that timing experiments of structural changes at the nanosecond level can be measured.

8.2 CCD Devices

Detectors have advanced well beyond Geiger and scintillation counters and film. (Film is still popular because of its relatively low cost, large active areas, and integrating properties.) Two major detector advances in the last decade have been the application of CCD detectors (similar to television cameras) and the development of storage phosphors. The CCD development involves the coupling of an x-ray image from a fluorescent screen to a CCD pixel array.

8.3 Storage Phosphors

Storage phosphors are a film replacement with some remarkable recording properties. The recording medium is a plastic sheet of sizes comparable to those used in standard medical applications of x-ray photography. An x-ray photon strikes the plastic that contains complex molecules of rare earth elements. These molecules are promoted to a metastable excited state with lifetimes of days. The plate is scanned by a narrow laser beam that stimulates the excited molecules to return their ground state emitting a distinctive pulse of visible light. These photons can be correlated to the laser beam position.

In many x-ray applications, storage phosphors have sensitivities that can be more than an order of magnitude greater than x-ray film and with dynamic ranges exceeding 10^4.

9. X-RAY DIFFRACTION METHODS

The diffraction techniques most often used in materials research and structure determination these days show the influence of the new synchrotron sources. Surprisingly, the more direct and simpler techniques survive.

9.1 Powder Diffraction

Most crystalline matter is available in polycrystalline form. Growing relatively large single crystals can be a difficult procedure, but in many cases the polycrystalline forms can be filed and ground to obtain large-volume samples of randomly oriented particles. When these are placed in a monochromatic x-ray beam, diffraction cones are generated and are explainable through a simple application of Bragg's law [Eq. (7)]. The cones intersect a film plane or detector slit and can be recorded with a single slit detector or a 2-D plate (CCD film or storage phosphor).

Because of the high collimation and monochromaticity of the source, each *hkl* reflection can be recorded and separated from its neighbors, allowing precise intensity measurements of each Bragg reflection. Highly sophisticated computer techniques can deconvolute the instrumental broadening. The final data can then be fitted to a model for the structure defined through the structure factor [Eq. (9)]. These new computer techniques allow one to solve moderately large unit cell structures without having to grow single crystals.

The powder method (also called Debye–Scherrer technique) is generally useful as an analytical tool for general-purpose material identification and is remarkable for its simplicity.

9.2 Laue Methods

The original discovery of the diffraction of x rays by von Laue in 1912 (Ewald, 1962) used the most primitive of all techniques: a collimated beam of polychromatic x rays strikes a crystal, and a film is placed behind the specimen to record the diffracted beams. For each Bragg plane (*hkl*) a particular wavelength is selected from the incident rays according to Bragg's law [Eq. (7)].

From the characteristic pattern one can identify the crystal orientation and make some comment about the crystal's symmetry. Until recently, the Laue method has not been an important tool for structure determination but is widely used as a general-purpose diagnostic. The development of synchrotron radiation has had a significant impact in increasing the technique's capabilities because of the intense broad-band fluxes it provides.

A conventional x-ray tube produces a few sharp characteristic lines and a weak polychromatic brehmsstrahlung background. The continuous beam from a synchrotron source is at least nine orders of magnitude higher.

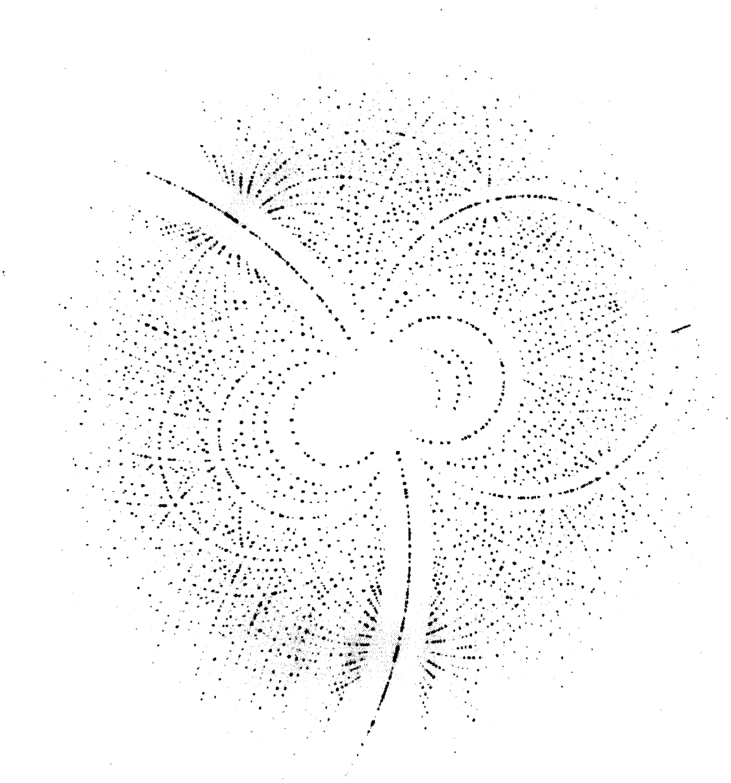

FIG. 11. The Laue pattern of an organic single crystal taken with synchrotron radiation.

Figure 11 shows a Laue pattern containing many thousands of spots. In appropriate cases, these exposures can be recorded in millisecond and even microsecond time scales. Attempts are under way to develop these techniques for studies of real time changes in structures promoted by external stimuli.

9.3 Single-Crystal Techniques

As we pointed out earlier, a highly parallel monochromatic x-ray beam incident on a crystal will be an unlikely candidate to produce a diffracted beam because of the geometrical restriction in satisfying Bragg's law. In the two techniques described above, these conditions are relaxed by allowing a wide range of wavelengths in the Laue case or a wide range of orientations with powder diffraction. For single crystals one relaxes the angular restrictions by rotating the crystal slowly so that different *hkl* planes can satisfy the Bragg diffraction condition. The pattern of the rhinovirus in Fig. 6 was taken in this manner. The crystal is exposed to a monochromatic synchrotron radiation beam as it oscillates over several degrees and a film is exposed. This is repeated over many crystal orientations to cover a large range of Miller planes *hkl.* For complex structures such as viruses and other large unit cell structures, the oscillation technique is the most simple and effective.

INTRODUCTION

Medicine is largely devoted to preventing disease or injury, diagnosing what is wrong when disease or injury may be present, and treating the patient to alleviate pain and, when possible, to cure the problem. Diagnosis is often a major challenge, as the patient's symptoms are frequently relatively unspecific and might be caused by a variety of conditions. Meeting this challenge usually requires conducting various tests, including laboratory analyses and imaging procedures. These tests are all products of technological advances in the practice of medicine that have occurred in the 20th century. A century ago, physicians were severely limited in the tools available to help them arrive at a correct diagnosis. Most diagnoses were made from a verbal description of the patient's symptoms, combined with the patient's history and supplemented by use of the physician's senses to detect unusual odors, visual appearances, abnormal sounds, physical sensations, and, at times, an odd taste. Although significant problems may have been present within the patient's body, they frequently provided few external clues, and the physician was guided toward a diagnosis largely by his (or, in a few cases, her) intuition and experience. Needless to say, the final diagnosis was uncertain or incorrect in more than a few cases.

A major advance in the physician's ability to detect and diagnose disease and injury occurred in 1895 with the discovery of x rays by the physicist Wilhelm Röntgen in Würzburg, Germany. Experimenting with a Crookes tube, Röntgen noted that crystals of barium platinocyanide on a bench across the laboratory gave off light when the tube was energized. He concluded that the fluorescence was caused by a new type of radiation, which he named x rays, that was emitted by the Crookes tube. He discovered that the radiation was reduced in intensity but not totally absorbed when an object was placed in its path and that an image of the object could be photographed by replacing the crystals with photographic film. If the object was an anatomical specimen such as the human hand, the image, termed a "projection radiograph," was a picture of the internal structure of the specimen. The first image, a radiograph of Frau Röntgen's hand, was produced a few days after x rays were discovered. When published a few months later, these results stimulated interest in many countries (Röntgen, 1895). In 1901, Röntgen was awarded the first Nobel prize in physics. By the turn of the century x rays were being widely employed for a variety of medical

conditions. X rays have been a very major contributor to the many advances in medicine that have occurred over the present century.

Today, x-ray imaging systems are used in hospitals, clinics, and physicians' offices worldwide for the detection and diagnosis of a wide spectrum of illnesses and injuries. In general, an x-ray imaging system consists of several components. An x-ray tube serves as the source of x rays that penetrate the patient and impinge on an image receptor such as a fluorescent screen or digital detector. The image is "captured" photographically or electronically and processed to accentuate anatomic features of interest in the patient. This image is interpreted by the physician to arrive at an opinion concerning the health status of the patient. The image may be stored physically or electronically for future referral.

1. PROJECTION RADIOGRAPHY

1.1 Nature and Production of X Rays

X rays are a form of electromagnetic radiation similar to infrared, visible, and ultraviolet light except higher in energy. They are widely used in medicine to produce images (radiographs) of virtually every region of the body. To achieve acceptable images, a source of x rays is required that

1. provides a sufficient number of x rays in a short interval of time,
2. allows the user to vary the x-ray energy,
3. produces x rays in a reproducible fashion, and
4. meets current standards of safety and operational efficiency.

The source almost universally employed for imaging is the x-ray tube. In this device x rays are released as high-speed electrons impinge on a target of a heavy metal such as tungsten.

The main components of a modern x-ray tube are shown in Fig. 1. As electrical current heats the tungsten filament in the cathode, electrons are boiled off (thermionic emission) and accelerated toward the target in the anode through a potential difference of from 20 000 to 150 000 V (20–150 kVp, where kVp denotes the peak kilovoltage across the tube). A focusing cup around the filament helps direct the electrons onto a small area (the focal spot) of an annular target that is embedded in a larger disk (the anode). X rays are released in all directions as the electrons interact in the target. The x rays are restricted by collimators outside the x-ray tube to confine the x-ray beam to the anatomic region of interest in the patient. Although intense bursts of x rays can be produced in this manner, most (>99%) of the electron energy is dissipated as heat in the target (Hendee and Ritenour, 1992). The anode rotates at several thousand revolutions per minute to spread the heat over a larger volume of target metal to keep the temperature of the metal from reaching its melting point.

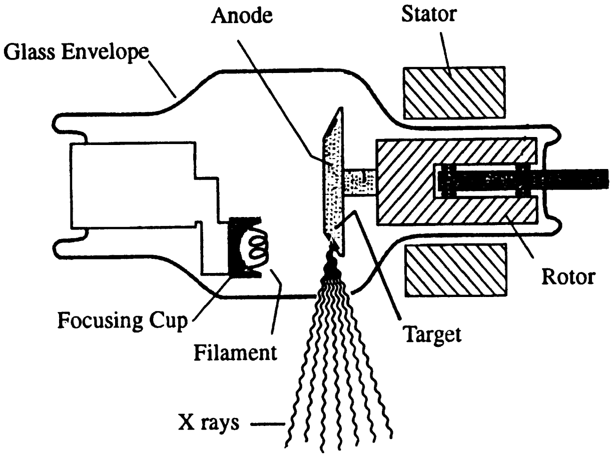

FIG. 1. Components of a modern diagnostic x-ray tube.

As the high-speed electrons penetrate the target metal, they interact with the electrons and nuclei of the target atoms through Coulombic (charged particle) interactions. During interactions with electrons, target atoms are ionized by ejection of inner-shell electrons, and x rays are released as the affected atoms regain stability by reordering of the electron shells. These x rays are termed "characteristic" x rays because their energy is characteristic of the type of metal employed as the x-ray target. For example, characteristic x rays of 58 and 67 keV are released from a tungsten target, where keV stands for kiloelectron volt, and the electron volt is a unit of energy equal to that gained by an electron accelerated through a potential difference of 1 V.

As electrons interact with nuclei of the target atoms, they are slowed down, and energy is released in the form of x rays termed bremsstrahlung (braking radiation). Bremsstrahlung provides a continuum of x-ray energies with a maximum value defined by the energy of the impinging electrons. For most x-ray beams used for medical imaging, bremsstrahlung is a more important contributor compared with characteristic x rays. A notable exception is the significant role played by characteristic x rays in beams employed for mammography (imaging of breast tissue), an application discussed later in this article.

To prevent the accelerated electrons from interacting with gas molecules on their way to the target, components of the x-ray tube are housed in a glass tube that is evacuated to very low pressure. The tube is contained within an oil-filled shielded housing that provides electrical insulation and prevents x rays from emerging in unwanted directions. During an x-ray exposure, the technique factors [tube voltage (kVp), tube current (mA), and exposure time (ms)] are monitored carefully to prevent overheating of the target and other components of the x-ray tube.

1.2 Interactions of X Rays

For a parallel, monoenergetic beam of x rays, the intensity I of x rays transmitted through a material of thickness z is

$$I = I_0 \exp\left[-\int \mu(z)dz\right],$$

where the line integral is taken over all tissues along the x-ray beam, I_0 is the intensity with no material present, and μ is the linear x-ray attenuation coefficient of the material, which may vary depending on the material's composition at each depth. If the material varies in composition laterally from one point to the next, the transmitted x rays also vary in intensity across the x-ray beam. By capturing the transmitted x-ray beam on a film or fluorescent screen, the pattern of variation in the material's composition is reflected in the image. As mentioned earlier, this image is termed a projection radiograph because it is formed through projection of a material into an image by transmitted x rays.

The linear attenuation coefficient μ is the sum of coefficients for various types of x-ray interactions that may occur in the material. For the energy range (20–150 keV) of x-ray energies used to produce medical images, two types of interactions are dominant. These interactions are the photoelectric effect, described by the photoelectric linear attenuation coefficient τ, and the Compton effect, described by the Compton linear attenuation coefficient σ. That is, $\mu = \tau + \sigma$. The dependence of these coefficients on x-ray energy is shown in Fig. 2 for interactions in human soft tissue. Additional information on x-ray interactions is available in INTERAC-

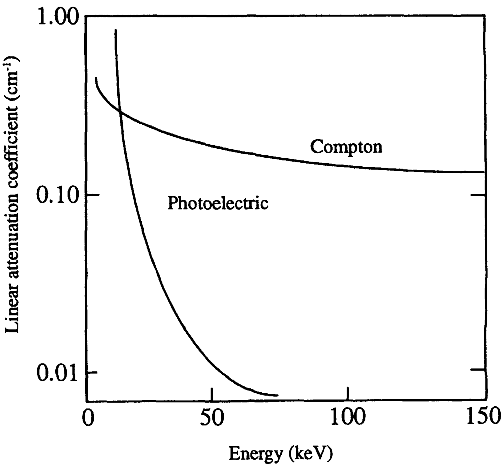

FIG. 2. The linear attenuation coefficient for x rays in soft tissue is the sum of two dominating contributions. Attenuation coefficients for these two contributions, Compton scattering and photoelectric absorption, are plotted as functions of the x-ray energy.

TION OF SOLIDS WITH PARTICLES AND RADIATION.

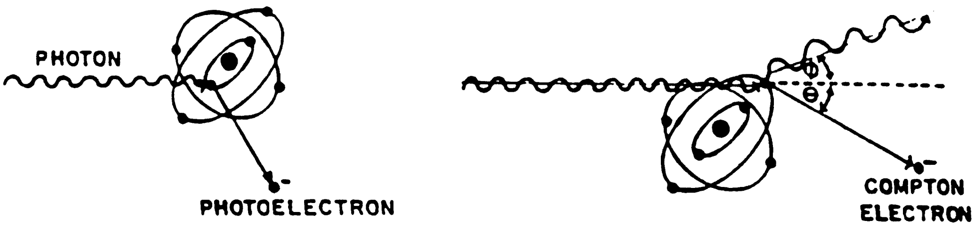
In a photoelectric interaction, the x ray interacts almost always with a tightly bound electron in an inner shell of an atom of the absorbing material. Because of the importance of tightly bound electrons, photoelectric interactions are strongly influenced by the atomic number Z, with the probability of photoelectric interaction per unit mass of material varying directly with Z^3 of the material. All of the energy of the x ray is transferred to the electron, which is ejected from the atom with a kinetic energy E_k of

$$E_k = E_{\text{x-ray}} - E_b,$$

where E_b is the binding energy of the ejected electron and $E_{\text{x-ray}}$ is the x-ray energy, which can also be expressed as $h\nu$, where h is Planck's constant (6.62×10^{-34} J-s) and ν is the frequency of the x ray. Since the x ray is only energy, it disappears during a photoelectric interaction and is essentially replaced by a high-speed electron and an ionized atom. Photoelectric interactions occur predominantly with low-energy x rays, and decrease in likelihood as $(h\nu)^{-3}$. A photoelectric interaction is depicted in Fig. 3(a).

A Compton interaction results in the scattering of an x ray in a new direction at reduced energy, rather than complete absorption of the x ray. Compton scattering produces most of the scattered radiation that degrades the quality of x-ray images. In this type of interaction, the x ray interacts with a loosely bound electron in an outer shell of an atom of the absorbing material. The electron is ejected with an energy equal to the difference in energy of the incoming and scattered x rays, with the assumption that the binding energy of the ejected electron is so small it can be neglected. Because the interaction occurs almost always with outer, loosely bound electrons, the Compton interaction is independent of the atomic number Z of the absorbing material. Compton interactions occur predominantly for the higher range of x-ray energies employed for medical imaging. The likelihood of these interactions decreases gradually with increasing x-ray energy. A Compton interaction is depicted in Fig. 3(b).

For both photoelectric and Compton interactions, the linear attenuation coefficient varies with the physical density (kg/m^3) of the absorbing material. Hence, the intensity of x rays transmitted through a material reflects the density of the material and, to varying degrees, the atomic number of the material, depending on the energy of the x rays and, therefore, the degree to which photoelectric interactions are responsible for reducing the intensity. By choosing the x-ray energy through selection of the voltage across the x-ray tube, an x-ray beam may yield a projected radiograph that accentuates or suppresses differences in atomic number among different constituents of an absorbing material. This characteristic is used to great advantage in medical imaging. For example, low-energy x rays may be used to amplify small differences in tissue composition that may be important for the detection of subtle abnormalities in soft tissue. Breast imaging is one example where low-energy x rays are used to amplify subtle soft-tissue differences. On the other hand, high-energy x rays may be needed to suppress relatively large differences in tissue composition so that more subtle features of tissue are not hidden by "shadows" cast by strongly absorbing struc-



(a) (b)

FIG. 3. (a) Photoelectric interaction; (b) Compton scattering.

tures. Chest imaging is one example where high energy x rays are used to penetrate the ribs and other strongly absorbing structures to reveal more subtle features of the underlying lung parenchyma. For x rays at any energy, those that are not transmitted through the patient are absorbed or scattered in the patient. These processes result in energy deposition in the tissues of the patient, where the energy deposited per unit mass of tissue is known as the "absorbed dose."

1.3 Image Production on Screens and Film

Image receptors employed for x-ray imaging include film, usually used in combination with fluorescent screens; fluorescent screens contained within an image intensifier for fluoroscopic imaging of dynamic processes; and solid-state detectors such as semiconductor detectors and photostimulatable phosphorescent plates for generation of electronic signals. Photographic emulsions are sensitive to x rays, and an x-ray image of exceptionally high quality can be formed by direct exposure of photographic film to an x-ray beam. This approach to medical imaging is occasionally used when exquisite detail is required in the image, as might be the case when hairline fractures in the bones of extremities are suspected. However, film by itself is an inefficient absorber of x rays, and for most applications it would require long exposure times that would yield images with unacceptable amounts of motion blurring. In almost all cases, permanent x-ray images are produced by sandwiching the film between "intensifying screens" that absorb x rays with reasonable efficiency (up to 50%) and emit visible light that in turn exposes the photographic film.

The first intensifying screens were developed by Edison and contained calcium tungstate ($CaWO_4$) as the active light-emitting ingredient. These screens remained popular until the 1970s, when they were replaced by screens with phosphors containing a rare-earth element such as gadolinium, lanthanum, or yttrium complexed with oxysulfide or oxybromide crystals embedded in a plastic matrix. Compared with $CaWO_4$ screens, rare-earth screens are better absorbers of x rays, and some yield more light for each x ray absorbed. Screens with thicker emulsions of light-emitting material are said to be "faster" (i.e., they have a higher "speed") because they require less exposure to release enough light to expose the film. This advantage is not without cost, however, because thinner screens (so-called detail screens) yield images with improved spatial resolution (less geometrical blurring). The choice of intensifying screens is a compromise between increased geometric blurring with fast screens and increased motion blurring with detail screens.

Most x-ray images are produced by sandwiching an x-ray film between intensifying screens in an imaging cassette that is tightly sealed (sometimes even evacuated) to produce intimate contact between the film and screens, thereby reducing geometric blurring. Cassettes are available to hold film of different sizes from 4 × 4 inches to 14 × 17 inches used for chest radiography. Once the film has been exposed to x rays or light from the intensifying screens, it contains a "latent image" that can be made visible by chemical processing. In the visible image, darker areas represent regions penetrated by a larger number of x rays, whereas lighter areas depict regions where more x rays are absorbed. In many cases, the lighter areas reveal bony structures because the higher density and atomic number of bone results in greater absorption of the impinging x rays.

1.4 Fluoroscopy

Projection radiography yields exquisite images that represent a "snapshot in time" of the patient's anatomy. In many cases these images are sufficient to detect an abnormal condition and to arrive at a diagnosis of the cause of the abnormality. But this is not true in all cases. Sometimes a continuous image is required that yields information about how the region of anatomy is changing or functioning over the course of a few seconds or minutes. The technique that yields such a continuous image is referred to as "fluoroscopy" because it captures the image instantaneously on a fluorescent screen and displays it in real time to the viewer.

Early applications of fluoroscopy employed a fluorescent screen that was viewed directly by the physician. The image was so dim, however, that the observer's vision had to be "dark-adapted," and even then only gross features could be detected. The viewing conditions resembled those present in a darkened movie theater. Although this approach was highly unsatisfactory, it was the only method available for fluoroscopy until the 1950s when the image intensifier was developed.

An image intensifier is depicted in Fig. 4. X rays impinging on the CsI input screen produce light that dislodges electrons from the photocathode. These electrons are accelerated toward the anode and are focused to pass through the aperture in this structure and onto the output screen. Here they produce a minified image that is thousands of times brighter than the image on the input screen. This image may be captured optically and projected through a system of lenses and mirrors for direct viewing by the observer. More often it is projected into a television camera and converted into an electrical signal that can be transmitted to a remote television monitor for reconfiguration and viewing. Since the image is converted from light to an electrical signal during this process, it can be converted easily to a digital image for integration into a digital imaging network.

Fluoroscopic methods are an essential part of medical x-ray imaging. They are widely employed in many types of x-ray studies, including those of the gastrointestinal tract and angiographic studies of the central and peripheral circulatory system. They also are used for image-guided therapy (e.g., coronary angioplasty, interventional neuroradiology, and minimally invasive surgery), a therapeutic approach that is growing rapidly in application because of its reduced morbidity and, often, lower cost compared with alternative therapeutic approaches.

1.5 Digital Imaging

The combination of intensifying screens and photographic film has many advantages for capturing and recording x-ray images. It is simple, portable, and inexpensive, and it yields images with excellent anatomic detail. This approach, however, has some disadvantages as well. It is limited to a rather narrow range of acceptable exposures and offers little flexibility for image enhancement or data compression. Film images are bulky to store and easy to misplace, and they must be transported physically from one location to another. Replacing this analog method of image production with an approach that yields digital images would eliminate these disadvantages. Hence, considerable interest in digital approaches to projection radiography has surfaced in recent years. In all likelihood, digital methods will capture an increasing fraction of the projection radiography market over the next several years.

In the digital radiographic unit shown in Fig. 5, the x-ray source and receptor are computer controlled to yield digital images that are displayed in real time on a video screen. Digital images can be stored on magnetic media or optical disk, and a film-writ-

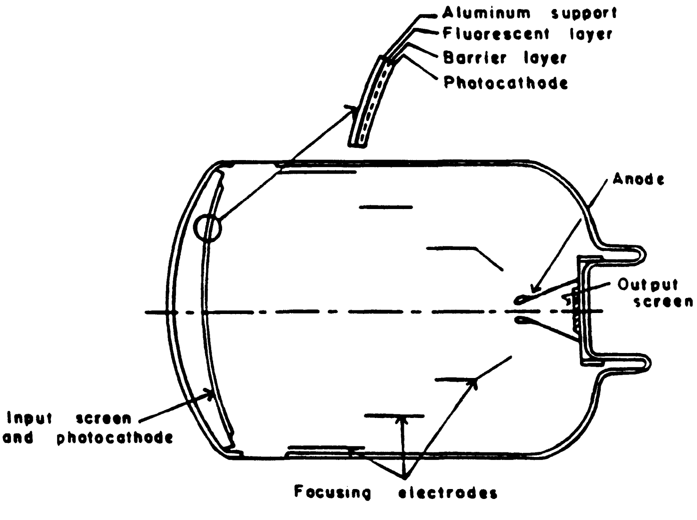


FIG. 4. X-ray image intensifier.

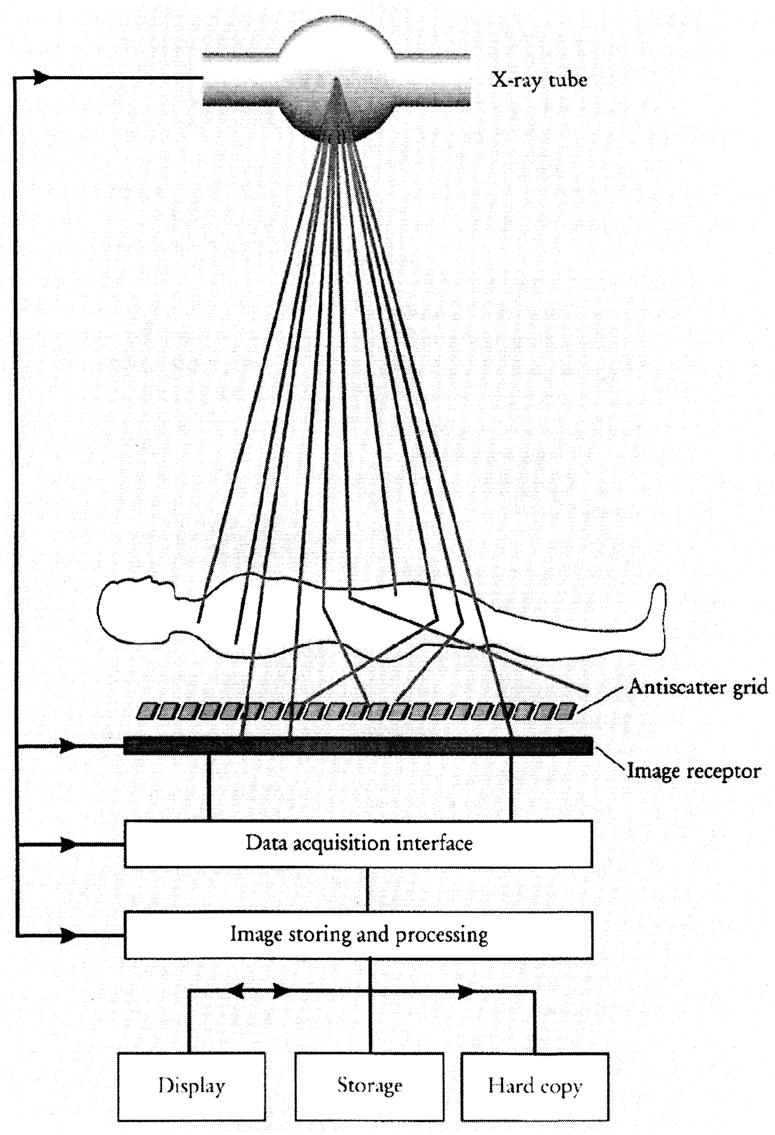

FIG. 5. Digital x-ray imaging system creates images that can be displayed in real time. X rays that traverse the patient unscattered are recorded by the digital image receptor, and the data are passed on for processing and display, storage and, when desired, production of hard-copy images. The antiscatter grid prevents scattered x rays from reaching the receptor. (Used with permission from Hendee, 1995.)

ing device can be used to produce permanent analog copies of the images if they are needed. Two types of image receptors currently are used in digital radiography. One type records the entire image simultaneously, while the other acquires a complete image by scanning the x-ray beam and receptor in synchrony across the patient, a technique known as scan-projection radiography. Various methods are employed for digital data acquisition, including the use of image intensifiers with frame-grabbing television cameras, ionographic chambers, solid-state detector arrays, and photostimulated-luminescence plates (Hendee, 1995a). Of these methods, all but photostimulated plates are impractical today for routine projection radiography. Commercially available stimulated-luminescence plates employ a phosphor that absorbs x rays and reradiates their energy as visible light when scanned with a laser beam. The emitted light is detected by a photomultiplier tube and digitized with an 8- or 16-bit analog-to-digital converter. The digitized image is displayed on a video monitor and can be stored for later recall.

Conventional projection radiographic films can be digitized with a scanning microdensitometer to yield digital radiographs. As with any other digital image, a digital radiograph can be transmitted electronically to distant sites for interpretation and consultation, a technique known as teleradiology. Digital radiographs can be integrated with other digital images into an electronic image network for correlation with other digital images such as those produced by computed tomographic techniques, as discussed later.

Digital x-ray images offer several advantages over screen and film radiographs. They can be computer-processed to highlight selected features (edge sharpening, contrast enhancement, and noise smoothing), and the data can be compressed for efficient transmission electronically to distant sites. They require less storage space, and copies can be easily presented for viewing without risk of misplacing the original data. Digital x-ray images sometimes require less radiation exposure compared with analog projection radiographs. Finally, computer subtraction of digital images taken at different times can often reveal changes that are not visible in the original images. Disadvantages of digital radiographs include the cost of the equipment required for their production compared with simple film-screen techniques and possible losses in image detail occasioned by the finite number of picture elements (pixels) used for image display.

1.6 Image Detail

The level of detail visible in an x-ray image is a compromise among four kinds of resolution: spatial, contrast, temporal, and statistical. Spatial resolution is related to the geometry of the image-forming process and the resolving capacity of the imaging device (often called the “image receptor”). Contrast resolution is affected by the differences in the absorption and scattering characteristics of the various tissues depicted in the image and by the impact of scattered x rays on the receptor. Temporal resolution refers to the blurring caused by the patient’s voluntary or involuntary movement (e.g., breathing, peristalsis, cardiac motion, or vascular pulsatile motion) during exposure to x rays. Statistical resolution is related to the number of x rays absorbed in the receptor to produce the image; the noise is inversely proportional to the square root of the number of x rays used to form the image. In most cases, improving any one of these resolution factors degrades one or more of the others. The compromise among them represents a balance so that no single factor strongly dominates the degradation of detail in the image.

X rays scattered from the patient during Compton interactions can be a major degrading influence on the visibility of detail in the image. Usually this influence is controlled by inserting a mechanical grid between the patient and the image receptor. The grid contains thin strips of lead or other high-*Z* material oriented parallel to the direction of impinging primary x rays. These x rays pass through the grid, while x rays that are scattered away from the direction of the primary radiation strike the grid strips and are absorbed.

The challenge of x-ray imaging is to capture subtle differences (i.e., modulation) in tissue composition by passing an x-ray beam through the tissue, and to transfer these captured differences onto an image receptor where they can be seen by the human eye. That is, the purpose of medical imaging is to transfer modulation in the tissue (object) into modulation in the image. The degree to which this modulation is transferred faithfully by an imaging system is described as its modulation transfer function (MTF). With most imaging systems, object modulation can be transferred to the image with high fidelity if the modulation is of relatively low frequency (i.e., the object is composed of relatively large structures that are well separated from adjacent structures). For smaller structures that are closer together, however, the integrity of modulation transfer may be less exact. Hence, the MTF is frequency dependent, as shown in Fig. 6 for two imaging systems. In this illustration, the fidelity of system 1 is superior to that of system 2, as evidenced by the higher values of MTF at higher frequencies.

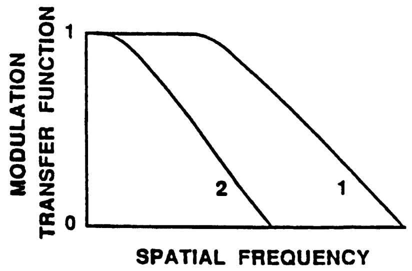

FIG. 6. Modulation transfer function (MTF) for two x-ray imaging systems, with system 1 providing higher spatial fidelity compared with system 2.

The MTF is a relatively simple (and somewhat simplistic) measure of the performance of an imaging system. To determine the MTF, one obtains an x-ray image of a very thin transparent slit in an otherwise opaque object. The image of the slit is scanned with a microdensitometer to determine the spread of the slit in the image. The resulting curve is described by a "line spread function" that can be characterized in frequency space through the process of Fourier transformation. The result is the MTF, expressed as a function of spatial frequency, as demonstrated in Fig. 6. The spatial frequency, expressed in units such as line pairs per millimeter or cycles per millimeter, is a measure of the frequency of variation per unit distance. It may be compared with the temporal frequency, expressed in units such as cycles per second or hertz, which is a measure of the frequency of variation per unit time.

2. IMAGE INTERPRETATION

Interpretation of medical images is a complex process that is as much art as science. It requires years of training, much of which is provided in a "master and apprentice" style since it has not been possible to model the interpretive process quantitatively. On the other hand, computer programs have been written to perform selected analyses of the patterns of information present in certain types of images such as chest radiographs and mammograms. By comparing these analyses to databases compiled from a large number of normal and abnormal images, a tentative diagnosis can be arrived at for presentation to the interpreter for confirmation. Such a decision-support system is referred to as "computer-aided diagnosis." Studies of this approach have shown that it increases the accuracy of diagnosis of the typical radiologist (Doi *et al.,* 1993).

Computer-aided diagnosis is a far step from the use of expert artificial-intelligence systems to provide a primary diagnosis from medical images without human intervention. Such systems would essentially have to mimic the thought processes of physicians interpreting images, including the incorporation of ancillary information such as the patient's history and data acquired by physical examination. These thought processes are largely intuitive, acquired through apprenticeship training and experience, and are almost impossible to articulate clearly. Replacement of the human interpreter of images with a computer algorithm for image interpretation would be a major challenge.

It is important to recognize, however, that an expert system for image interpretation does not have to be perfect. Instead, it must function only at a level at least comparable to the accuracy of the average radiologist. With this criterion in mind, exploration is occurring of expert systems for image interpretation in medicine. Some of these explorations employ "neural networks," algorithms that use feedback information from humans to build decision rules based on the successes and failures of past decisions. Medical imaging is still a long way from automated diagnosis, as contrasted with computer-aided diagnosis, which relies ultimately on human confirmation or rejection of a proposed diagnosis. Still, progress in expert systems in other imaging disciplines, including military surveillance and space exploration, has been spectacular over the past two decades, and the application of such systems to medical imaging remains promising.

The ability of a computer to transcribe voice dictation of radiology reports automatically would be a major advance in getting the reports quickly to physicians who are caring for ill and injured patients. This approach would also reduce the costs associated with manual transcription of dictated reports, especially since radiologists dictate over 130 million reports annually in the United States alone. Speech-processing computer-based systems are available commercially, and their application to radiology reporting is under exploration in a number of imaging centers. Voice patterns are as distinctive as fingerprints, and automatic dictation could enhance the security and reduce unauthorized access of patient information associated with medical imaging procedures.

3. X-RAY TOMOGRAPHY

In a conventional radiograph, all structures within a three-dimensional volume of tissue exposed to x rays are projected "in focus" onto the two-dimensional image receptor. As a result, an anatomic structure of interest is often obscured in the image by the shadow of objects that lie above or below it in the patient. Removing the presence of these obscuring shadows often helps reveal the structure of interest. Two approaches, analog tomography and computed tomography, are available for removing the image of obscuring structures. As computed tomography has grown over the past two decades, analog tomography has diminished in popularity.

3.1 Analog Tomography

Analog tomographic images are produced by keeping structures in focus in a selected image plane in the patient, while blurring the image of structures above and below the imaging plane. The blurring is accomplished by moving the x-ray tube and image receptor during exposure through an angle with a pivot (fulcrum) in the image plane. In actuality, the image plane has a finite thickness (and is more properly referred to as an image section) that can be reduced by increasing the angle of motion. The location of the section within the patient may be changed by positioning the patient appropriately with respect to the pivot of the tomographic angle. Although the shadows of overlying and underlying structures are blurred, they are not completely removed from the image, and they frequently appear as "ghostlike" artifacts that interfere with the clarity of structures of interest. In addition, analog tomography has the limitations that conventional image receptors are unable to resolve small differences (1–2%) in the intensity of incident radiation, and the wide-area x-ray beams employed produced considerable scattered radiation that interferes with the visualization of subtle detail in the image. Analog tomography is still used for certain applications such as a supplement to chest radiography. For other tomographic needs, however, it has been replaced by computed tomography because this approach reduces the limitations often encountered with conventional tomography.

3.2 Computed Tomography

The mathematical model used in computed tomography (CT) was described in 1917 in a remarkable work by the Austrian mathematician Radon (Radon, 1917). The model was first used in applications of image reconstruction to radio astronomy, electron microscopy, and optics. In 1972, the first commercially available x-ray transmission CT unit for studies of human anatomy was announced. In 1979, the developer of this unit, G. Hounsfield (1973), shared the Nobel Prize in Medicine with a physicist, A. Cormack (1963), who did early work on image reconstruction. The first commercial CT unit employed a narrow beam of x rays scanned across the patient in synchrony with a scintillation detector moving on the opposite side of the patient. The intensity I of x rays measured by the detector is given by

$$I = I_0 \exp\left(-\sum \mu_i x_i\right),$$

where μ_i represents the linear attenuation coefficient of each of several structures in the path of the narrow x-ray beam and x_i represents the thickness of each of the structures.

With a single measurement of x-ray transmission, the separate attenuation coefficients cannot be determined. With multiple transmission measurements obtained at different orientations, however, the separate coefficients can be distinguished to yield a two-dimensional distribution of linear attenuation coefficients across the imaging section defined by the thickness of the scanning x-ray beam. This distribution can be mapped as CT numbers determined from the formula

$$\text{CT number} = 1000(\mu - \mu_w)/\mu_w,$$

where μ is the coefficient at a specific location in the section and μ_w is the linear attenuation coefficient of water for the x-ray energy employed for CT scanning. From this expression it can be appreciated that the CT number for water is zero and the CT number for air, with a very small value of μ, is close to -1000. The CT number would be about $+1000$ for a structure such as compact bone or colon containing barium contrast medium, because the physical density would be almost twice that of water. The CT numbers can be presented as various shades of gray to provide a visual display of the distribution of tissues across the image section. This display is referred to as a CT image.

The x-ray tube and scintillation detector of early CT units scanned the patient along a linear path perpendicular to the axis of rotation of tube and detector. Measurements of x-ray transmission were obtained every 2.5 mm over the linear path of 40 cm length to yield a total of 160 transmission measurements. Then the angular positions of the x-ray tube and detector were advanced 1°, and another scan of 160 measurements was obtained. This process was continued over 180° to provide 28 800 transmission measurements. These data were then transmitted to a computer equipped with a mathematical package for reconstructing a cross-sectional image of the scanned section. Initially, reconstructed images were computed by a time-consuming iterative mathematical model. More recently, faster algorithms using a convolution (filtered back-projection) model for image reconstruction have been employed (Kak and Slaney, 1988; HOLOGRAPHY, ACOUSTICAL). These algorithms rely on a Fourier transformation of x-ray projection data into frequency space, permitting use of ramp and cutoff-frequency filters to improve image quality and enhance subtle features in the image (see FOURIER AND OTHER MATHEMATICAL TRANSFORMS).

The combination of translational and rotational motion employed in early CT units yielded satisfactory CT images, but several minutes were required for data acquisition, limiting the method to studies of structures such as the head and extremities where voluntary and involuntary motion of the patient is not a problem. There was great interest in applying CT to thoracic and abdominal studies, but the scan time had to be decreased from minutes to seconds if these areas were to yield satisfactory images. Major efforts to reduce scan time led to the development of successive generations of CT scanners as depicted in Fig. 7. The initial translate-rotate scanner (first generation) is shown in Fig. 7(a), whereas an array of detectors (second generation) that tracks the linear motion of the x-ray beam is shown in Fig. 7(b). A purely rotational design (third generation) for CT scanning is depicted in Fig. 7(c), and a fourth-generation design is shown in Fig. 7(d) in which an x-ray tube rotates around the patient within a stationary ring of x-ray detectors. With the rotational scanners, data for a single section can be acquired in just a few seconds. By combining these geometries with the patient gantry moving continuously along its long axis, cross-sectional images of many slices can be obtained in minimum time, a process known as "spiral" or "helical" scanning (Heath *et al.*, 1995). Finally, images of vertical (sagittal or coronal) slices through the body can be produced by compiling arrays of attenuation coefficients along axes parallel to the patient's long axis.

Although the evolution of CT scanning geometries shortened the time to acquire images, none of the geometries permitted data acquisition in a time (less than 0.1 s) short enough to capture images of the heart and other blood-perfused organs without significant degradation caused by motion. For CT images of these organs, a way is needed to produce x-ray projection data without mechanical motion in the scanner. A scanner of this sort is known as a fifth-generation scanner (Hendee, 1983). It employs an electron-beam gun that generates x-ray beams in different directions by scanning over a stationary concave metal target. The resulting scan times are as fast as 50–100 ms.

CT images are most commonly displayed as cross-sectional representations of patient anatomy. By examining continuous cross-sectional images, radiologists can intuitively integrate the imaging information into a three-dimensional model of anatomy. This integration can also be accomplished physically by recognizing that a data set of contiguous two-dimensional sections in computer memory is in actuality a three-dimensional database. By mathematically compiling data across planes that cut across this database in preferred directions, coronal and sagittal images, as well as images at oblique

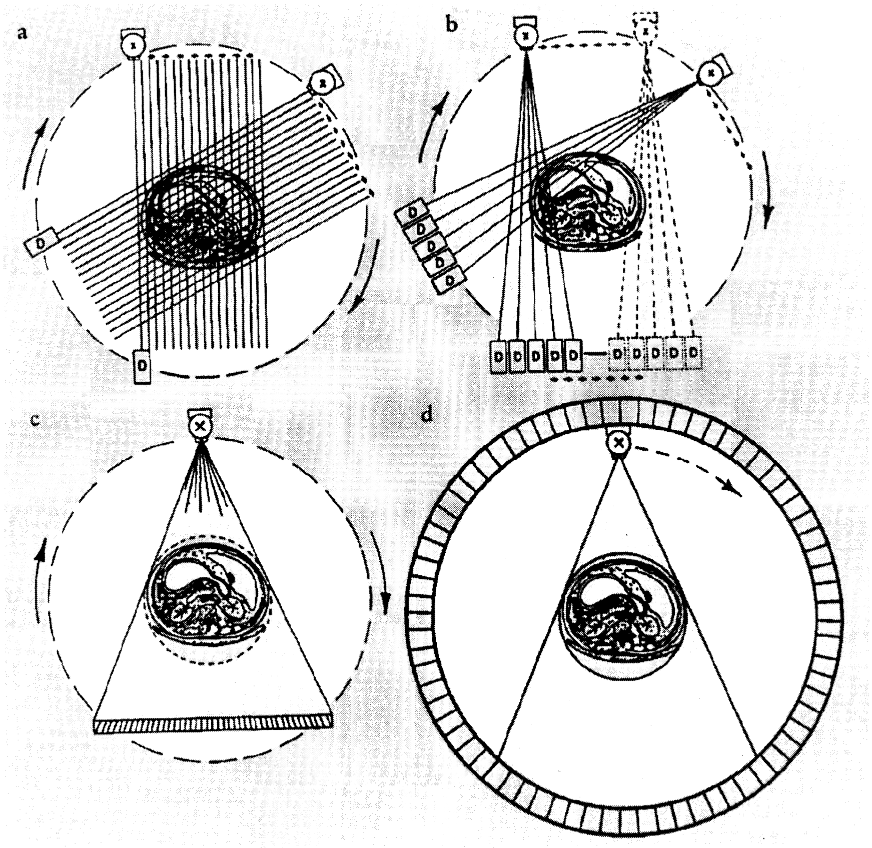

FIG. 7. Evolution of geometries of x-ray CT scanners. (a) First-generation scanner, in which the pencil x-ray beam is both translated and rotated to cover the region of the body being imaged; (b) second-generation scanner, with a diverging fan beam and detector array that are translated and rotated; (c) third-generation scanner, with a fan-beam source that rotates around the body, together with its detector bank; (d) fourth-generation scanner, with a rotating fan-beam source and a stationary ring of detectors.

angles, can be produced. Furthermore, the three-dimensional database can be analyzed to yield images that give the distinct impression of being three-dimensional. They also can be windowed to yield images of specific ranges of CT numbers corresponding to selected types of tissue (Fishman *et al.*, 1989). An example of a three-dimensional CT image is shown in Fig. 8.

4. IMAGE NETWORKING

Medical imaging includes several systems, including x-ray computed tomography and magnetic resonance imaging, that present imaging data in a digital format. Linking these systems electronically in a picture archiving and communications system (PACS) [referred to as an image management, archiving and communication system (IMACS) when connected into other information networks such as the radiology and hospital information systems] offers several advantages, including these: images can be stored electronically in a central location, images from different systems can be called up for display and comparison in a viewing center, and images can be transmitted to remote locations for viewing by specialists without loss of the central file of data. A PACS has the potential of expediting diagnoses, improving diagnostic accuracy, enhancing information to other physicians, and eliminating misplaced and lost films. With the availability of digital x-ray imaging methods, PACS can be expanded

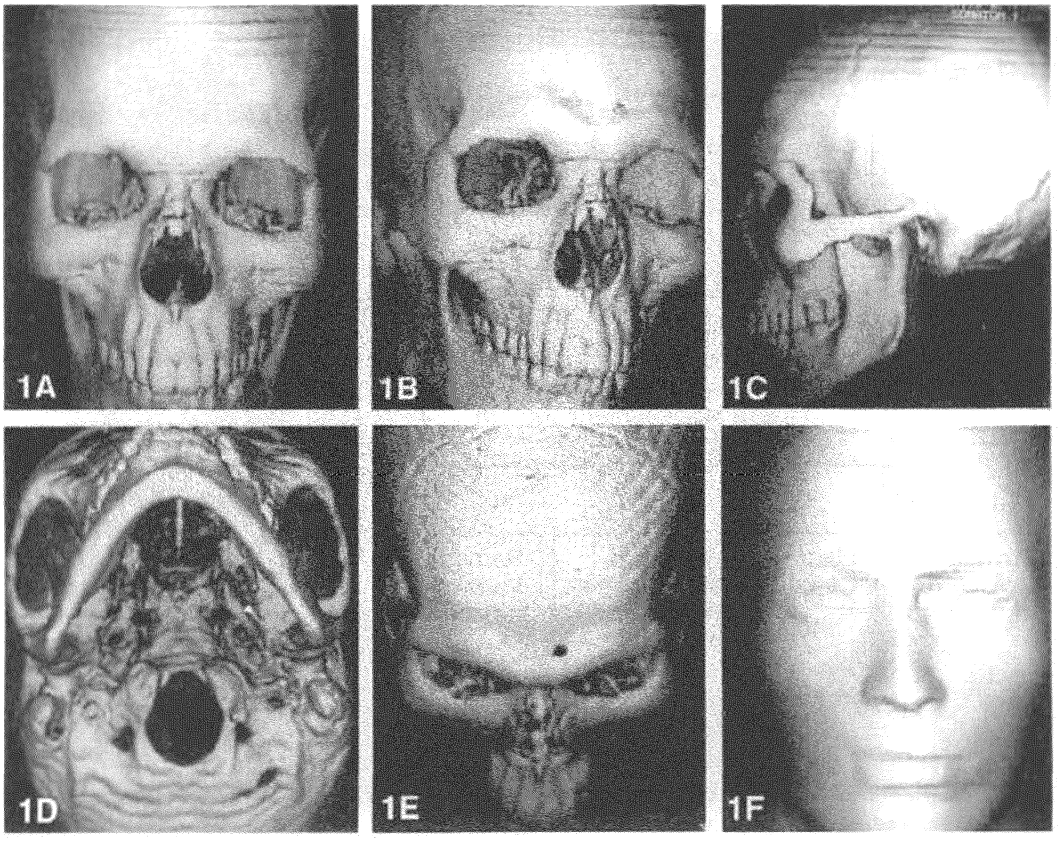

FIG. 8. 1.3-D standard views: (a) full frontal face, (b) right and left 45° oblique, (c) right and left lateral, (d) worm's view, and (e) bird's-eye view. (f) 3-D images can also be displayed in soft tissue format. (Used with permission from Fenlon and Breatnach, 1995.)

to encompass essentially all imaging systems employed in medicine. Many leaders in medical imaging believe that a fully integrated PACS represents the radiology department of the future. Others are convinced that the expense of converting fully to a PACS (several million dollars for a typical imaging facility) will prevent most departments from converting completely to PACS, at least in the near future. Instead, they believe their conversion will occur incrementally, with film remaining as the preferred detector for some applications (e.g., mammography and chest imaging) for some time to come.

In the common star network configuration depicted in Fig. 9 (Wolbarst, 1993), a computer and PACS management system can have access to images from any one of several peripheral digital imaging systems and can transmit these images to any other peripheral site. Some of the peripheral sites consist of stand-alone imaging systems complete with their own image and display workstation, image archive, and image-processing computer. Other peripheral sites are "dumb terminals" that can receive transmitted images for viewing but lack the capacity for image modification. The latter sites are typically placed in clinical locations, such as critical-care units, emergency rooms, and outpatient clinics, where images are important to decisions about the care of patients.

Within a hospital or clinic, imaging data are usually transmitted on-line by copper or optical-fiber cable. For communication over greater distances, modems are used with direct or acoustic coupling to transmit image data over standard telephone lines, typically at rates of 14.4 or 28.8 kilobits per second

(kbps). Higher transmission rates up to 2 megabits per second (Mbps) can be achieved with special "T1" lines that can be leased from the local telephone company. Also, microwave carriers can be used either directly for line-of-sight transmission or by satellite transmission for longer distances. The replacement of standard "twisted pair" telephone lines with fiber-optic cabling in many locations in the United States greatly enhances the transmission of large databases such as those employed for medical imaging. The transmission of medical images over long distances is termed "teleradiology."

5. APPLICATIONS

The use of x rays is so ubiquitous in medicine that almost everyone has had an x-ray examination. Most examinations are for routine purposes such as to detect dental caries, confirm that a fractured bone has been set properly, provide a routine examination of the chest to rule out pneumonia, or perform a barium swallow or enema to study the integrity of the gastrointestinal tract. Many more applications of x rays to medicine exist, however. Even though these applications may be encountered less frequently, they are critically important to the patients who need them. Two specific applications are described here as examples of the many interesting challenges presented to physicists and engineers working in the discipline of medical physics.

5.1 Mammography

One of every eight women will develop breast cancer in her lifetime, and many will die as a result. The most effective measure against this disease is periodic screening of the breasts with x rays for detection of cancer before it has a chance to spread. Many voluntary and professional organizations recommend annual screening with x rays for women 50 years of age and older, and some recommend screening every 1 to 2 years for women between 40 and 50 years of age. X-ray imaging of the breasts is referred to as mammography.

A mammographic x-ray image must be able to reveal very subtle differences in the composition of soft tissues of the breast, as well as the presence of tiny (<100 μm) specks of calcium hydroxyapatite (calcifications) that suggest the presence of malignant cells. That is, mammographic images must bring out very small variations in contrast and must also yield exquisite detail within a background of relatively low noise. These images must depict the relatively thick tissues near the chest wall without losing detail in thinner regions of the breast. These demands place inordinate requirements on systems for production of satisfactory mammographic images. They also necessitate periodic evaluation of image quality and radiation dose by a physicist experienced in inspection and quality control of mammographic units (American College of Radiology, 1993).

Subject contrast is enhanced in mammography by the use of low-energy x rays that interact strongly by photoelectric processes. Reliance on these interactions yields the greatest difference in transmission among structures that are similar, although not identical, in chemical composition. The use of low-energy x rays also aids in the identification of calcifications. In most cases today, mammography is performed with special x-ray units that employ an x-ray tube operated at 20–35 kVp and a film and single-screen image receptor designed specifically for mammography. The x-ray tube has a molybdenum target that produces characteristic *K* x rays of 17.4 and 19.8 keV superimposed on a bremsstrahlung x-ray spectrum with a maximum energy equal numerically to the peak voltage expressed as kVp. The x-ray beam is filtered with a thin sheet of molybdenum that is relatively transparent to the characteristic x rays but absorbs higher-energy x rays with high efficiency because of the existence of the *K* absorption edge above 20 keV. A typical x-ray energy spectrum suitable for mammography is depicted by the solid line in Fig. 10. The dashed line in this illustration depicts the x-ray spectrum for a nondedicated x-ray unit with a tungsten target.

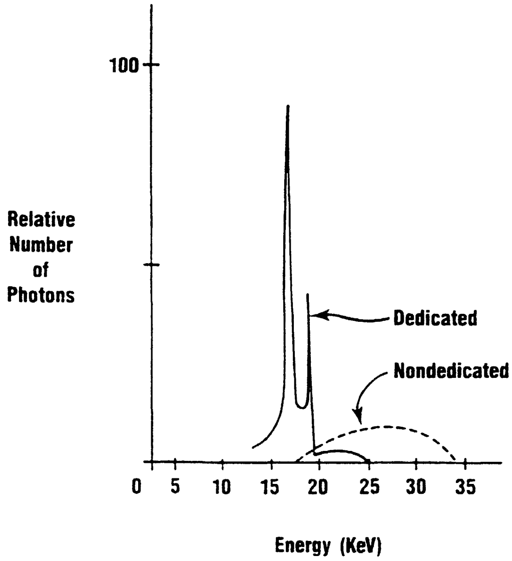

FIG. 10. X-ray spectra (normalized to equal area) for a molybdenum-target dedicated x-ray unit and a tungsten-target nondedicated x-ray unit for mammography. The dedicated unit employs a molybdenum (Mo) target, a 0.03-mm Mo filter, and a tube voltage of 25 kVp; the nondedicated unit uses a tungsten target, aluminum filtration, and a tube voltage of 35 kVp. (Used with permission from Hendee, 1995b.)

Screen–film mammography is an exquisitely sensitive and useful imaging method. Still, it may be possible to improve breast imaging by replacing screen–film receptors with digital detectors. Unlike film, digital systems acquire, display, and store images independently, so that each of these functions can be optimized without interfering with the others. Also unlike film, the response of digital detectors varies linearly over a wide range of exposures. In addition, digital images can be "windowed" to enhance the contrast of specific regions of tissue. Both of these attributes of digital detectors improve the contrast sensitivity of digital mammographic methods compared with analog screen–film methods. These advantages may well outweigh the disadvantage of a slightly lower spatial resolution with digital methods. Although digital detectors have high potential, the practicality, dependability, and low cost of film continue to make it the preferred detector for mammography in clinical settings.

Radiation can induce cancer as well as detect it. (Radiation can also be used to treat cancer, which is the medical specialty of radiation oncology.) In the past, concern has been expressed that screening large numbers of asymptomatic women for breast cancer could induce as many cancers as are cured through the process of early detection. This concern was primarily a result of the relatively high doses delivered to patients with earlier, less sensitive methods of image production. With today's ultrasensitive screen–film combinations, together with the use of low-energy, highly filtered x-ray beams, the induction of cancer is much less likely. The overwhelming balance of benefit over risk in screening programs for older women has largely dispelled concern over the possible induction of cancer in the screened women (Kimme-Smith, 1992). Nevertheless, efforts to reduce radiation dose further in mammography should be continued until each examination uses no more than the essential number of x rays to reveal underlying pathology.

5.2 X-Ray Treatment Planning

Cancer is characterized by an abnormally rapid proliferation of cells. The successful treatment of cancer with x rays requires that the cancer is localized and that that cancer and its microscopic extensions into normal tissue receive a dose of radiation sufficient to kill the cancer cells. At the same time the dose to nearby normal tissues must be kept low enough to avoid serious complications. The balance between these doses is depicted in Fig. 11 (Wolbarst, 1988). The probability $P_{\text{tumor}}(D)$ that the cancer will be controlled by killing tumor cells increases with D, the radiation dose. The probability $P_{\text{organ}}(D)$ that life-threatening complications from radiation damage can be avoided is, of course, a decreasing function of D. The probability $P_{\text{patient}}(D)$ that the patient will survive both the disease and the treatment is

$$P_{\text{patient}}(D) = P_{\text{tumor}}(D) \times P_{\text{organ}}(D).$$

The patient's survival probability as a function of radiation dose is the lower curve in Fig. 11. If the dose is low, the tumor is likely to recur. At high doses, the therapy itself is likely to cause unacceptable complications, perhaps threatening the patient's life. Between these extremes the physician seeks to maximize the patient's survival of both the cancer and the treatment. If the radiation dose that optimizes the balance between curative treatment and complications is so high that the patient experiences extreme discomfort, the physician may be forced to settle for a lower dose even though the patient's chance of surviving the cancer is reduced.

Radiation-dose optimization demands accurate delineation of the margins of the cancer. That in turn demands good medical imaging. Before CT, cancer localization and treatment planning depended principally upon projection radiography combined with clinical and surgical (if available) information about the patient, together with knowledge of the natural course of the disease. But projection radiography has many disadvantages. It is frequently hard to see the cancer clearly, and it is often difficult to transcribe

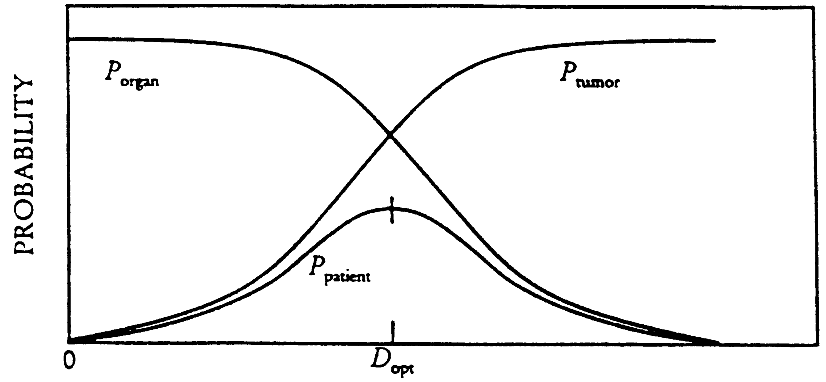

FIG. 11. Therapeutic outcome probabilities for cancer patients undergoing x-ray treatment, plotted schematically as functions of radiation dose D. The probability of success (P_{patient}) is the product of the probability that the tumor will be destroyed (P_{tumor}) and the probability (P_{organ}) that the treatment will not cause life-threatening damage to normal tissue.

the radiographic information onto a cross-sectional plane through the patient for designing the treatment plan describing the orientation and relative weighting of radiation beams used for treatment.

CT and, more recently, magnetic resonance imaging have largely overcome these problems. Many treatment centers have a CT unit dedicated to treatment planning and monitoring. The images provide not only a cross-sectional picture of the patient's anatomy, including the cancer and surrounding tissues, but also an accurate representation of the body contour and organs that are particularly sensitive to radiation. Because the data are digital, they can be entered immediately into the treatment-planning computer so that proposed treatment plans can be superimposed directly onto the CT images. Once an acceptable plan is accepted, it can be implemented on the x-ray treatment machine. This entire procedure must be carefully monitored to ensure that no misalignment occurs and that the treatment plan accurately reflects the radiation administered during treatment. Monitoring of this process is the responsibility of the medical physicist.

In most radiation therapy centers, commercial imaging units are used to generate CT information for treatment planning. In an effort to improve alignment of the CT information with the treatment geometry, a few medical physicists have built CT scanners on treatment-simulating gantries. Although these units yield spatial resolution inferior to that with commercial CT units, they duplicate the treatment geometry and provide images good enough to be useful for treatment planning.

Most x-ray treatments involve the use of multiple fixed radiation fields converging on the cancer from different directions. In this manner the dose is concentrated in the cancer while much lower doses are administered to surrounding normal tissues. In some cases a better dose distribution can be achieved by continually rotating the gantry of the treatment machine around the patient during treatment so that only the cancer is constantly in the path of the x-ray beam. One complication is that cancers are almost always asymmetrical. Therefore, the size of the x-ray beam must be expanded or contracted continuously during rotation. The dose distribution could be improved even more by simultaneously varying the dose rate during rotation. This approach, termed "conformal therapy," is being pursued in several centers in the United States and overseas (Mageras *et al.*, 1994). It requires detailed three-dimensional knowledge of the anatomy of the irradiated tissue, together with exquisite computerized control of the x-ray unit itself, as well as the x-ray gantry and patient couch position.

A significant advance in conformal therapy would be the convergence of CT and x-ray therapy in a single gantry, so that tomographic images could monitor alignment and dose distribution continually during treatment. This hybrid approach remains to be developed and is being pursued by a few groups of medical physicists (Convery and Rosenbloom, 1995; Mackie *et al.*, 1993). It presents magnificent technical challenges, but the potential of real benefits to patients as well (Hendee, 1995a).

6. CONCLUSIONS

The use of x rays for medical imaging is a prototypical example of "high-tech" medicine. It illustrates the contributions of medical physicists working with physicians to improve the health and welfare of patients. Much remains to be done, especially in refining the growing convergence of imaging with therapeutic techniques to cure disease and prevent the debilitating effects of injuries.

Physicists have played an instrumental role in the evolution of x-ray imaging. The American Association of Physicists in Medicine, a member society of the American Institute of Physics, includes almost 4000 members (AAPM, 1996). Graduate and postdoctoral training programs in medical physics increasingly attract bright young physicists. These individuals are among those destined to accomplish many of the advances that remain to be made.

GLOSSARY

Absorbed Dose: The energy absorbed per unit mass of an irradiated material.

Artificial Intelligence: The property of a machine capable of logical, systematic reasoning by which it can learn functions normally associated with human intelligence.

Characteristic X Rays: Electromagnetic radiation emitted as a result of rearrangements of the electrons in the inner shells of atoms; the spectrum consists of lines whose wavelengths depend only on the element concerned and the energy levels involved.

Compton Effect: Scattering of x rays by electrons of an atom when the energy of the x rays is large enough that the binding energy of the electrons can be neglected.

Computed Tomography: The process of producing an image showing body organs in cross section by first electronically detecting the variation in x-ray transmission through the body section along various paths at different angles, and then processing this information in a digital computer to reconstruct the x-ray absorption coefficients of the tissues at an array of points representing the cross section. Abbreviated CT. Also known as computerized axial tomography (CAT).

Digital Radiography: An x-ray imaging method in which x rays transmitted through the patient are recorded as a series of digital signals.

Dynamic Range: The amplitude range of signals that can be detected by an imaging system without distortion or disappearance into background noise.

Expert System: A computer system composed of algorithms that perform a specialized, usually difficult professional task at the level of (or sometimes beyond the level of) a human expert.

Fluoroscopy: Use of a fluorescent screen or image intensifier to convert an x-ray signal into an optical image to permit direct visual observation of x-ray images of objects interposed between an x-ray tube and the screen or intensifier.

Gantry: An extended mechanical structure holding elements of an imaging system.

Image Intensifier: An electronic device that receives an x-ray beam as an input signal and produces a bright and/or contrast-enhanced optical image as an output signal.

Intensifying Screen: A device used in x-ray imaging in which incident x rays cause the emission of light that in turn exposes a photographic film.

Linear Attenuation Coefficient: Fractional rate of attenuation of x rays in an absorbing medium.

Mammography: X-ray imaging of the breast.

Modulation Transfer Function (MTF): A measure of the ability of an imaging system to register fine detail present in the object.

Neural Network: An information-processing system that utilizes a large number of simple modules, to transmit, receive, and store digital information.

Photoelectric Effect: The liberation of an electron by electromagnetic radiation incident on a substance.

Pixel: The smallest area that can be displayed by an imaging system; a larger image is composed of many pixels.

Projection Radiography: The technique of producing a photographic image of an opaque specimen by transmitting a beam of x rays through it onto an adjacent photographic film; the image results from variations in thickness, density, and chemical composition of the specimen; used in medicine and industry.

Real-Time Display: A display that is able to follow changes in the object that occur at physiologic rates.

Subtraction: A process of image-contrast enhancement in which the brightness of corresponding parts of images of the same region made under different imaging conditions are subtracted from each other to remove distracting background structures and highlight structures of interest such as blood vessels.

Teleradiology: The transmission of medical images over long distances.

Tomography: The technique of making radiographs of plane sections of a body or an object; its purpose is to show detail in a predetermined plane of the body, while blurring the images of structures in other planes. Also known as laminography, planigraphy, and stratigraphy.

INTRODUCTION

Ice is a common constituent of the atmosphere and influences our world in diverse ways. Much of this ice, occurring as discrete particles of solid water within or emanating from clouds, resides entirely within the atmosphere over the course of its existence. Individual ice particles may form in the cold parts of clouds, where they grow for a time before encountering drier or warmer environments and evaporate or melt. Some ice particles, however, grow large enough to fall against the updrafts that spawn the clouds, appearing later as snow, sleet, or hail on the ground and then often hindering our routine activities as winter snow and ice storms and during summer thunderstorms. Surface snow tends to remain in place, because of its solid and immobile character, and accumulates when the local temperatures remain sufficiently low. In this way atmospheric ice contributes importantly to the maintenance of mountain glaciers and the formation of the seasonal snowpack that serves as a valuable resource for freshwater and recreation. Having had its origin in the atmosphere, such surface ice differs fundamentally from other types of ice on earth, such as sea or lake ice, but it similarly influences the radiation budget of the earth and therefore climate. Under some meteorological conditions, ice also arises on surfaces in the form of frost, rime ice, or glaze *via* processes closely related to those that form ice in clouds. The processes of atmospheric ice formation are thus important not only in their own right, but also through their impact on surface ice and human society.

Man's perception of atmospheric ice undoubtedly started with his encounter with snow. As nowadays, people of ancient times probably found snow to be both a nuisance and a wonder. The properties of snow cause it to hinder visibility, especially during high winds, and to pile up in most inconvenient ways. At the same time, one must marvel at the structure of snow, both in the macroscopic patterns that form on and around objects and in the intricate beauty of the individual crystals. It has been recognized for centuries that snow crystals exhibit a sixfold symmetry, but it was not until the end of the nineteenth century that the crystals were formally classified broadly as columnar (developed mainly along the principal axis) and plate-like or tabular (developed laterally). The endless variations in shape afforded by single ice crystals, as well as by the many polycrystalline forms found in

digital Encyclopedia of Applied Physics

snow, hail, and sleet, make atmospheric ice one of the most mysterious solids in man's experience.

Virtually all natural ice as we know it on earth, whether appearing in the atmosphere or on the surface, is a crystalline solid in which the water molecules are arranged in an open lattice exhibiting hexagonal symmetry. This crystallographic structure, formally designated "ice Ih" to distinguish it from the several other possible solid phases or polymorphs of water, gives ordinary ice many of its unique properties. The external shape or morphology of single ice crystals grown by vapor deposition reflects this hexagonal symmetry rather directly. Other formation processes, such as those involving the freezing of liquid water, may yield ice particles of different morphologies, but invariably the molecular structure of all ordinary ice is fundamentally similar. The wide variety of ice forms found in the atmosphere results in large measure from the diversity of environmental conditions under which atmospheric ice originates and subsequently grows.

This article aims to provide an overview of the types of ice particles found in the atmosphere and to show how such forms arise from the set of physical processes we know to take place in the atmosphere. In the first section, some methods for observing and studying atmospheric ice are described, followed by a presentation of the diverse forms actually found. Then, in Secs. 2 and 3, extended discussions are given of the processes by which ice particles form initially and then grow into their various types. Some effects of ice on clouds and other atmospheric phenomena are considered in Sec. 4 before the main discussion ends with an overview of how nature produces snowstorms, in Sec. 5. Finally, Sec. 6 highlights some areas needing further study and affirms that atmospheric ice offers a fascinating and still incompletely understood topic for scientific investigation.

1. OBSERVED FORMS

1.1 Observational Methods

Atmospheric ice particles may be observed in a number of ways, depending on the type of information one wishes to obtain. When the properties of individual particles are desired, then one needs to use one of several *in situ* methods. On the other hand, the properties of a population of particles are best investigated with remote sensors. Here, some of the more commonly used techniques are mentioned briefly.

1.1.1 *In Situ* Methods *In situ* techniques are especially valuable when the sizes or shapes of the particles need to be known with some precision. Inspection of particle morphology, in particular, tells much about the origins and growth mechanisms of the ice particles, from which one can sometimes infer the environmental conditions during their growth. Often *in situ* methods start with the actual collection of ice particles near the ground or higher in the atmosphere from aircraft or balloons, although high-speed electro-optical devices now make it possible to characterize the particles nondestructively.

The direct collection of ice particles is usually done on a surface that has suitable natural characteristics or one that has been specially prepared. Probably the simplest way of sampling snow is to let the crystals fall onto a dark-colored, thermally insulating material, such as black felt. Direct visual observation or photography is then possible, once suitable precautions have been taken to avoid the melting or evaporation of the particles. Many of the classic studies of natural and artificial snow crystals, such as those by Nakaya (1954), Bentley and Humphreys (1962), and Magono and Lee (1966), were conducted with this straightforward method. Some of the earliest *in situ* observations of ice crystals in the mid- to upper troposphere were made by Weickmann (1945, 1949), who used microphotography aboard aircraft to identify the types of crystals that arise in different classes of clouds. Knowledge of the environmental conditions that give rise to specific crystal types allows one in turn to use the crystals themselves as aerological sondes and infer the state of the atmosphere at the time of their formation (Weickmann, 1957).

When immediate characterization is not possible, the sampled particles may be either preserved intact or replicated. Bulk snow samples and hailstones are typically collected in

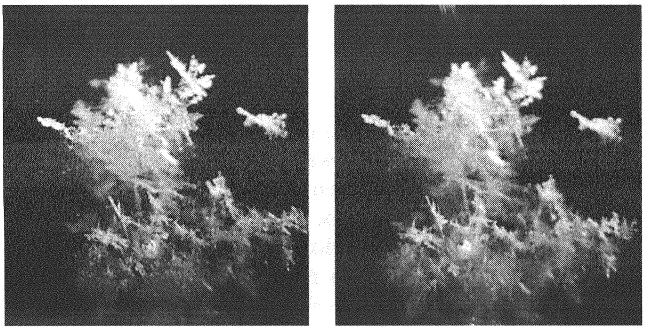

FIG. 1. Stereophotograph of a snow aggregate nearly 1 cm across.

clean containers on the ground and stored in freezers until appropriate physical or chemical analyses can be performed. Cryogenic preservation of snow samples has been used only occasionally, but astonishingly high-resolution photographs are possible when the crystals thus preserved are later viewed with a suitable electron microscope (*e.g.*, Wergin *et al.*, 1995). Replication involves physical contact between the sampled crystals and a prechilled liquid solution of an organic compound [*e.g.*, poly(vinyl formal) resin, known under the trade names "Formvar" and "Vinylec"] that then conforms to the shape of each crystal without melting it. After the solvent has evaporated, a thin solid film remains that retains the form of the original particle, allowing the replica to be viewed some time later at room temperature. Variations of this technique include briefly exposing precoated slides containing the ice samples to the solvent vapors, thereby preserving fine details of the crystals (see Hobbs, 1974, p. 652). The liquid replication technique has often been used aboard research aircraft that fly directly into the regions of clouds where the particles form and grow. Special balloon-borne replicators have also been developed to enable sampling in regions not readily accessible by aircraft. When relatively large ice particles, such as hailstones, are encountered, research aircraft may be equipped with special impactors in which imprints of the particles are made on strips of aluminum foil.

With modern electronic capabilities it is becoming increasingly common to characterize individual ice particles directly, without forcing them to strike a surface or otherwise destroying them. Commercial electro-optical instruments exist that yield discrete shadow images of the particles as they pass rapidly through a laser beam. Huge numbers of particles may be imaged within clouds from aircraft or during snowfalls on the surface. Although such methods have provided a wealth of information about the evolution of ice in clouds, shadow images lack depth information and resolve features only larger than about 50 μm. When greater detail is needed, one may again have to resort to photographic methods. As shown in Fig. 1, it is possible to capture the three-dimensional detail of delicate snow particles as they fall naturally through the air. Some holographic methods are also under development and show great promise for imaging ice particles in their natural state. New developments in the detection of small ice particles, those in the size range of 1–50 μm, are very much needed.

1.1.2 Remote-Sensing Methods The extraction of information about cloud properties from remote locations typically depends on the interaction of electromagnetic radiation with the suspended bits of matter that comprise the clouds. Remote sensing not only circumvents the need to travel to the cloud itself, but the type of information obtained usually represents a much more integrated measure of cloud properties than can be obtained *via in situ* methods. These advantages are, however, offset somewhat by the limited spatial resolution and the relative lack of detail about the individual particles that is obtainable. Moreover, detailed radiative-transfer models must often be employed in order to obtain the parameters of interest. Still, remote-sensing methods are being developed that yield an ever-expanding wealth of information about clouds and the ice they contain.

Remote sensors vary greatly in operation and how they can be used. The sensors may be deployed on the ground, aboard aircraft that may circle the clouds under study, or within satellites orbiting the earth. Typically, the sensors are classified by the wavelengths of radiation employed and whether they are "active" (energy-emitting and -receiving) or "passive" (energy-receiving only). Most commonly, remote sensors operate in the microwave, visible, and infrared regions of the electromagnetic spectrum. Modern science, of course, depends heavily on sophisticated electronic equipment, but we should not forget that much early and valuable information about clouds, even the ice they contain, was derived using the most natural of passive remote sensors operating in the visible range of wavelengths, the human eye. Astute observations by experienced personnel can still lead to important insights about the physical processes active in clouds.

Examples of the two classes of remote sensors are radar (active) and radiometers (passive). Radars have been the traditional means by which clouds are remotely interrogated, but recent innovations in technology have placed modern research radars far ahead of the weather-surveillance radars that emerged during the 1940s. Beyond simply measuring the received signal power (reflectivity), current radars can also measure velocity spectra and various polarization states of the returned signals. Vertically pointed radars operating at frequencies of 94 or 35 GHz have proven particularly useful for the study of cirrus clouds from the ground (Mace *et al.*, 1997). Radiometers gather path-integrated radiation emitted by cloud particles. Because the rotations of water molecules within the ice lattice are hindered, ice particles emit microwave radiation only very weakly. Nevertheless, microwave radiometers sensitive to liquid water are useful for identifying clouds conducive to later ice formation, especially when that water is supercooled. Infrared sensors aboard satellites are commonly used to identify cold cloud tops where ice is likely to exist. Field studies, such as that conducted in the mid-1980s to study the feasibility of augmenting the snowpack of the Sierra Nevada of California, are often designed around a coordinated suite of *in situ* and remote-sensing systems (see Reynolds and Dennis, 1986).

In the visible range, the most useful active device is the lidar (light detection and ranging). One or more wavelengths of radiation are transmitted (often vertically from the ground), while a telescope gathers the radiation scattered from the cloud particles. As with radars, some lidars can measure the Doppler-shifted frequencies, as well as the polarization state of the returned signal. Changes in the polarization of the returned radiation from that of the emitted beam are particularly sensitive to the physical phase of the particles, so that ice particles can often be uniquely identified in high clouds, even those in the stratosphere. Especially when used in combination, remote-sensing systems can yield much information about the occurrence of ice in the atmosphere and even some important microphysical properties, such as size, fallspeed, and crystal habit.

1.2 Types of Atmospheric Ice

Atmospheric ice is found in an extremely wide variety of forms, both as single crystals and as polycrystals. Single crystals, whether occurring individually or clumped together as "aggregates" (such as that shown in Fig. 1), exhibit some of the most spectacular forms in appearance and provide a unique record of their individual growth histories. Despite the broad range of possible shapes, single crystals tend to form regular geometric solids bounded by two hexagonal "basal" planes that lie perpendicular to the principal crystallographic (c) axis and six rectangular "prism" faces aligned parallel to the c axis (see Fig. 2). The "aspect ratio" of a crystal is defined quantitatively as the ratio of its dimension along the c axis to its maximum dimension between opposing prism-face edges, that is, along one of the lateral a axes. The c/a ratio thus identifies the primary habit of the crystal, which may be broadly classified as "plate", when $c/a < 1$, and "column", when $c/a > 1$. As we shall see later, the primary habit exhibited by any given crystal depends on the relative growth rates of the basal and prism faces.

The secondary habit of a single ice crystal

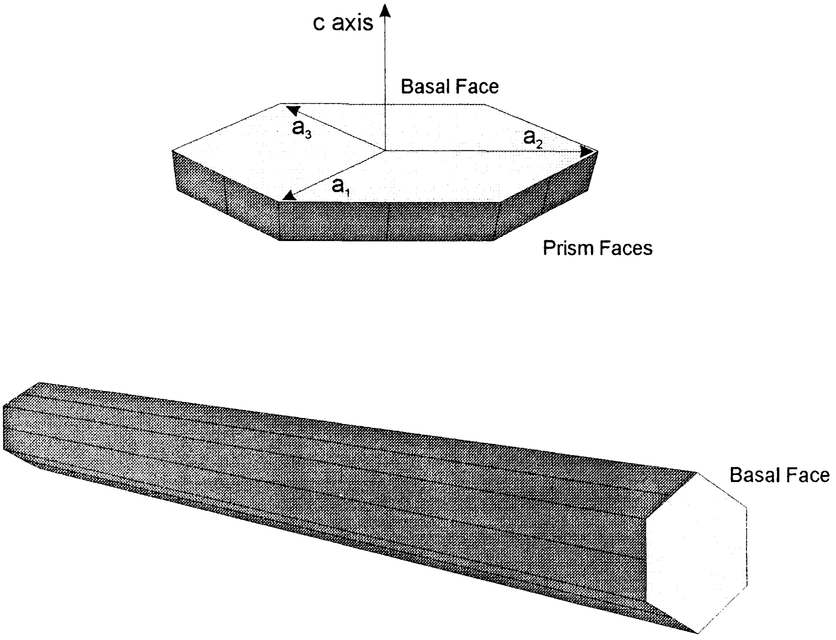

FIG. 2. Schematic diagram of the primary habits of vapor-grown ice crystals, showing perspective views of the hexagonal symmetry and the crystallographic axes. Top: plate. Bottom: column.

represents one of the myriad of possible variations in form that may be superimposed upon a given primary habit. The corners of a plate may grow preferentially, for instance, yielding a set of protruding branches of the type shown in Fig. 3(a). In this example, we clearly see the underlying hexagonal shape of the basal face as an interior feature, upon which the branches are superimposed. The brighter spots on the branches are the places where supercooled cloud droplets collided with the crystal and froze on impact once the crystal had grown large enough and gained an appreciable fall-speed. Despite the complexity of its overall morphology, this lightly rimed crystal is clearly classified as a plate because the dimensions across the branches (along any of the three *a* axes) greatly exceed its thickness (dimension along the *c* axis, here perpendicular to the plane of the photograph). Other subclasses of plates, many examples of which have been presented by Bentley and Humphreys (1962), include sector plates, broad-branch plates, stellar crystals, and dendrites.

Columnar crystals tend to exhibit a narrower range of secondary habits compared with those found on plates. As shown in Fig. 3(b), a "needle" crystal arises when the *c*-axis dimension greatly exceeds the *a*-axis dimension and fine points emerge from the corners of the basal faces. Other columnar crystals may exhibit hollowing of the basal faces, in the extreme yielding almost completely hollow forms called "sheaths". Sometimes, several columns originate from a common frozen droplet, yielding a combination form called a "bullet rosette". If such crystals break apart, each of the individual columns is called a "bullet" because of the pointed end that appears. Other columnar forms include "scrolls", especially common in some hoarfrost, and "capped columns", a combination form in which plates grow on the ends of the columns.

Polycrystalline ice particles contribute greatly to the variety of ice types found in snow and cloud ice. Figure 4 gives some idea of the diversity that can arise in individual snowfalls. In addition to a number of columnar crystals, we see frozen drops ("sleet") and heavily rimed particles called "graupel", both of which are subclasses in the category of "ice pellets". Careful inspection of the photograph reveals that broken branches from dendrites that subsequently rimed probably contributed to this particular snowfall as well. When the temperature of the ground is below the thermodynamic melting point (0 °C), slightly supercooled rain may form a heavy coating of "glaze ice" on all exposed surfaces, a phenomenon particularly prevalent in valleys that trap cold air in winter. At the other extreme of small drops that are strongly supercooled, surface structures may develop a thick layer of "rime ice", a situation common in mountainous regions when wintertime clouds intercept the elevated terrain. In extremely cold environments ice fogs may yield "droxtals", frozen droplets that exhibit crystallographic features on close inspection. In the summertime, some regions of the world experience damaging hail, precipitation composed of polycrystalline ice particles larger than 5 mm in diameter and exhibiting numerous layers alternating between clear and opaque ice when dissected. With the wide varieties of forms possible within any one category of ice, coupled with the huge number of combination forms that are conceivable, we begin to appreciate how complex the subject of atmospheric ice can be.

1.3 Distributions

The diverse forms of atmospheric ice are found over broad geographic regions, depending on the local conditions of temperature and

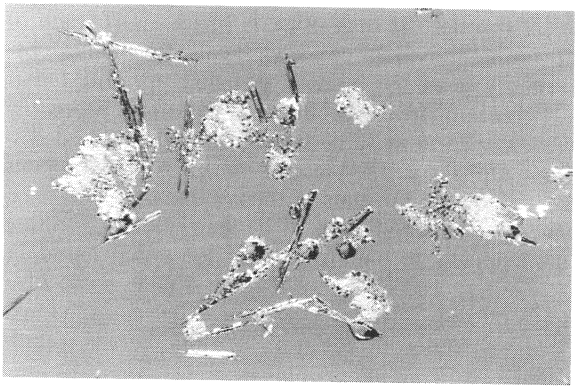

FIG. 4. Polycrystalline forms of ice comprising an aggregate.

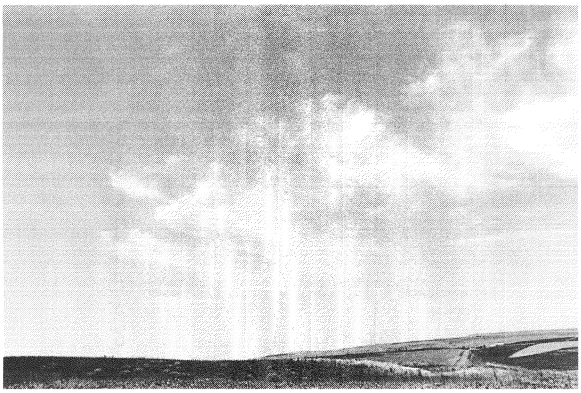

FIG. 5. Cirrus uncinus, a common form of ice cloud in the upper troposphere, showing fallstreaks.

humidity. Because the air temperature typically decreases with increasing height in the troposphere, the altitude of the terrain or of the cloud becomes a relevant factor in determining the distribution of atmospheric ice. Thus, whereas polar regions are generally conducive to the formation of ice even near sea level, high mountains in all latitude belts may allow for the formation and accumulation of ice and snow. Even in summer, most thunderstorms involve ice in their upper portions, as evidenced even from the ground by the fibrous appearance to the cloud tops, the occasional appearance of hail, and, very likely, the occurrence of lightning. Air exiting a storm near its top carries residual moisture that may later deposit on aerosol particles in the upper troposphere, yielding ice clouds, such as the cirrus uncinus shown in Fig. 5. Small ice particles also form, despite relatively dry conditions, in the polar regions of the lower stratosphere and upper mesosphere, where temperatures can fall below −100 °C. Ice must be viewed as an important component of the atmosphere during all seasons of the year, not just in winter, and in all climatic regimes, in the tropics as well as at high latitudes.

The occurrence of specific types of vapor-grown ice crystals has been shown, through repeated observation in the atmosphere and experimentation in the laboratory, to depend strongly on both the temperature and humidity of the air at the time of growth. To a good first approximation, the temperature seems to be the environmental variable that most controls the primary habit, as shown in Fig. 6. As ice crystals originate and grow at progressively lower temperatures, the primary habit is found to alternate between plate and column, with transition temperatures at approximately −3, −8, and −22 °C. The abundance of "excess" moisture, that is, the vapor density in excess of the equilibrium value, seems to determine the secondary habit: the larger the excess vapor density, the more extreme the secondary growth features. Thus, as summarized in Fig. 6, in the plate regimes we find simple plates at low excess vapor densities, but progressively longer extensions and complexities of the branches protruding from the corners as the excess vapor density increases. The simultaneous presence of liquid water in a cloud restricts the magnitude of excess vapor density available (shown by the dashed curve), and so the most intricate (dendritic) structures are found in the middle of the colder plate regime, where the liquid-water saturation effect is close to a maximum. Similarly, columns with the greatest aspect ratio (*i.e.*, needles) appear in the presence of liquid cloud droplets when the growth temperature is near −6 °C. Compact columns, crystals with near unity aspect ratio, form near the primary-habit transition temperatures.

Vapor-grown ice crystals exhibit a number of interesting features that depend on the conditions of growth. The rate with which water mass accumulates on a crystal in clouds near liquid-water saturation varies with the growth temperature in an unusual manner. As shown in Fig. 7, the mass growth is maximum at two temperatures, not just one, as might be ex-

pected from the distribution of excess vapor density with temperature when liquid water is present (dashed curve in Fig. 6). It appears that the mass growth rate is linked closely to the habit of the crystal, the highest growth rates appearing when the axial ratios are most extreme (as with needles, an extreme form of columnar growth, and with dendrites, an extreme type of plate-like growth).

The axial ratios of vapor-grown crystals depend not only on the temperature and supersaturation, but also on the dimensions and habits of the crystals themselves. As a summary of many observations of crystals, Fig. 8 shows that the dimensions of vapor-grown ice crystals along the *a* and *c* axes follow power-law relationships only up to a certain point. Once the dimension along the rapidly growing axis exceeds about 100 μm, the growth along the other axis seems to be limited. Although one cannot readily ascertain whether the growth along the minor axis actually de-

creases, the fact that this change in growth behavior occurs just when the crystal fallspeed becomes appreciable suggests that the growth along the major axis preferentially increases as a result of the enhanced ventilation of the most protruding parts of the crystal (Chen and Lamb, 1994).

2. ORIGINS OF ATMOSPHERIC ICE

The processes that give rise to ice particles in the atmosphere are as yet only partially understood. Typically, clouds develop initially as a collection of liquid water droplets that cool gradually as they are carried aloft by atmospheric motions. Once the local temperature decreases below 0 °C, the droplets begin to supercool and persist for a time in this metastable state. The first ice to appear in the supercooled cloud forms by one of several "primary" nucleation mechanisms. Later, additional ice-formation mechanisms may operate to generate a second generation of ice particles from the first, leading to "secondary" ice. Here, an overview of some of the more important ice-initiation processes is given.

2.1 Primary Nucleation

Ice in most clouds originates in the presence of supercooled liquid-water droplets at temperatures below the thermodynamic melting point of ice. Current nucleation theory suggests that pure water can supercool by as much as 45 °C, depending on the sizes of the droplets (Pruppacher and Klett, 1997, p. 341). The first ice to appear in some upper-level clouds seems to be consistent with a mechanism of homogeneous nucleation of liquid solution droplets, but at lower levels in the atmosphere the first ice appears in the −8 to −12 °C temperature range. Thus, a heterogeneous mechanism is needed to explain most primary ice formation.

Heterogeneous nucleation refers to the catalyzing influence that some foreign (nonaqueous) substances can have on the nucleation rate. Although a detailed understanding of the mechanism is still lacking, it appears that a solid substrate is needed that has lattice characteristics similar in some way to those of ice. For instance, crystalline silver iodide, often produced artificially to induce ice formation in supercooled clouds, is particularly effective because its lattice exhibits hexagonal symmetry and has cell dimensions differing only slightly from those of ice. Suitable ice-nucleating materials in nature are typically insoluble substances of either mineral or biogenic origins, such as clay particles or fragments of bacteria, respectively. Natural ice nuclei always comprise a minute subset of the atmospheric aerosol (often less than 1 in 10^6), but these few particles are responsible for much of the ice found in the atmosphere.

Once brought into an appropriate part of a supercooled cloud, the ice nuclei may interact with the cloud droplets in one of several ways. The nucleus is said to act in the "freezing" mode if it has already become immersed inside the cloud droplet sometime prior to the freezing event. Other nuclei, particularly small and mobile particles, seem to initiate freezing of the cloud drops on "contact" with the liquid surface. A third mode of action occurs when supersaturated water vapor deposits directly onto the particle and forms ice without the obvious presence of any liquid water. This "deposition" or "sublimation" mode of nucleation thus differs in concept from the freezing and contact modes.

The ability of any given particle to activate the solid phase is a strong function of the temperature and supersaturation with respect to ice. Whereas earlier views held that the temperature and supersaturation effects were independent, many now think that the main factor is supersaturation, temperature playing a secondary and largely implicit role. Measurements of ice nuclei acting in the freezing or deposition modes exhibit an exponential dependence on supersaturation in the temperature range between −5 and −20 °C, yielding a concentration of ice in the order of 10^3 ice particles m^{-3} at −10 °C in the presence of liquid cloud droplets (Meyers *et al.*, 1992). Because of the difference in the equilibrium vapor pressures of ice and liquid water, higher concentrations of ice can be expected in supercooled clouds at lower temperatures.

The first ice to form in supercooled clouds typically arises from the freezing of a small fraction of the cloud droplets. The freezing of these droplets takes place in two sequential stages. In the first stage, a dendritic mesh of ice spreads rapidly throughout the drop volume, releasing latent heat that warms the slush to 0 °C within about 1 ms. This initial stage is effectively adiabatic, because of the small time available for thermal exchange with the environment, and allows an approximate fraction $c_w \Delta T/\lambda_f \cong \Delta T/80$ of the liquid to be converted into ice, where ΔT is the supercooling, c_w is the heat capacity of liquid water, and λ_f is the latent heat of fusion. The remaining liquid in the slush freezes more slowly during the second stage, the process being limited by the rate with which the latent heat can be dissipated by conduction to the surrounding air. At the relatively high temperatures (between about −8 and −12 °C) at which first ice forms in many clouds, the probability of generating a stable embryo of ice within the liquid is low, so that these frozen droplets are usually single crystals.

These first frozen droplets, by virtue of the numerous, still-liquid droplets present, experience a high supersaturation and rapid deposition of vapor onto their surfaces. This growth takes place mainly on the prism faces because the nucleation occurs in the plate regime (−8 to −22 °C). As depicted in Fig. 9, the form of the first ice, commonly detected by *in situ* sampling, is typically a double plate, two plate-like crystals separated by the original frozen droplet. Ice that forms by droplet freezing at much lower temperatures (below about −20 °C) typically shows evidence of polycrystalline nucleation and preferential growth along the *c* axes of each crystal, yielding bullet rosettes.

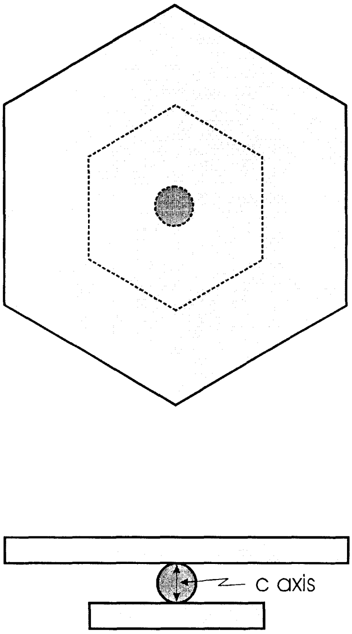

FIG. 9. Schematic diagram of a "double plate". Top: view along the *c* axis. Bottom: view normal to the *c* axis (arrow).

2.2 Secondary-Ice Formation

Secondary ice forms as a consequence of physical processes involving ice particles that already exist. The concept of second-generation ice is needed in part to account for high concentrations of ice particles found in some clouds. In some cases, the observed concentration of ice particles exceeds the concentration expected from primary nucleation events by a thousand times or more. Some snowstorms, too, seem to be prolific sources of needles, a crystal type known to grow only within a narrow temperature range around −6 °C, under conditions unfavorable to primary nucleation. Both laboratory experimentation and field observations confirm that new ice particles can be generated in supercooled clouds once some ice has already formed in the cloud (Young, 1993, p. 97).

A search for the likely mechanisms by which secondary ice forms has been under way for nearly three decades with modest success. Difficulties arise in most investigations in part because the conditions conducive to the generation of secondary ice appear to be narrow. That is, whereas clouds and primary ice form under a broad set of relatively predictable conditions, secondary ice tends to form only in narrow temperature zones and possibly only when a restricted set of cloud particles is present. Reproducing the required set of conditions in the laboratory or finding them in nature can be difficult. Nevertheless, some generalities can be made.

The mechanisms responsible for secondary-ice formation typically involve the interactions of cloud particles. Sometimes these interactions are rather indirect; other times they involve actual collisions between particles. One line of research has suggested that the so-called secondary ice is actually primary ice stimulated by local fluctuations in conditions. Thus, by way of example, an aerosol particle that would not normally be active as an ice nucleus under average cloud conditions (say, liquid-water saturation at $-10\,^\circ$C) might happen to pass through the strong gradients of temperature and moisture in the wake of a graupel particle or of a large drop in the process of freezing. Such a particle might become active in the transient high-supersaturation environment of the existing ice particle and cause a new ice particle to form (Fukuta and Lee, 1986). Direct collisions between two ice particles are relatively common and have been thought by some to yield daughter particles. Such a "fragmentation" mechanism is expected to operate when either or both of the particles is structurally delicate, as dendrites are naturally or as many crystals become during evaporation or melting. Of particular importance, the process of accretion (discussed in Sec. 3.3) involves many collisions of supercooled cloud droplets with graupel particles, some fraction of which yields small ice "splinters". Considerable evidence (see Pruppacher and Klett, 1997, p. 357, for history) has been amassed in both the laboratory and the field that this "rime-splintering" mechanism can operate in the columnar-growth regime (-3 to $-8\,^\circ$C) when the graupel particles are sufficiently large (≈ 0.5 mm in diameter). The consequences of secondary-ice formation are discussed later within the context of cloud glaciation.

3. GROWTH PROCESSES

Once formed, ice particles must grow by the accumulation of water mass to sizes that allow them to interact with other cloud particles or fall out of the cloud as precipitation. The mechanisms by which such growth takes place are discussed here. The various processes may all take place simultaneously, but for clarity each is considered separately.

3.1 Vapor Deposition

The first stage of growth usually involves the direct deposition of water vapor onto the exposed surfaces of an ice particle. As water molecules are removed from the vapor phase in the immediate vicinity of the growing ice crystal, gradients of vapor density are set up that drive the molecular diffusion of vapor from more "remote" regions (several particle diameters) about the particle. The process of vapor deposition is sometimes referred to as "diffusional" growth because the rate of growth is typically limited by this phenomenon of molecular diffusion through the surrounding air. However, unlike the diffusional growth of liquid droplets, which can be explained fully by consideration of radial gradients alone, the nonspherical shapes assumed by ice crystals implies that nonradial vapor gradients and the processes responsible for incorporation of the impinging molecules into the ice lattice, *i.e.*, the "surface kinetics", must also be taken into account.

The probability that a given vapor molecule is incorporated into the crystal lattice and contributes to the growth of the ice particle is related to the surface characteristics of the particular face it contacts. Laboratory measurements show that this efficiency factor, often called a "deposition coefficient", varies strongly with the crystallographic orientation of the face. Whereas the deposition coefficients

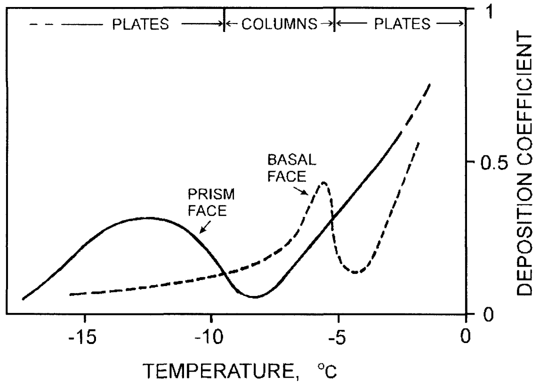

FIG. 10. Dependence on temperature of the deposition coefficients of the basal face and prism faces. Adapted from Lamb and Scott (1974).

of all high-index faces are close to unity, those of the low-index basal and prism faces vary strongly with the temperature and supersaturation at the time of growth. As shown in Fig. 10 for constant excess vapor density, these deposition coefficients each decrease with decreasing temperature from values near unity at the thermodynamic melting point, but not monotonically. The deposition coefficient of the basal face has a local maximum near −6 °C, whereas that of the prism face exhibits a broad maximum between −10 and −15 °C. The temperatures at which the curves cross are close to the observed primary-habit transitions and represent equal likelihood of growth on the basal and prism faces. At lower excess vapor densities the deposition coefficients become smaller, but the crossing points remain relatively invariant.

The reason for the complicated variation of the deposition coefficient (and therefore the primary habit) with temperature is probably related to surface structure and to systematic changes that may occur on the basal and prism faces of ice. Each of these low-index faces advances by the propagation of terraces or steps across the surface. The advancement of each step relies on a supply of adsorbed water molecules that migrate by surface diffusion to "kink sites" along the step, favorable locations for molecular incorporation into the lattice (see Fig. 11). The greater the surface migration distance, the greater the molecular supply rate and the larger the probability of incorporation. In this mechanistic picture the linear growth rates and, ultimately, the habits of ice crystals depend on a balance between the probabilities of molecular desorption (which determines the lifetime in the adsorbed state) and surface diffusion (which determines the speed of migration). The strong temperature dependence of the deposition coefficient is therefore likely to be related to the adsorption enthalpy and the activation energy for diffusion, both of which depend on the as yet unknown molecular structure of the crystal surface. A real understanding of crystal growth must await further research in this area.

As complicated as the molecular-scale processes responsible for the vapor growth of ice crystals are, they must also be put into the context of the growth environment experienced by the particle as a whole. The interactions that occur between the surface processes and the ambient vapor field introduce complexities that ultimately account for the diversity of crystal habits found in nature. The incorporation of the water molecules into the ice particle locally alters the vapor density and its gradients in the gas phase. Any changes in the local vapor density in turn affect the magnitude of the deposition coefficient (*i.e.*, the efficiency of growth).

When reasonable allowance is made for the interactions arising between the ice surface and the surrounding vapor field, we can see a likely mechanism for the formation of the many observed secondary habits, as exemplified in Fig. 12 for the case of a spherical ice particle growing in the plate regime. Initially, the high-index faces grow out rapidly, leaving only the low-index basal and prism faces. At low supersaturations (Fig. 12, top), the weak vapor gradients allow growth steps to propagate uniformly across each prism face and the form of a simple hexagonal plate to be maintained. At

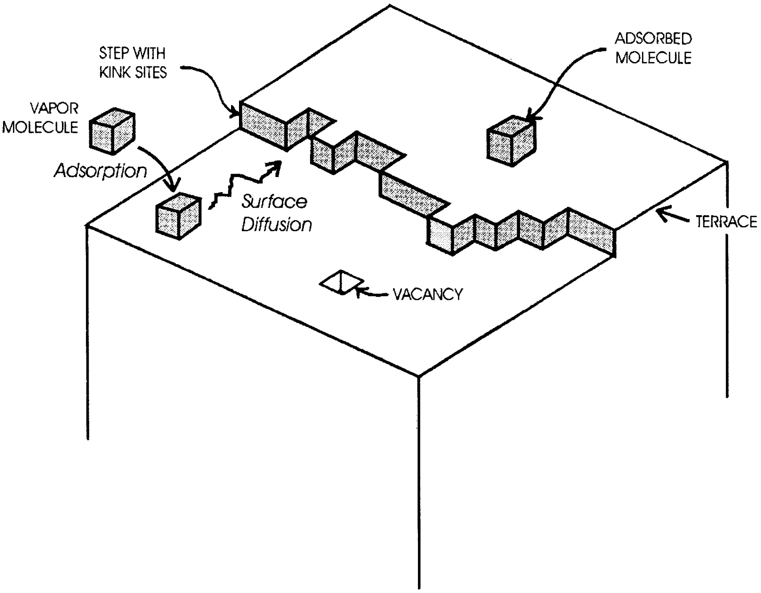

FIG. 11. Schematic representation of molecules incorporating into a low-index face.

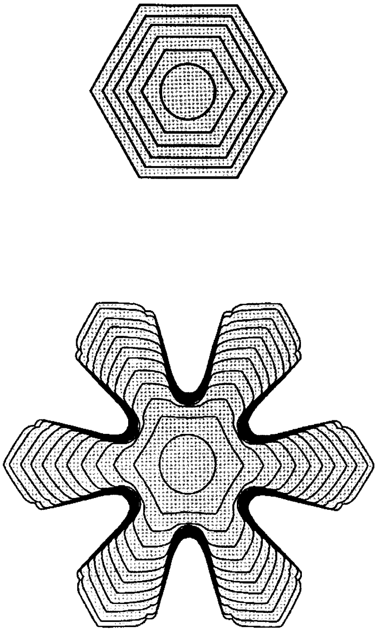

FIG. 12. Schematic illustration of the evolution of secondary habits in the plate regime from an initially spherical frozen droplet. Growth at low (top) and high (bottom) supersaturations. Adapted from Yokoyama (1993).

larger supersaturations (Fig. 12, bottom), the gradients of vapor density become appreciable, and so steps that propagate toward the center of each face, where the local supersaturation is relatively small, slow up and "bunch" together. The edges bounding neighboring prism faces experience the largest supersaturations, leading to rapid growth locally, the formation of protruding branches and crystals classified as "broad-branch plates". At still larger ambient supersaturations, the gradients and their effects on the growth become larger still, to the point where a "stellar" crystal forms. At high supersaturations, the shape of the crystal itself affects the distribution of excess vapor across its surfaces and hence the subsequent growth of the crystal. Protruding parts invariably command the greatest vapor supply and the highest probability of continued growth.

3.2 Aggregation

The growth process of aggregation differs fundamentally from that of vapor deposition. Crystals that have already achieved a certain size by the deposition of vapor may, by chance, collide with neighboring crystals and adhere, forming ice particles of larger mass and generally more complicated morphology. When continued for some time under appropriate conditions, this process can lead to "aggregates" containing dozens or even hundreds of separate crystals that each grew individually from the vapor phase. The large aggregate shown in Fig. 1 provides an example of the morphological complexity that can result. One must also appreciate that such ice particles are rather fragile and may fragment during some collisions.

Aggregation, because it involves collisions between particles, is one of several growth processes classified as "collection". As with all collection processes, aggregation tends to form fewer, but larger, particles at the expense of the large number of smaller particles in a cloud. The collection process is inherently discrete and stochastic in nature. In principle, when an appropriate account is taken of all of the pairwise interactions in a population of particles, a collection equation arises that can be used to evaluate the rate of change of the particle size distribution:

$$\frac{\partial n(m)}{\partial t} = \frac{1}{2}\int_0^m K(m_x, m - m_x)n(m_x) \times n(m - m_x)\,\mathrm{d}m_x - n(m)\int_0^\infty K(m, m_x)n(m_x)\,\mathrm{d}m_x. \quad (1)$$

Here, $n(m)$ is the particle mass distribution function, and the collection kernel is

$$K(m_\mathrm{L}, m_\mathrm{S}) = E(m_\mathrm{L}, m_\mathrm{S})\pi(r_\mathrm{L} + r_\mathrm{S})^2(v_\mathrm{L} - v_\mathrm{S}), \quad (2)$$

where the effective "radius" of the large ("collector") particle is r_L and the radius of the small ("collected") particle is r_S. The corresponding particle fallspeeds are given by v_L and v_S, and the collection efficiency is $E(m_\mathrm{L}, m_\mathrm{S})$. The factor of $1/2$ prevents the over-counting that would otherwise occur from the first integral. Note that the particle concentration (n) appears in the equation as a product with itself, and so the collection process is inherently nonlinear.

Whereas solutions to the collection equation have been used numerous times in the past to calculate the spectrum of liquid drops in clouds, complications associated with the nonspherical shapes of ice particles make this approach difficult and uncertain. Nonspherical solid particles often fall irregularly, especially at high particle Reynolds numbers. Vortices formed in the rear of some particles may cause them to slip sideways or even tumble, for instance, so that large uncertainties exist in both the area swept out and the fallspeeds used in Eq. (2). The collection efficiency, too, is complicated by the fact that it represents a conditional probability of two events, collision and coalescence, the sticking of the two particles together once contact has been made. Relative to droplets, the nonspherical nature of ice particles may actually augment the collision probability, but solid particles can often collide without adhering to each other. Such bounce-off events have positive implications for some cloud processes (*e.g.*, electrification), but they will not lead to growth of aggregates.

Empirical studies have most often yielded the more definitive information regarding the aggregation process. Measurements from both inside and below clouds show that aggregation is favored at relatively high temperatures, although the shapes of the crystals may also play a role. The largest aggregates, their diameters sometimes exceeding a centimeter, are found when the observation temperature is higher than about −5 °C. Conventional thinking holds that ice within a few degrees of the melting point forms a "quasiliquid" or at least a highly disordered layer of water on its surface. The mechanism of coalescence may therefore be associated with sintering. A secondary peak in particle size is often found between −10 and −15 °C and has usually been ascribed to the mechanical interlocking of the dendritic arms of separate crystals. In general, it appears that the main mechanistic limitation to aggregation is crystal coalescence.

3.3 Accretion

Accretion is the technical term given to the process by which ice particles or other structures collect supercooled drops, yielding a milky, granular deposit of rime, or alternatively a clear, smooth deposit of glaze, depending on the accretion rate and degree of supercooling. Ice mass accumulates as the drops collide with the object and freeze on contact. Accretion is an important process by which precipitation is formed in summertime convection, as well as in winter snow storms, but it can also lead to the buildup of ice on aircraft or structures attached to the Earth's surface, such as buildings, power lines and trees. Surface accretion is particularly prevalent in elevated terrain, as when supercooled clouds envelop mountain tops and yield thick coatings of rime on trees and rocks. Similarly, the sedimentation of supercooled drizzle and rain onto surface objects can quickly leave them with a thick coating of clear glaze ice.

As with aggregation, accretion is a collection process, but it otherwise differs in many ways from aggregation. Accretion involves the collection of liquid droplets that invariably freeze. This phase change has several consequences that cause rimed particles to behave uniquely in the atmosphere. Whereas aggregation leads to snowflakes with an open, low-density structure, accretion leads to compact, dense ice particles that tend to be structurally strong. Their compact forms mean that rimed particles offer relatively large mass and low aerodynamic resistance, so that their terminal fallspeeds are higher and even increase in rough proportion to the degree of riming.

Growth of ice particles by accretion proceeds by stages. Individual ice crystals first begin collecting supercooled cloud droplets after having achieved certain minimal sizes by vapor deposition. For plates, the threshold for collection is crossed once the semi-major dimension approaches 150 μm, whereas for columns the onset of riming occurs when the radius along the minor (*a*-axis) dimension exceeds about 25 μm. Figure 3(a) provides an example of a lightly rimed crystal. With continued accretion, crystals gradually become encased in a mass of frozen droplets and eventually lose their identity. At this point, the ice particles are termed "graupel" (sometimes "snow pellets"), as exemplified by the larger particles shown in Fig. 4. At some point, typically when the graupel diameter exceeds 5 mm, the particle fallspeed and collection rate increase to such an extent that the droplets do not have time to complete their freezing process before subsequent droplets are collected. The accreted water mass then flows across the surface and freezes relatively slowly, resulting in a layer of clear ice and the birth of a hailstone. The alternating layers of opaque and clear ice characteristic of hailstones arise as the individual hailstones successively encounter regions in a cloud of relatively low or high liquid water concentration and grow in "dry" or "wet" regimes, respectively.

These phenomenological aspects of accretion can be understood from a consideration of the energy budget associated with an individual ice particle that is simultaneously collecting supercooled droplets and interacting with the vapor field. Once well beyond the threshold size for riming, an ice particle (graupel or hail) of equivalent radius r_p accretes water mass continuously at a rate that can be expressed approximately as

$$\frac{\mathrm{d}m_\mathrm{p}}{\mathrm{d}t} = K\omega_\mathrm{L}, \tag{3}$$

where $K = \pi r_\mathrm{p}^2 E v_\mathrm{p}$ is the collection kernel, E is the collection efficiency, v_p is the particle fallspeed, and ω_L is the liquid water concentration (collective mass of cloud droplets per unit volume) encountered by the falling particle. The freezing rate implied by this accretion rate causes the particle to gain enthalpy at the rate $\lambda_\mathrm{f} K\omega_\mathrm{L}$, where λ_f is the latent heat of fusion. The particle warms, decreasing or even reversing the rate of vapor deposition. In a steady state, the energy gained by the particle through the freezing of accreted water must be balanced by the energy lost by sublimation and heat conduction to the surrounding air. Thus,

$$\lambda_\mathrm{f} K\omega_\mathrm{L} = 4\pi r_\mathrm{p} f_\mathrm{v} D_\mathrm{V}(\rho_s - \rho_\infty)\lambda_\mathrm{s} + 4\pi r_\mathrm{p} f_\mathrm{h} k_\mathrm{T}(T_\mathrm{s} - T_\infty), \tag{4}$$

where f_v and f_h are ventilation coefficients for vapor and heat transfer, respectively, while D_V is the diffusion coefficient of water vapor in air, λ_s is the latent heat of sublimation, k_T is the thermal conductivity of the air, ρ_s is the vapor density immediately over the particle surface at temperature T_s, and ρ_∞ is the vapor density remote from the particle, where the temperature is T_∞. The threshold value of ω_L for wet growth, the so-called Schumann–Ludlam limit, occurs when the particle temperature reaches the melting point T_0 and is

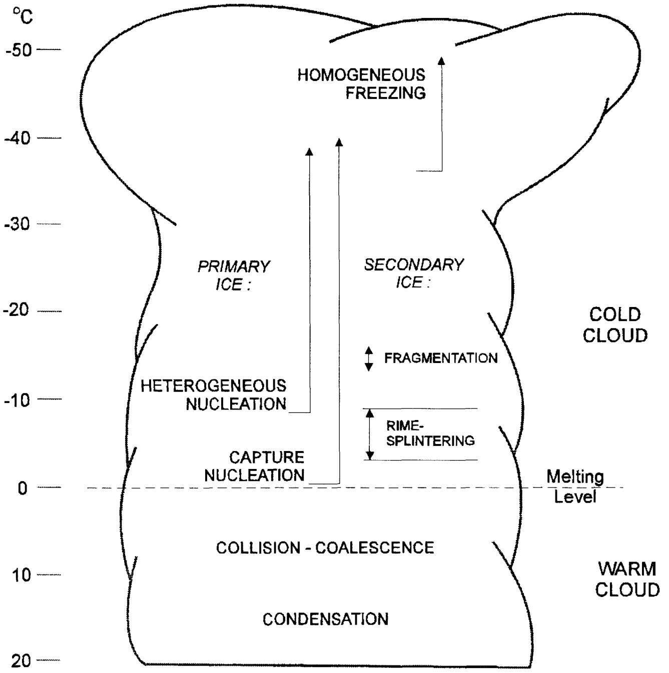

FIG. 13. An overview of the mechanisms that contribute to cloud glaciation.

given by

$$\omega_{\mathrm{L,wet}} \geq \frac{4}{E r_{\mathrm{p}} v_{\mathrm{p}} \lambda_{\mathrm{f}}} [f_{\mathrm{v}} D_{\mathrm{V}} (\rho_{\mathrm{s}} - \rho_{\infty}) \lambda_{\mathrm{s}} + f_{\mathrm{h}} k_{\mathrm{T}} (T_0 - T_{\infty})]. \qquad (5)$$

As a large ice particle, such as a hailstone, falls relative to the surrounding air and encounters liquid water concentrations alternately above and below this instantaneous threshold value (ω_{L}), it forms layers of clear and opaque ice, respectively. At very high liquid-water concentrations the rate of accretion may exceed the particle's ability to retain all of the water, in which case "shedding" of excess water occurs.

4. EFFECTS OF ATMOSPHERIC ICE

4.1 Cloud Glaciation

In an atmospheric context, glaciation refers to the formation of ice in a cloud, usually the complete transformation of an initially all-liquid (supercooled) cloud to an all-ice cloud. The mechanisms by which this phenomenon can occur are still speculative, for it must be appreciated that clouds represent water in a highly dispersed phase. Freezing events in some parts of a cloud do not automatically affect other parts of the cloud, yet it often appears as if an entire supercooled cloud, especially when convective, converts into ice within a matter of minutes. The processes responsible for rapid glaciation very likely involve secondary-ice generation and can account for the relatively high concentrations of ice found in some clouds, as discussed earlier in Sec. 2.2. Here, some mechanistic possibilities and the effects associated with glaciation are explored.

Ice can arise in a number of ways within supercooled clouds. The schematic diagram given in Fig. 13 provides an overview of the possibilities in convective clouds. Homogeneous freezing can generate many ice particles (frozen droplets) very rapidly, but not unless the temperature is below about −35 °C, meaning that only the upper parts of a cloud glaciate by this process. Heterogeneous nucleation is needed to explain ice lower in the cloud, but this mechanism is weak at temperatures higher

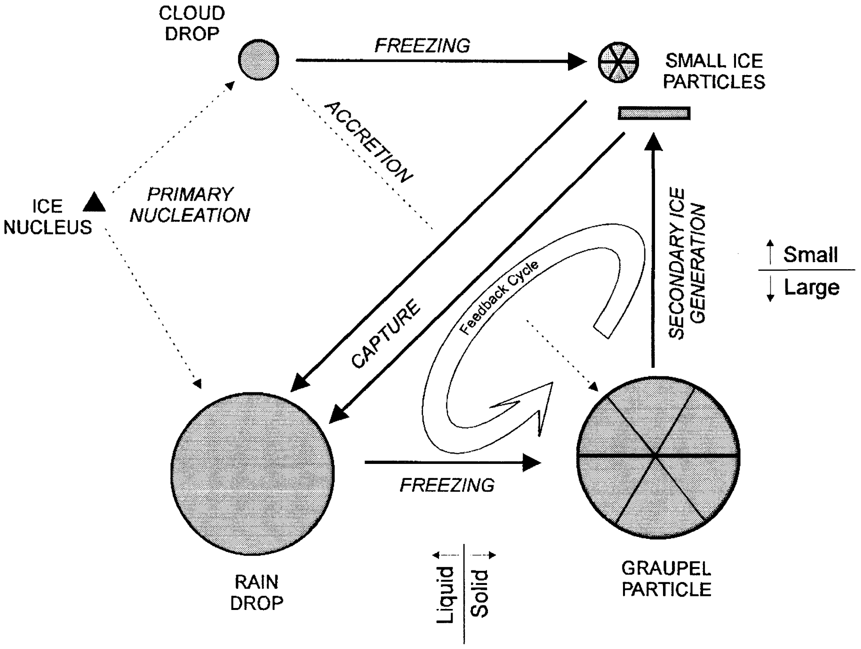

FIG. 14. Schematic diagram of possible interactions between various classes of cloud particles during the glaciation of a supercooled cloud. Adapted from Lamb *et al.* (1981).

than about −8 °C. "Capture nucleation", a freezing event initiated by the hydrodynamic collision (or capture) of a small ice particle with a relatively large supercooled drop, is effective for enhancing the mass of ice anywhere within a supercooled cloud, but it presupposes that such small ice particles exist. The formation of secondary ice *via* fragmentation or rime-splintering, each operating within a relatively narrow band of temperatures, generates new ice particles and so offers the main hope for explaining rapid glaciation and high ice concentrations.

Ice multiplication has been offered as a mechanism for the rapid transformation of some supercooled convective clouds to ice. As the name implies, the number concentration of existing ice is increased by some multiplier greater than unity. The secondary-ice formation mechanisms do this naturally, by definition, but the real power of multiplication emerges when the secondary ice can itself induce additional secondary ice. The stage is then set for the possibility of regenerative feedback and the exponential buildup of the ice population.

A simple conceptual model, based on the rime-splintering mechanism of secondary-ice generation in a way first developed by Chisnell and Latham (1976), helps illustrate the principle of ice multiplication. As suggested by the schematic diagram of Fig. 14, cloud particles may be classified broadly as small or large, liquid or solid. The "small" particles are the supercooled liquid cloud droplets or pristine (unrimed) ice crystals originating by either primary or secondary mechanisms. Such particles are typically some tens of microns in size, have small fallspeeds, and therefore follow the air motions. The "large" particles, often greater than 500 μm in diameter, are either supercooled rain drops, that likely grew by the collision–coalescence process within the "warm" cloud below the 0 °C level, or frozen raindrops that subsequently serve as riming centers (*i.e.*, graupel particles) that accrete the small cloud droplets. Given the difference in fallspeeds of the raindrops and the small ice particles, it is inevitable that some "capture" events will take place whenever these two classes of particles coexist in the same volume of cloud. Then, if the temperature is between

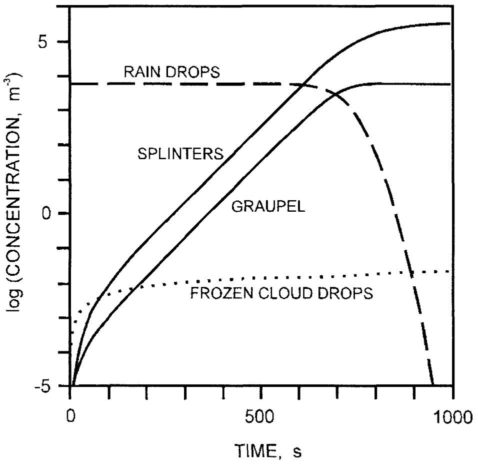

FIG. 15. Computed concentrations from the glaciation model employed by Lamb *et al.* (1981).

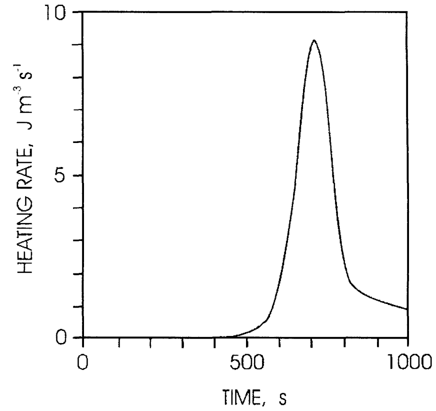

FIG. 16. Computed heating rates evolved during the buildup of the ice shown in Fig. 15. Most of the heating arises from the freezing of the large supercooled rain drops depicted in Fig. 14.

−3 and −8 °C, secondary ice ("splinters") would likely be released during the riming growth of the newly frozen raindrops. In this way, a cycle is set up (curved arrow in Fig. 14) whereby splinters are captured by the raindrops, which then freeze rapidly and throw off a new generation of splinters to perpetuate the process until all of the raindrops have been exhausted.

A straightforward analysis of the interactions depicted in Fig. 14 can be used that shows how the population of ice particles builds up with time when the dynamic structure of the cloud permits the "large" ice and liquid drops to remain for a time in the active secondary-ice production zone (between the −3 and −8 °C levels). The result of calculating the rates of interactions among the various cloud particles is shown in Fig. 15. The concentrations of both the splinters and the graupel are seen to increase exponentially until the process is cut off by the depletion of the raindrop population. Note that the initially all-liquid cloud was completely transformed into an ice cloud within less than about 12 min. Such an exercise demonstrates the complicated nature of cloud processes and the power of ice multiplication processes when opportunities for positive feedback exist.

Ice formation in supercooled clouds has a number of consequences. In some cases, the effects are immediate and strong; in other regards, they may be more persistent and perhaps subtle. When the glaciation proceeds rapidly, as when positive feedback processes are active, the sudden change in phase strongly affects the energy budget of the cloud: The latent heat released, particularly that due to the freezing of supercooled rain drops, leads to a warming of the cloudy air and an increase in the buoyancy of the cloud at mid levels. Results of the computations of the heating rate from the same glaciation model that was just considered are shown in Fig. 16. Because of the exponential nature of the glaciation (refer again to Fig. 15), significant heating appears only near the end of the process. A pulse of heating then results, the rate of which is comparable to that from the formation of the liquid cloud in the first place. Such large pulses of heating and buoyancy generation can occur naturally, or intentionally through cloud seeding, and lead to the "explosive" growth of convective clouds. More frequently, less dramatic effects occur, but the circulations of the cloud are stimulated nevertheless, often at an important stage in its development.

Precipitation of all types, both liquid and solid, is frequently initiated by the formation of ice in supercooled clouds. At one time, mainly during the middle decades of the twentieth century, it was thought that virtually all precipitation in the temperate zones resulted from the so-called cold-cloud or ice-crystal mechanism. Because of the inherent difference in vapor pressure of the solid and liquid phases of water, any ice particles that form in the presence of supercooled droplets grow rapidly by vapor deposition at the expense of the droplets. This phase change in effect destabilizes the colloidal nature of the cloud, permitting water mass to be transferred from the many small, nonsedimenting cloud droplets to a relatively few ice particles that can fall effectively against the updraft and later gather additional water by accretion. This mechanism of precipitation initiation appears to be important in many clouds, but we now recognize that the growth of precipitation by the all-liquid collision–coalescence mechanism is important for producing precipitation itself under some meteorological conditions, as well as for setting the microphysical stage for cloud glaciation.

4.2 Electrical and Chemical Phenomena

Cloud electrification is another likely consequence of ice formation, especially when it occurs in the large convective cells of summertime thunderstorms. Although the details by which the observed, vertically oriented dipole arises in convective clouds are still uncertain, it appears that collisions between graupel particles and relatively unrimed ice crystals play a fundamental role. The electrical nature of the surfaces of these two classes of particles is likely to differ, so that small amounts of electric charge would be transferred from one particle to the other when they collide and rebound without coalescing. Laboratory studies have shown that the sign of this microphysical charge transferred depends on the temperature, the liquid water concentration, and the degree of chemical impurities in the environment. For typical clouds with about $1\,\mathrm{g\,m^{-3}}$ of liquid water, the graupel particles gain negative charge and the ice crystals gain positive charge when the temperature is below about $-20\,^{\circ}\mathrm{C}$ (Saunders, 1993). Both the frequency of collisional interactions and the rate of macroscopic separation of the charges within the cloud are aided by the relatively large difference in fallspeeds of these two types of particles. The upper, glaciated reaches of thunderstorms thus become positively charged relative to the lower, mixed-phase portion of the cloud. With sufficiently vigorous convection, the potential difference between these charge centers, or between one of them and ground, can lead to electric breakdown of the air and the violent discharge known as lightning.

Interactions between ice and the various trace chemicals in the air can have potentially important consequences. Some electrification studies have implicated contaminants in the exchange of charge during collisions between ice crystals and graupel particles, but the mechanism is unclear. The supercooled cloud droplets accreted by the graupel particles invariably contain ions acquired at the time of their formation and subsequently during in-cloud scavenging events, and so it is logical to expect the chemical composition and therefore the electrical nature of graupel and vapor-grown ice to differ. However, past studies have indicated that the chemical effects are weak. Some researchers, by contrast, argue that the "contact potential" that may be responsible for the charge transfer on the particle scale depends only on the growth rates and temperatures of the colliding surfaces. Much research is needed on the nature of the ice surface and how it interacts with atmospheric trace chemicals before cloud electrification is understood.

Other interactions of trace chemicals with ice may have other, more direct impacts, however. Recent studies indicate that some trace gases, such as HNO_3 and SO_2, adsorb onto the ice surface over a broad range of time scales. In some cases, the ice surface seems to serve as a catalytic medium for reactions as well, leading to possible roles for heterogeneous reactions involving ice in the chemistry of the upper troposphere and lower stratosphere. This area of research is in its infancy and should be worth watching.

4.3 Interactions with Radiation

By interacting with electromagnetic radiation, atmospheric ice gives rise to numerous optical phenomena and affects the radiation budget of the Earth. The beautiful 22° halo frequently seen around the sun or moon, for instance, occurs as light is refracted through two of the prism faces of regular hexagonal ice crystals in thin ice clouds. Some optical phenomena, among them the familiar parhelia or "sun dogs", provide the observer with unique information about the type and orientation of the crystals contributing to the display. In this case, the crystals tend to be plates with their principal axes vertical. Such optical displays arise because the regular geometry of the crystals causes solar radiation to be scattered in well-defined directions.

More commonly, however, the ice-particle morphology is not so regular, and the incoming radiation is scattered more diffusely. Some fraction of the solar energy scattered from thin ice clouds returns to space, but most of it is forward-scattered toward the earth, so that the impact of cirrus clouds on the short-wave radiation budget is minimal. At infrared wavelengths, on the other hand, high-level ice clouds can have substantial influence. Ice readily absorbs upwelling terrestrial (infrared) radiation, but the re-emission of thermal radiation is weak at the low temperatures found in the upper troposphere. High ice clouds therefore tend to contribute to a general warming of the earth in the same sense that the radiatively active trace gases do.

5. SNOW AND ICE STORMS

Snow and ice storms represent one of the most direct intersections of atmospheric ice with humans. When ice particles in the atmosphere grow large enough to fall to the surface as snow, the impacts may be as benign as a beautiful blanket of white over the landscape or as devastating as a raging blizzard. Large snow storms may yield millions of tons of snow that clog highways, close airports, and generally create havoc on human activities. Floods may ensue once warmer weather arrives and cause another bout of devastation. On the positive side, however, snow that falls in mountainous terrain may persist well into the warm season and supply much-needed water to urban areas during drier times of the year. As much as half of the land mass of the northern hemisphere may become covered with snow each winter, generating a seasonal snowpack that reflects a significant fraction of the incoming solar radiation and thus affects the Earth's climate. The storms that give rise to such effects are described in a general way here, first from a meteorological perspective, then in terms of the microphysical processes discussed earlier.

5.1 Meteorological Settings

Snow and ice storms typically result from cyclones that form during wintertime in the mid latitudes. Driven by the sharp contrasts in temperature that develop across the polar front, these storms convert atmospheric potential energy into kinetic energy and serve to reduce the meridional temperature gradients of the earth. In a typical sequence of events, waves of relatively short wavelength develop in the airflow (jet stream) of the upper troposphere and cause the surface pressure to decrease beneath the poleward-flowing branch of the wave. The cyclonic (counterclockwise in the northern hemisphere) circulation that is established about the center of low pressure causes warm air to flow poleward and cold air to flow equatorward. At this point, the polar front is transformed into well-defined warm and cold fronts that radiate out from the center of the low-pressure system. Because of density differences in the cold and warm air masses, vertical components to the air motions are established. Adiabatic cooling of the air during upward motion leads to supersaturation development and cloud formation along both fronts. The latent heats of condensation and freezing that are released from the changes in phase augment the circulations and help maintain the energy of the cyclone.

Although mid-latitude cyclones exhibit a life cycle lasting several days and so cannot be treated as steady-state phenomena, a generic structure may be described that pertains to the system during the mature stage, the period during which the warm and cold fronts remain distinct. Figure 17 depicts the airflow pattern and conveys the three-dimensional structure of a typical storm during this stage. The relatively warm, moist air arising in the warm sector is lifted up and over the cooler air flowing beneath the warm front, by virtue of its relatively low density. This airstream, the so-called "warm conveyor belt", provides the cyclone

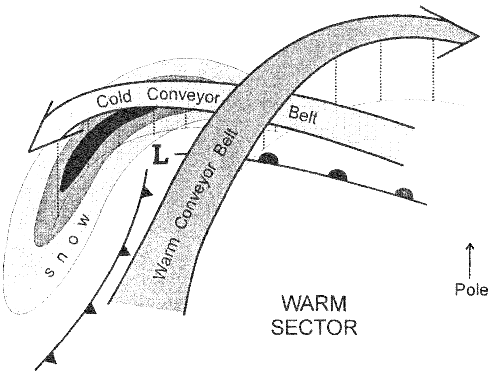

FIG. 17. The airflow pattern during the mature stage of a typical mid-latitude cyclone. Based in part on the study of Browning (1983).

with a steady supply of moisture for cloud and precipitation formation. Poleward of the warm front, the "cold conveyor belt" brings a steady stream of surface air beneath the warm conveyor belt before it, too, ascends over the still colder air behind the cold front. In some situations, such as those of the "Nor'easters" that frequent the east cost of North America, the air of the cold conveyor belt can be relatively very moist, so contributing greatly to the precipitation of the system.

5.2 Formation of Snow and Ice

Precipitation forms in the ascending branches of cyclonic systems by the same microphysical processes described in Sec. 3. As moist air cools by adiabatic ascent, such as in the warm and cold conveyor belts shown in Fig. 17, supersaturations develop and cause cloud to form. The temperatures vary nonuniformly in the vertical, first decreasing with altitude (beneath the warm front), then increasing in a narrow band through the front before again decreasing with altitude in the warm overrunning air. The warmest air is thus found in a layer aloft, about where the cloud base is located. Still, in a typical wintertime situation, this maximum temperature is near 0 °C, so that most of the cloud is supercooled. The coldest parts of the system are found near cloud tops. Especially along the warm conveyor belt, the air can become convectively unstable on account of the lifting of relatively warm, moist air beneath the colder, drier air of the upper troposphere. Convective towers form on top of the otherwise smooth, stable flow and lead to localized regions of very large supersaturations and high probabilities of ice nucleation.

As primary ice particles form, they grow rapidly by vapor deposition due to the large difference in the equilibrium vapor pressures of ice and liquid water. This "Bergeron process" leads to relatively large single crystals that sediment against the updraft and grow further by aggregation and accretion. The relative contributions of the various growth mechanisms to the overall mass gain of the snow depend on the relative abundances of liquid and ice particles, as well as on the geometry of the storm-scale flow patterns. In some cases, it appears that a "seeder–feeder" mechanism leads to the efficient production of snow when the vapor-grown ice crystals (seed particles) formed in the warm conveyor belt fall into the underlying cold conveyor belt, where they continue their growth by collection (Browning, 1983). The growth of the snow particles in the lower, feeder cloud is particularly effective when the air of the cold conveyor belt is forced to rise against mountainous terrain.

The distribution of snow and ice formed in a wintertime cyclone depends on a number of factors. As a rule, the maximum rate of snow formation occurs where the vertical flux of moisture is maximum. Thus, where moist air ascends rapidly, as where it crosses a frontal boundary or where it encounters a topographic barrier, the rate of condensate and precipitation formation will be large. The total accumulation on the ground, however, depends also on the wind speed and the movement of the storm as a whole. Relative to the moving system, the main region of snowfall typically appears in a crescent-shaped band behind the cold front and wrapping around the center of low pressure. If the temperatures are significantly below zero everywhere, then one can expect all precipitation to arrive at the ground in the form of snow; otherwise one may encounter rain in some parts, possibly freezing rain in other parts. The favored location for freezing rain is on the cool side of the warm front, where the lowest layer of air can be below the freezing point at the same time that the warmer air above the sloping frontal zone is above 0 °C. Such situations are not uncommon in the northeastern United States of America and are exacerbated by the evaporative cooling of precipitation falling below the cloud base. Only minor changes in the temperature profile above a given location are sufficient to alter the form of precipitation, but the consequences to humans can be profound.

6. CURRENT UNCERTAINTIES AND RESEARCH AREAS

As can be appreciated from the discussion of snowstorms, precipitation on the ground represents the culmination of a number of meteorological and microphysical processes operating on a hierarchy of spatial and temporal scales. The processes interact with one another, so that precipitating systems tend to be complicated. Predicting the arrival of a new weather system, or its consequences, is difficult in part because the complexities in the systems tend to make them sensitive to the initial conditions. Especially in the case of freezing rain, considerable precision is needed in forecasts because of the sudden change in the phase of water near 0 °C. Through ongoing research efforts, considerable progress is being made in the area of regional forecasting of wintertime precipitation. Similar arguments apply to the prediction of hail storms, but there the problem is further complicated by the small scales of thunderstorms and our incomplete understanding of the evolution of hail in a convective environment.

Major uncertainties still exist in understanding some of the microphysical processes of ice and snow formation. Whereas we can categorize processes and have general understandings of how they operate, details are lacking in such areas as the concentrations of ice nuclei and their modes of action, the causes of the peculiar variation of crystal habit with temperature, the mechanistic basis of secondary ice formation, and quantitative relationships of atmospheric ice concentration to rainfall from cumuliform clouds. Both the warm-cloud and cold-cloud mechanisms of precipitation formation occur simultaneously, but we cannot yet quantify their relative contributions to precipitation amount. Both field programs and computer modeling serve to enhance our understandings of cloud-scale phenomena, but often laboratory experimentation is needed to resolve the details of specific microphysical mechanisms. Of particular importance to the advancement of our understandings on the particle scale are experimental studies aimed at characterizing the molecular nature of the ice surface under realistic atmospheric conditions. The findings from such research would undoubtedly yield insights into the reason for the variation of deposition coefficients and habits with temperature, for instance, as well as provide a foundation upon which to explain the phenomenon of charge transfer during collisions between ice particles. Chemical interactions, too, require detailed research at the molecular level. It is clear that, despite much progress in recent years, diverse methods of research are still needed before we really understand atmospheric ice.

GLOSSARY

Bergeron Process: The microphysical mechanism by which water is transferred *via* the vapor phase from liquid drops to ice particles that then serve as embryos for precipitation. Named after Tor Bergeron (1891–1977), the Swedish meteorologist who recognized that the difference in phase leads to the colloidal instability of clouds.

Cold Cloud: The generally upper parts of a cloud containing ice particles.

Cold Front: The leading edge of an advancing cold air mass.

Dendrite: A platelike crystal grown from the vapor that exhibits a treelike branching structure.

Freezing Rain: Rain that falls as supercooled liquid drops and freezes upon contact with the ground, resulting in a coating of relatively clear ice (glaze).

Graupel: Snow pellets, soft ice particles up to 5 mm in diameter formed by the accretion of supercooled droplets.

Hail: Precipitation in the form of irregular lumps of ice greater than 5 mm in diameter that grew partially by the "wet" accretion of supercooled droplets.

Polar Front: The quasistationary boundary between cold, polar air and the warmer air toward the equator.

Sleet: Precipitation formed by the freezing of supercooled rain before contact with the ground.

Troposphere: The lowest 10–20 km of the atmosphere, characterized by decreasing temperature with increasing height and vertical air motions that contribute to the formation of clouds and weather.

Ventilation Coefficient: A factor to account for the motion of a particle relative to the air. In the case of crystal growth from the vapor, for example, the mass ventilation coefficient is the ratio of the actual vapor flux toward a sedimenting crystal to the flux toward a similar, but stationary, crystal.

Warm Cloud: The lower, warmer parts of a cloud containing only liquid drops.

Warm Front: The leading edge of an advancing warm air mass.

INTRODUCTION

Biomimetic ceramic processing is a relatively new field within materials engineering that seeks to imitate or mimic the procedures Nature has used to produce biological ceramics such as bones, eggshells, and seashells. The interest in biomimetic ceramic processing stems primarily from an admiration of the complex shapes and remarkable physical and chemical properties displayed by biological ceramics, given their generally mundane chemical makeup. For example, seashells, which contain 98–99% calcium carbonate, can be twice as hard and several thousand times more fracture-resistant than nonbiological calcium carbonate (Laraia and Heuer, 1990; Kuhn *et al.*, 1996a, Jackson *et al.*, 1988). The exceptional properties of biologically produced ceramics can be directly correlated to the complex microstructures (microarchitectures) created by organisms through a highly controlled and precise sequence of assembly. In the case of the seashell, for example, the high toughness is directly related to structure on several levels, a hierarchical structure. While shell microstructures vary between marine organisms (Bøggild, 1930), the toughest materials exhibit a laminated multi-layered microarchitecture containing structure on five length scales; each macroscopic layer is composed of microscopic layers that are in turn composed of even finer layers. The macroscopic toughness is increased because the layers act to deflect cracks, and thus dissipate the energy associated with incipient mechanical instability among many fine-scale noncatastrophic microcracks (Laraia and Heuer, 1990; Kuhn *et al.*, 1996a). A technological advancement potentially capable of improving the toughness of ceramics by several orders of magnitude is especially significant; it may further the acceptance of ceramics

by structural designers in a variety of advanced applications, a long-held goal.

Biological ceramics are laminated microcomposites, with each layer of biomineral separated from its neighbor by organic "matrix" constituents (primarily acidic proteins). These matrix proteins regulate and control the structure and composition of the biomineral phase during initial formation. It is this organic matrix control that forms the basis of biomimetic processing approaches. Other natural systems, in particular bacteria and unicellular organisms (Mann, 1996), can also provide inspiration for novel magnetic, electronic, and mechanical devices, and are briefly mentioned below.

Although many of the detailed steps involved in the formation of biological ceramics are not yet well understood, general processing paradigms have emerged that have significant implications for materials science. The three primary processing principles examined in this chapter are illustrated with examples involving the formation of bones, seashells, and eggshells. In turn, examples of how each principle has been used to develop a biomimetic ceramic processing approach will be discussed. From the description of property improvements available from a biomimetic approach, biomimetic processing of ceramics appears to hold much promise.

1. CONVENTIONAL CERAMIC PROCESSING

In order to appreciate the recent and potential advances of biomimetic ceramic processing, the conventional methods of producing ceramic components are first briefly reviewed.

1.1 Powder Processing

Ceramic substances of interest here (refractory oxides, nitrides, carbides, and similar materials) cannot easily be melted and cast into near net-shape components because of their high melting point; therefore, powder processing approaches are the rule. Furthermore, their hard and brittle nature makes machining of ceramic components to exacting tolerances difficult and expensive, and so net-shape processes are preferred.

The processing of ceramics generally begins with formation of a powder compact, and the sintering shrinkage that invariably accompanies the subsequent densification of powder compacts must be accounted for at this stage. Basic consolidation methods used to form complex shapes at ambient temperatures from ceramic powders include dry powder pressing, isostatic pressing, injection molding, extrusion, slip casting of slurries, wet plastic forming, gel casting, or cementatious bonding. With the exception of cementatious bonding, consolidation is followed by a densification step at elevated temperatures (pressureless sintering, hot pressing, or hot isostatic pressing), which "fuses" or "bonds" the individual powder grains and allows pore shrinkage. The resulting sintered body is a cohesive, dense (or nearly dense) monolithic structure.

Care must be employed to avoid introduction of deleterious defects during powder processing and subsequent finishing to final dimensions. Common ceramic processing concerns include control of residual porosity and other two-dimensional or three-dimensional defects that may weaken the part, as well as differential shrinkage, which can introduce residual stresses and crack-like defects. To obtain the high strength and reliability necessary for advanced or "high-tech" non-clay-based ceramics for structural or electronic applications, it is necessary to have stringent control of the size and shape of the starting powders. Organic processing additives—dispersants, deflocculants, binders, surfactants, *etc.*—that improve powder flow and packing, and allow for molding into "green" (unfired) parts with good handling characteristics, are commonly employed. A mixture of powder sizes packs most efficiently, provided the particles exhibit good flowability. Ceramic powders may be obtained from grinding and milling of natural raw materials, but control of particle size and shape is more usually achieved by a variety of chemical powder synthesis methods. Precipitation from aqueous and nonaqueous solutions, thermal decomposition of inorganic salts, hydrolysis of alkoxides and other organometallics, sol–gel techniques, pyrolysis of polymeric precursors, flame hydrolysis, hydrothermal techniques, and condensation from a vapor phase are commonly used to obtain micrometer- and submicrometer-sized powders.

Detailed descriptions of conventional powder synthesis can be found in standard references (Messing *et al.*, 1987; Segal, 1989). Some of these methods are relatively expensive and do not lend themselves to large-scale production.

Colloidal technologies are an important component of modern ceramic processing approaches. These usually involve the use of suspended particles in a slurry containing various additives. The aim is to control interparticle forces with adsorbed charged additives to achieve stable suspensions, which lend themselves to production of high green densities during subsequent consolidation. [Without additives, interparticle interaction from van der Waals forces can cause uncontrolled aggregation that effectively increases the particle size and leaves undesired voids in the finished product (Lange, 1983).]

1.2 Thin-film Deposition and Layered Materials

There is much interest in the formation of thin films of ceramic materials for electronic, magnetic and optical devices, as well as for thermal, corrosion and abrasion protection. Important thin-film materials include high-T_c oxide superconductors, oxide and nitride dielectric interlayers, nonmetallic magnetic films, and ferroelectric films for electro-optical and memory devices (Ohring, 1992). The conventional methods for formation of thin ceramic films on substrates include sol–gel deposition or other solution techniques and vapor-phase techniques including plasma spray deposition, molecular-beam epitaxy (*q.v.*), laser ablation, sputtering (*q.v.*), and chemical vapor deposition [see CVD (Chemical Vapor Deposition)] (Feldman and Mayer, 1986).

There are a number of limitations associated with conventional thin-film deposition methods. In order to control physical and chemical properties of thin films, it is necessary to control film density, crystal orientation, grain size, degree of crystallinity, and thickness. This is difficult with sol–gel and colloidal processes because they generally undergo significant densification during final sintering. Furthermore, the high processing temperatures prohibit the use of polymer substrates. Vapor-phase deposition methods usually require expensive fabrication systems and deposition rates are very slow. Crystal orientation is very important because many magnetic, ferroelectric, and superconducting properties are anisotropic, yet the choice of substrates for oriented growth is very limited. These limitations provide a strong motivation for the development of biomimetic thin-film processing.

2. CERAMIC PROCESSING IN NATURE

There are a myriad of fascinating biominerals found in Nature, with complex shapes and microstructures and equally fascinating and complex methods of fabrication (Omori and Watabe, 1980; Nancollas, 1982; Mann *et al.*, 1989; Lowenstam and Weiner, 1989). The structure and formation of the most widely studied biological ceramics—mammalian bones, eggshells, and seashells—are described in this section. We illustrate the complex microarchitectures and their development, which demonstrate an exquisite level of control of the spatial regulation of both the nucleation and growth of the biomineral. Given the relatively modest properties of the basic building materials, the resultant structures demonstrate the remarkable properties that are possible with cell-mediated, organic matrix-modulated assembly.

2.1 Examples of Biomineralization

2.1.1 Bone Structure and Formation Much study has been devoted to the structure of mammalian bone, primarily motivated by biomedical applications (Glimcher, 1959; Pechak *et al.*, 1986; Giraud-Guille, 1988; Landis *et al.*, 1993; Kim *et al.*, 1995; Robey and Boskey, 1996; Ziv *et al.*, 1996); bone development is thus a natural source of inspiration for biomimetic ceramic processing. Bone is a complex material with unique architectures at many different length scales that are customized for the several functions that bone must provide (Fig. 1). In addition to the obvious structural applications, bone acts as an ion reservoir for maintaining chemical homeostasis and as a repository for healing cells (Glimcher, 1959; Pechak *et al.*, 1986; Robey and Boskey, 1996).

Macroscopic features of note include dense,

FIG. 1. Bone structure, part I. Bone is a complex material with unique architectures at many different length scales. The long bones such as the femur have a dense shell of cortical bone with a central cell-filled marrow cavity. Porous trabecular bone reinforces the ends of the bone. A twisted plywood structure can be observed at the microstructural level, with each layer comprised of lamellae of mineralized collagen fibrils, which themselves are comprised of mineralized microfibrils.

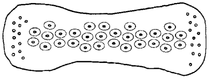
The mineral phase of bone nucleates in the gaps or hole zones between the ends of the collagen molecules, which also have a complex architecture: a triple helix of three strands of protein.

but hollow, shells of cortical bone enclosing cell-filled marrow cavities, and larger, broader ends of bone reinforced with porous trabecular bone to absorb mechanical energy and optimize weight transfer and friction across joints (Fig. 1). The microarchitecture is one of repeating layers of mineral-reinforced bundles of structural fibrillar proteins, offset in a twisted plywood structure (Giraud-Guille, 1988; Ziv *et al.*, 1996) (Fig. 2); the mineral is calcium phosphate in the form of carbonated apatite containing other ions such as HPO_4 and Na and Mg (Kim *et al.*, 1995), *not* hydroxyapatite as is frequently suggested in the literature. Each layer is made up of sheets containing collagen fibers arranged side by side. Each fiber is actually a bundle of layered microfibrils that contain layered collagen molecules in a triple helix assembly (Fig. 2); the mineral "reinforcement" occurs at the microfibrillar level. In addition to apatite (65 wt%) and collagen (30 wt%), there are a variety of other proteins, proteoglycans, and glycoproteins present in bone that are well described by Robey and Boskey (1996).

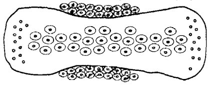
Materials selection charts that allow a rapid selection of the optimal material for a given application indicate that the best strength/modulus ratio can be obtained when the size of the reinforcement decreases (Ashby, 1993). Bone mineral, with its nanometer-sized apatite crystals, represents a near-ideal configuration that no synthetic system has yet attained.

In long bones like the femur, bone formation is accomplished by cellular activity around a structural precursor composed of cartilage (Fig. 3). During embryogenesis, cells first de-

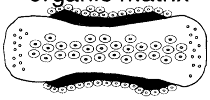
(a) Cartilage model



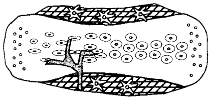
(b) Pre-bone cells form a layer around the model



(c) Bone cells secrete mineralizing organic matrix



(d) Bony collar starves cells inside, degradation begins.



(e) Finished bone with cartilage on ends and marrow within.

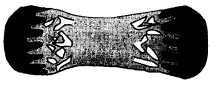


FIG. 3. Bone formation begins with the formation of a cartilage model that defines the macroscopic dimensions of the bone. Pre-bone cells form a layer completely around the model and then differentiate into bone-producing cells, osteoblasts. A bony collar is formed around the model when the matrix secreted by the cells mineralizes. An ingrowth of blood vessels brings in osteoclasts, which degrade the cartilage and open a cavity for marrow cells and bone trabeculae formation.

posit a collagen-based cartilage form that defines the dimensions of the bone, and then assemble in layers around it (Pechak *et al.*, 1986). The cells then secrete a different, bone-specific collagen that self-assembles into the fibrillar sheets described earlier that have compartments in which mineralization occurs. Prior to mineralization, the cells secrete matrix vesicles that contain high concentrations of calcium and phosphorus throughout the collagen network (Wuthier, 1997). There are acidic proteins [*e.g.*, bone sialaprotein (Kinne and Fisher, 1987)] within the compartments of collagen that are believed to concentrate calcium ions. Mineralization commences when enzymatic processes release phosphorus from the phosphoproteins in the surrounding milieu to effect locally high concentrations of phosphate ions. After a rigid, bony collar has formed around the cartilage preform, the cartilage is intentionally degraded by other cells that enter through the collar of bone and proceed to break down (decompose) the cartilage [Fig. 3(d)]. Vasculature, *i.e.*, the formation of blood-carrying vessels, develops and allows transport of the cartilage residues, emptying the central canal, which is then filled with marrow. The lamellar structure is not well defined upon initial formation, and this early structure is referred to as woven bone. It is only during "remodeling" that the lamellar structure develops; remodeling is a phenomenon whereby certain bone cells called osteoclasts resorb bone, and other cells called osteoblasts rebuild the bone.

Mineralization of bone involves the following coupled mechanisms:

1. Cells adjacent to the site to be mineralized secrete organic components that self-assemble into an organic collagen scaffold with uniformly sized compartments that subsequently mineralize.
2. A specific mineral of a defined shape in specific orientation is nucleated with assistance from acidic proteins bound to the structural proteins. Bone mineral crystals are unique in that they are nearly monodisperse, nanometer-sized plates of carbonated apatite of similar dimensions to the organic compartment. No other mineral phases are present and the crystallographic *c* axes of the apatite crystals are parallel with the collagen fibril axis.
3. Complex hollow and porous macroscopic shapes are generated by the repetition of self-assembly of structural proteins that arrange themselves in layered sheets with a twisted plywood structure around a predefined, space-holding preform. The cartilage preform is temporary, as it defines the macroscopic shape of the bone to be formed and is afterwards degraded. The layered architecture of bone hinders crack propagation and enhances toughness. Strict biomimesis of mineral–polymer composites based on the structure of bone would involve regularly spaced aligned filler particles

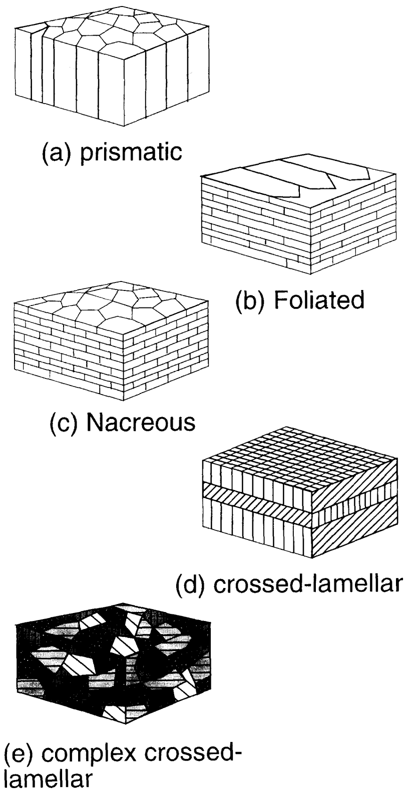

FIG. 4. Five common mollusk shell microstructures.

that are nanometer-sized plates present at a high volume fraction (more than 60% in bone).

2.1.2 Seashell Structure and Formation Most mollusk shells are calcium carbonate with a small amount of organic material (0.01–5 wt%), known as conchiolin. A variety of material architectures within mollusk shells have evolved, based on the environment of the marine organism. The currently accepted material architectures are still those defined by Bøggild (1930), several of which are illustrated in Fig. 4. The crossed-lamellar structure is the most specialized, and the most common within the phylum; it can be found in conch shells. The best known structure is mother of pearl, or nacre, the iridescent inner shell layer of oysters and abalone. These two microstructures are discussed in detail in this section.

The *Strombus Gigas* (pink conch) is a burrowing mollusk with an extremely hard and tough crossed-lamellar shell structure (Fig. 5). The microstructure within this shell consists of layers of aragonitic calcium carbonate at five length scales (macroscopic layers, first-, second- and third-order lamellae, and polysynthetic twinning at the 10 nm level), separated by a tenuous organic matrix present at less than 1 wt% (Taylor and Layman, 1972). The internal structure of the three macroscopic layers [each 2–5 mm thick and denoted i (inner) next to the organism, m (middle), and o (outer) in Fig. 5] are rotated by approximately 90° from one layer to the next. The first-order lamellae within layers are 25–40 μm thick and several mm long and are oriented such that adjacent lamellae are rotated by 70–90°. The second-order lamellae are 1–10 μm thick and 20–50 μm wide, and are aligned parallel within a first-order lamella; the third-order lamellae within them are also aligned. Each of the third-order lamellae are twinned single crystals of aragonite, 100–500 nm wide and less than 50 nm thick, the very-fine growth twins being about 10 nm wide (Laraia and Heuer, 1990). The aspartic-acid–rich organic matrix has been observed by TEM (transmission elecron microscopy) as a thin layer that envelops each of the third-order lamellae (Weiner, 1984).

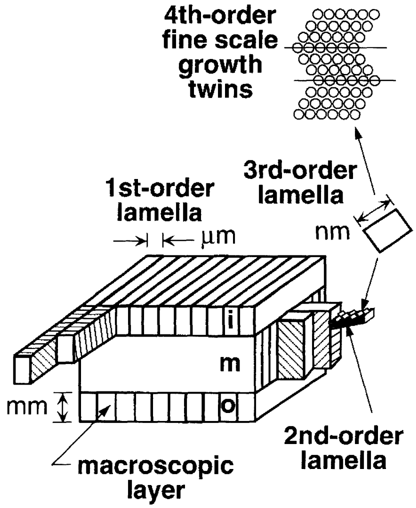

FIG. 5. The crossed-lamellar microstructure is composed of multiple layers of lamella at five length scales ranging from millimeter to nanometer thicknesses: i, m, and o denote the inner (closest to the organism), middle, and outer (exterior) layers, respectively.

mantle cells (epithilium) secrete components for shell formation

FIG. 6. Mollusk shell formation proceeds with the deposition of an organic scaffold, the periostracum, that acts as a substrate for the deposition of nucleating and growth controlling organic matrix molecules. The mantle cells secrete the extrapallial fluid, which contains all the components for biomineralization.

This highly specialized mollusk shell structure possesses a fracture resistance around 1000 times that of mineral aragonite, and a hardness substantially greater (factor of 2) than that of mineral aragonite (Taylor and Layman, 1972; Currey and Kohn, 1976; Laraia and Heuer, 1990; Kuhn *et al.*, 1996a). Fractographic observations of test specimens taken from mature shells reveals delocalized damage in the form of multiple microcracks, crack bridging, crack branching, and delamination cracking that greatly increases the total crack area and frictional dissipation of strain energy during fracture.

The shell of the abalone has a nacreous inner structure [Fig. 4(c)], which has 1–4 wt% organic material and is the strongest of the shell structures (Taylor and Layman, 1972; Currey and Taylor, 1974). The abalone shell also has an external layer of vertically oriented calcite crystals arranged in the prismatic structure [Fig. 4(a)]. In nacre, small platelets of aragonite are stacked in a brick-and-mortar fashion. The platelets in different layers are crystallographically related to each other, with the *c* axis normal to the shell surface and the *a* or *b* axis twisted relative to the layer (Sarikaya, 1994). The polypeptide chain directions in three different mollusk species are parallel to the direction of the *b* crystallographic axis of the aragonite crystals (Weiner *et al.*, 1983); this may be a general phenomenon.

Shell formation proceeds with secretion by the mantle cells of a nonmineralizing organic layer called the periostracum, that hardens and acts as a substrate for the subsequent deposition of proteins that form mineral templates (Gregoire *et al.*, 1955; Wilbur, 1973; Krampitz and Graser, 1988) (Fig. 6); the external crystal form and pattern of the biomineral conforms to the microtopography of the periostracum (Wilbur, 1973). In addition to the secretion of a group of matrix constituents with significant polysaccharide content, the ions necessary for mineral formation are also secreted into the space between the periostracum and the mantle tissue. This extrapallalial fluid has a severalfold supersaturation with respect to calcium carbonate, similar to the supersaturation of sea water. A mineral-confining envelope is defined by the self-assembly of freshly secreted matrix above the periostracum, after which nucleation and growth of mineral commences in the compartment. Crystal growth continues inwards towards the organism and normal to the shell until impingement upon the next matrix layer, and lateral growth continues until terminated by impingement with other mineral grains. The five-layered organic "mortar" of the nacreous structure is presumed to self-assemble above the growing crystals, and the beta-sheet acidic protein structure of the outer proteins, combined with the acidic proteins, is believed to concentrate calcium and induce oriented nucleation (Fig. 6) (Lowenstam and Weiner, 1989). Recent studies on nacre have shown that the mineral formation is in fact continuous from layer to layer and not separated completely by an organic matrix compartment (Morse *et al.*, 1993). In the crossed-lamellar structure, the organic mortar is only a thin layer of acidic proteins (Weiner, 1984).

The following are key features of biomineralization in marine organisms:

1. Cells adjacent to the site to be mineralized secrete organic matrix constituents that self-assemble against the organism into a structural organic scaffold. The texture of this structure defines the surface texture of the shell. There is subsequent secretion of additional matrix components that assemble

into uniformly sized mineralizing compartments. Mineralization occurs within the compartments, whose thickness thus limits the size of the crystals. The structure is approximately monodisperse—95% of the crystallites within seashells are within 30% of the average thickness of 0.5 μm.

2. Fixed polyanions assist nucleation by providing a negatively charged surface that interacts electrostatically with cations. The distribution of the polyanions on a structural organic scaffold is believed to provide a stereochemical template for adsorbing a layer of cations, such that a particular phase of mineral is nucleated with a specific crystal orientation.
3. Biominerals of specific shape are built by self-assembly of incremental units that assemble in concert in a predetermined order.

2.1.3 Eggshell Structure and Formation

The common avian eggshell represents another example of how careful materials processing can transform ordinary materials into exceptional articles—in this case the production of a seamless, elliptical, crack-resistant protective container of $CaCO_3$ for embryo development. Eggshell architectures are less complex than those of bone or seashell, which is probably related to the fact that they develop more rapidly than either bone or seashell (5 g of $CaCO_3$ are formed in 24 h). Despite this, the material serves several functions for the developing embryo—providing structural protection, acting as an ion reservoir (a source of Ca for development of the skeleton of the developing embryo), and providing continuous micropores for the ready transport of gases during respiration. In the schematic of the cross section of an eggshell (Fig. 7), large columnar grains of calcitic calcium carbonate can be seen to traverse the entire shell thickness. The calcite columns ($\approx 70\,\mu m$ in diameter and 200–300 μm thick) are oriented single crystals and show uniform birefringence and single-crystal electron-diffraction patterns (Dennis *et al.*, 1996). The size of the crystals is unusually large for crystals grown in a few tens of hours.

The columns of mineral, known as palisades, are attached to the collagen-based shell membranes that surround the yolk and white of the egg. There is both an outer and an inner shell collageneous membrane, with the outer membrane generally more porous and composed of larger-diameter collagen fibers than the inner membrane (Fig. 7). At the base of the columnar mineral structure is the so-called calcium reserve assembly (CRA), which is a cluster of organic vesicles that are calcium-rich and carbonate-poor (Dieckert *et al.*, 1989). The CRA is preferentially resorbed by the developing embryo as a calcium source during skeletal development (Dieckert *et al.*, 1989). The outermost layer of the eggshell, the cuticle, is $\approx 10\,\mu m$ thick and is a sugar-rich proteinaceous layer containing calcium phosphate needles (Dennis *et al.*, 1996) that cover the entire shell, sealing the biomineral structure against microbial invasion and excessive H_2O loss. Coloration is added to this layer in certain species.

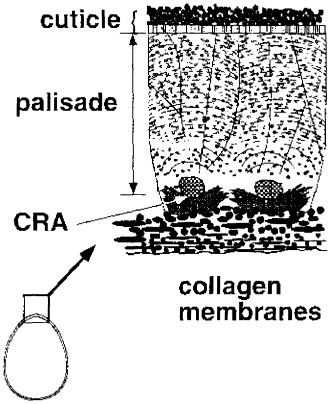

FIG. 7. Diagrammatic representation of the microstructure within the eggshell of a domestic chicken. Large columns of calcite form the palisade layer, which is anchored to the collagen membranes through the calcium reserve assembly (CRA) baseplates.

Although the avian eggshell is essentially a brittle material, quail eggs can undergo "graceful" failure and sustain loads after first cracking of as much as 70% of the load required to initiate fracture (Bond *et al.*, 1986). This behavior is related to the intermittent attachment between the compliant, fibrous membrane and the hard, brittle calcite columns. When growing microcracks reach the unattached regions, the crack is "blunted" as the load is spread over a much larger volume.

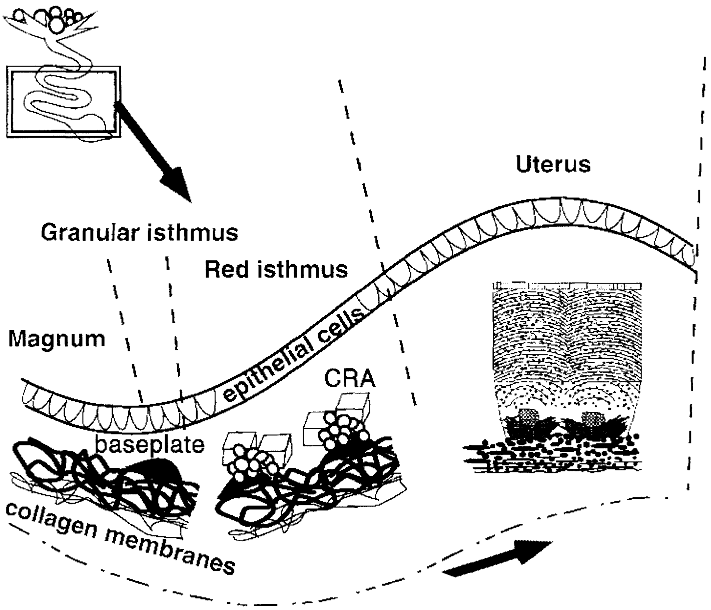

FIG. 8. Schematic partial cross sections of the avian eggshell at various stages of development in the oviduct. The bulk of eggshell crystal growth occurs in the uterus, where the egg remains for 20 h. Mineral nucleation occurs before this in the red isthmus on the organic structures known as baseplates, which are attached to the collagen membranes.

A schematic drawing of an avian oviduct, which serves as a kind of tubular bioreactor operating on a 24 h cycle, is shown in Fig. 8. During the passage of the egg through the oviduct, a number of extracellular matrix layers are sequentially processed onto the avian egg yolk by specialized secretory cells populating the subregions of the oviduct (Solomon, 1983). The first structural layers covering the egg, after albumen deposition in the magnum, are the inner and outer shell membranes. These membranes are secreted in the isthmus and self-assemble into random mats of collagenous fibers.

Mineralization of the eggshell is initiated in the final region of the isthmus (Creger *et al.*, 1976; Stemberger *et al.*, 1977). This process is first observed when the CRA particles, 1–10 μm in diameter, reach a maximum density of 2700 mm^{-2} on the outer surface of the shell membrane (Dieckert *et al.*, 1989). These particles are anchored in the membrane and serve as the bases of the large columnar calcite columns that develop to their full size while the egg rotates in the uterus.

In contrast to bone, the cells involved in eggshell formation are not intrinsic components of the shell; mineral deposition is effected by specialized oviduct cell populations in an "assembly-line" sequence as the egg is transported down the oviduct. The oviduct cells have more specialized control of distinct parts of eggshell fabrication—the cells in the isthmus portion of the oviduct secrete membrane components, and also the initial calcified structures upon which subsequent crystal growth proceeds. However, the bulk of the mineral phase is deposited in the uterus (the shell gland). Because the secretory cells do not become an intrinsic part of the eggshell, and because the secretory events occur in a relatively short time frame, there is only a limited portfolio of regulatory mechanisms available to the cells of the oviduct.

In terms of biological processing principles, the following key steps of biomineralization in eggshells have been identified:

1. Avian eggshell crystallization sequences are accomplished under cellular control. Cells

lining the hen's oviduct secrete organic matrix components that self-assemble around the shape-defining egg yolk to form a structural organic scaffold that will subsequently mineralize.
2. The spatial location and initiation of mineralization is defined by the clustering of certain interactive proteins that appear to bind to a specific region of the structural matrix and, at the same time, sequester large amounts of one of the mineral-phase constituents. The interactive proteins are predominantly anionic, rich in specific arrays of carboxyl phosphate groups, and may present β-sheet-like structures.
3. Successive layers of mineral/matrix composite are then deposited onto the membrane to form the eggshell proper.

2.2 General Biological Processing Principles

Mineralization processes used in biological systems exhibit a number of interesting features that have significant implications for material scientists and engineers seeking highly efficient and/or unique ceramic processing strategies. Biomineralization is of potential value because it is a form of environmentally sound ("green") colloidal ceramic processing based on biocompatible materials and mild conditions with no toxic by-products. In contrast to the high temperatures and/or high pressures associated with conventional shape-forming processes, the goal of a high-density, net-shape structure is accomplished with apparent ease by cellular deposition of an organic "matrix" that regulates where, when, and in what form mineralization will occur. The result of this molecular assembly is often a nanostructured composite with a complex microstructure, containing microarchitectures on a number of length scales. Dense crystalline films are synthesized, and sometimes patterned, without subsequent thermal treatment, on polymer substrates of complex geometry. Exceptional chemical and mechanical properties can derive from the fine composite structure, as described earlier.

Although many of the details of biomineralization are not yet well understood, general processing paradigms have emerged from analyses of biomineralizing systems. The three general biological processing principles governing the composition, architecture and methods of assembly of a variety of biological ceramics can be succinctly summarized (Heuer *et al.*, 1992).

1. *The compartment principle*. The initial stage in the fabrication of biominerals is the construction of an organized reaction environment or compartment. Biomineralization occurs within specific subunit compartments or microenvironments, which implies stimulation of crystal production at certain functional sites and inhibition or prevention of the process at all other sites.
2. *The specific mineralization principle*. A specific mineral is nucleated within the compartment with a defined crystal size (frequently in the nanometer range), shape, and orientation. Nucleation and growth of the biomineral phase are carefully and exquisitely orchestrated by a complex spectrum of organic matrix biopolymers. These matrix molecules appear to have been engineered through evolutionary processes to regulate a single, precise step in either the nucleation or the growth portion of the production of the mineral phase. Although specific details are not yet available for any organism, it is generally considered that the assembly of mineral nuclei is governed by electrostatic, structural, and stereochemical complementarity at the inorganic–organic interface (Mann, 1988).
3. *Net shape by self-assembly of incremental units principle*. Macroscopic shape forming is accomplished by self-assembly of many incremental units around a genetically defined scaffold or mandrel of structural proteins. Slow, repetitive processing results in a net-shape composite with layered microarchitecture that can impart exceptional mechanical properties. Rapid mineralization may be characterized by columnar growth patterns and one-time exposure to nucleating proteins.

An important feature of biomineral processing is that integration of the three general principles is the norm rather than the exception, as is illustrated in the examples of formation of bones and shells. Another powerful feature of biomineral processing is that, in some systems, remodeling and regeneration of the original mineral structure occurs, as needed, to optimize strength, accommodate organism growth, maintain mineral ion equilibrium, and effect repairs. While this extremely "intelligent" processing is currently too advanced for exact imitation, a few examples of novel synthetic routes inspired by biological mineralization are discussed next to suggest the potential of the biomimetic approach.

3. BIOMIMETIC CERAMIC PROCESSING

The next three sections offer representative examples of the three main areas of biomimetic ceramic processing: compartmentalized processing of particulates, thin-film formation, and net-shape formation of structures with layered architectures. Each area has developed around one of the three general biological processing principles. In a few cases, two of the three principles have been integrated with even greater advantage.

3.1 Compartmental Processing of Particles and Particulate Networks

Historically, the control of crystallization has been achieved empirically. The size, morphology, and polymorphic expression of a crystalline material can be controlled by changing the ambient temperature, supersaturation, solvent, and impurity level during crystallization. Biomimetic approaches seek to attain specific control over crystal habit, texture, and morphology by selective use of organic molecules.

3.1.1 Nanoparticles from Single Compartments Unicellular creatures (bacteria, algae, protozoa) use single, enclosed protein cages and lipid vesicles (compartments) to mineralize discrete nanometer-sized crystals and crystal clusters that do not assemble into complex, hierarchical structures such as bone and shell (Blakemore *et al.*, 1979). Recognizing the unique electrical, optical, and chemical quantum-sized effects possible in nanoscale particles (Ozin, 1992), as well as the high strength and superplastic deformation associated with nanostructured materials (Gleiter, 1992; Siegel, 1992), many different nanoparticles have been synthesized using isolated organic compartments (Table 1). Specific references can be found in two review articles (Mann, 1996; Kuhn *et al.*, 1996b).

Table 1. Biomimetic approaches to nanoscale particle synthesis.

Product	Systems	Materials
Clusters	Reverse micelles	CdS
	Microemulsions	Pt, Co, metal borides, Fe_3O_4, $CaCO_3$, $LaNiO_3$, $BaFe_{12}O_{19}$
Nanoparticles	Vesicles	Pt, Ag, CdS, ZnS, Ag_2O FeOOH, Fe_3O_4, $CoFe_2O_4$ Al_2O_3, Ca phosphates
	Ferritin	MnOOH, UO_3, FeS, Fe_3O_4
	Langmuir–Blodgett films	CdS
	Polystyrene resin	γ-Fe_2O_3

Microemulsions and reverse micelles are versatile systems because the reaction environment can have variable diameters (1–500 nm) and the surface functional group can be modified by straightforward chemistry. For example, phospholipid vesicles and reversed micelles formed by surfactant–water mixtures have been used to obtain unimodal, nonagglomerating, nanometer-sized metal oxide powders (Table 1) (Fig. 9) (Archibald and Mann, 1993), while the inverse microemulsion technique has been used to synthesize a fine $LaNiO_3$ powder (Gan *et al.*, 1994) (Fig. 10). Since each particle is surrounded by a bilayer membrane of several nanometers thickness, particle-to-particle interactions are negligible and reaction rates can be diffusion-controlled.

The utility of these techniques is limited, on account of the sensitivity of phospholipid or surfactant assemblies to changes in phase behavior and the dynamic behavior of reverse micelles. Protein cages with nanometer-sized internal cavities are more robust and have been successfully utilized to synthesize uniform and monodisperse Fe_3O_4 particles (Meldrum

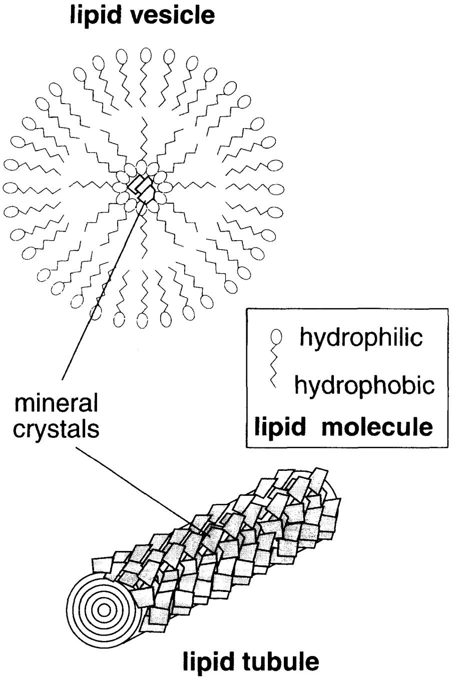

FIG. 9. Lipids provide versatile compartments for nucleation of nanometer-sized mineral particles.

et al., 1992); use of such protein cages appears to represent an integration of principles (1) and (2).

3.1.2 Nanoparticle Networks A combination of traditional sol–gel processes and polymer chemistry has been used to fabricate biomimetic films of particle-filled polymer composites. The inorganic reinforcing phase is formed when the alkoxide in a polymer–alkoxide–solvent mixture undergoes hydrolysis. Both SiO_2- and TiO_2-filled organic–inorganic hybrids have been formed with a wide range of polymers (Mark and Calvert, 1994). As might be expected, sol–gel composites, which are interpenetrating networks of organic and inorganic phases, are much stiffer and glass-like than the polymer-matrix materials.

The surge of activity in mesoporous silica and zeolites is based on the principle of co-organization of mineral and organic components in a synergistic process and can also be considered biomimetic. One-, two-, and three-dimensional liquid-crystal-like periodic arrays of inorganic–organic assemblies have been formed from surfactant molecules and inorganic ions (Firouzi *et al.*, 1995).

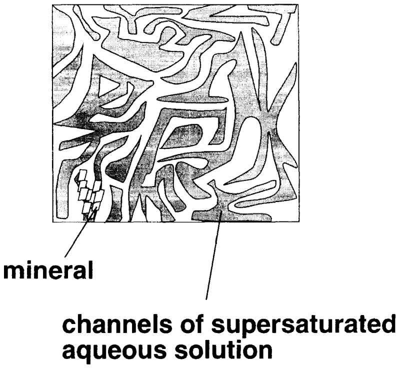

FIG. 10 Nanoparticle networks are formed in the supersaturated aqueous channels of a microemulsion.

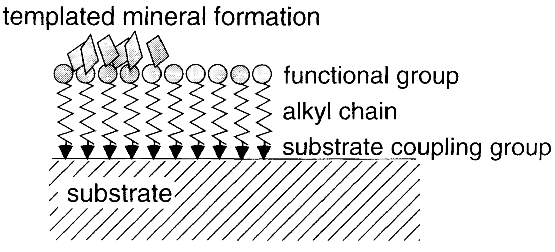
3.2 Specific Mineralization (Application to Thin Films)

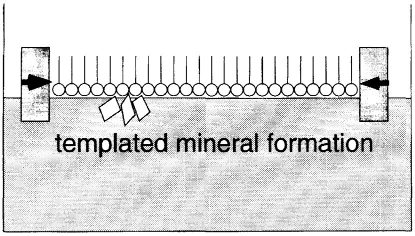
3.2.1 Self-assembled Monolayers The concept of a functionalized surface that will initiate specific crystallization [principle **2**] has been used to produce ceramic coatings through low-temperature processing routes. In some ways, these approaches are the most overtly biomimetic processing techniques yet studied.

Methods to create surfaces derivatized with specific functional groups that will initiate crystal nucleation and growth have embraced a variety of chemical approaches, including supramolecular templates and templates made from inorganic polymers, organic polymers, or biomolecules. The aqueous formation of dense polycrystalline films of FeOOH, Fe_2O_3, SnO_2, CdS, and $Al(OH)_3$ onto surfaces functionalized by self-assembled monolayers (SAMs) have been reported (Bunker *et al.*, 1994). The surfactant molecules within SAMs consist of three parts:

1. a silane coupling agent to the substrate;
2. the alkyl chain; and
3. a variety of functionalized end groups with variable chemistry, *i.e.*, $-COOH$, $-SO_3H$, $-H_2PO_4$, $-CH_3$, and $-NH_2$ (Fig. 11).



(a) Self Assembled Monolayer



(b) Langmuir Blodgett film

FIG. 11. Templated mineral formation on functionalized monolayers: (a) self-assembled monolayers (SAMs) or (b) Langmuir–Blodgett films.

The ordered structure and durability of siloxane-anchored organic SAMs are related to the monolayer-to-substrate bonding and to the van der Waals interactions among the linear alkyl chains of the SAM. The chemical attachment of the SAM is based on the siloxane network formed by the spontaneous, self-assembling reaction (Ulman, 1991) of the trichlorosilyl ($-SiCl_3$) group of the alkylsilane with the hydrated surface of the oxide on the substrate. The strong interactions with the substrate and the short-range van der Waals forces between the chains allow for the formation of a highly ordered and close-packed monolayer film. This attachment yields monolayers highly resistant to adverse conditions such as prolonged exposure to aggressive solvents. Significant advantages for oxide film formation are thus accrued. First, a functional group on the SAM surface can be chemically modified without disrupting the monolayer. Thus, a directly deposited SAM, bearing a chemical functionality that is suited for incorporation into the alkyltricholorosilane and desired for SAM deposition, can be chemically altered after the SAM is deposited. In the context of coating technology, such functionality may be desirable for its ability to participate in and/or induce the formation of an inorganic oxide layer, though it could not stably coexist with the trichlorosilane used for attachment to the substrate in the initial SAM formation. Second, SAMs can survive temperatures approaching 100 °C while exposed to solutions ranging in *p*H from strongly acidic to mildly basic, thereby providing a workable range of conditions for the formation of various oxides from aqueous or organometallic solutions. This technology has been applied to the formation of high-quality TiO_2 films with possible microelectronic applications (Collins *et al.*, 1996).

These biomimetic processes have significant advantages over vapor deposition techniques for the formation of oxide thin films. Vapor techniques primarily involve line-of-sight deposition, whereas the solution process can be applied to complex shapes and a wide variety of surfaces. With vapor techniques, the coverages and properties of the deposited films depend on the design of the reaction chamber and (typically) empirical determination of the optimum deposition conditions. Most importantly, achievement of the desired properties with vapor deposition routes generally requires heating the substrate (often to several hundreds of degrees Celsius), either during deposition or subsequently, to convert the usually amorphous as-deposited material into a well-ordered crystalline film. Finally, with vapor deposition, when a specific crystallographic orientation of the film is required, the choice of substrate is usually restricted to a single crystalline material whose surface interatomic spacing closely matches that of the desired crystalline film, enabling epitaxial growth. However, the use of organic substrates may accommodate some lattice mismatch because of their high compliance.

3.2.2 Biomimetic Lithography Traditional lithography methods can generate patterns of electronic circuits on substrates with dimensions of the order of 0.3 μm or less, and straightforward photolithography was used to form patterned films of TiO_2. Thioacetate (SCOOH)-terminated hexadecyl trichlorosilane SAMs were deposited onto Si(100) wafers, providing modestly hydrophobic films, which do not encourage oxide thin-film formation. The thioacetate functionality can be photolytically oxidized through a mask to an acidic sulfonate (SO_3H) moiety, rendering the exposed portions of the film hydrophilic. Upon immersion into an aqueous medium, even one that is strongly acidic, the sulfonate groups will deprotonate, becoming negatively charged, while the nonphotolyzed thioacetate-terminated regions remain unchanged. Thin films of nanocrystalline TiO_2 (anatase polymorph) form via heterocoagulation of homogeneously nucleated colloidal particles on the SO_3H-terminated regions of the film (Collins *et al.*, 1996).

A complementary technique has been used for patterned deposition of dielectric oxides (Pb, La)TiO_3 and $LiNbO_3$ (Jeon *et al.*, 1995). In this approach, a hydrophobic SAM acts as a resist layer to which sol–gel deposited oxides do not adhere. This approach relies on the removal of poorly adsorbed oxides from the SAM-coated regions by mechanical abrasion.

Electron- and ion-beam lithographic techniques can also be used to pattern SAMs with functional organic groups that either inhibit or promote mineral deposition (Fig. 12). Patterned films of iron oxyhydroxide several micrometers in width were deposited on areas patterned with nucleation sites (Rieke *et al.*, 1994). A hydrophobic SAM was first deposited over the entire substrate (again a silicon wafer). In the second step selected regions were etched with an ion or electron beam to define the pattern. These regions were backfilled with a second SAM terminated with end groups functionalized to promote mineralization, which commenced after immersion of the treated substrate in an aqueous solution.

A number of other biomimetic approaches to surface patterning have recently been developed that utilize self-assembly of organic molecules, such as protein or lipid systems (Douglas *et al.*, 1986), or the microcontact printing technique (Kumar *et al.*, 1994), to create specific patterns on the substrate surface. These systems are potentially capable of creating patterns on a nanometer scale.

3.2.3 Langmuir–Blodgett Films Surfactants or other amphiphilic molecules compressed to form monolayers on the surface of an aqueous liquid are known as Langmuir–Blodgett films [Fig. 11(b)]. These monolayers can be removed intact from the surface by dipping a substrate into the film, and they can also be stacked to form multilayers. Both the phase and orientation of mineral crystals that nucleate on these films can be controlled in a biomimetic manner, by appropriate choice of the Langmuir–Blodgett monolayer substrate and the solution concentration. For example, stearate ($C_{17}COO$) monolayers have a distance between the psuedohexagonal net of long-chain carboxylate molecules that matches the distances between the coplanar Ca ions on the $\{1\bar{1}0\}$ plane of calcite, which facilitates the oriented nucleation of crystals with this habit (Heywood *et al.*, 1991). Similar geometric correspondences are present for the (100) face of $BaSO_4$ crystals nucleated under long-chain alkyl sulfate or phosphonate monolayers (Heywood *et al.*, 1992).

Particulate films at the air–water interface have been formed by dispersing surfactant-stabilized nanoparticles on an aqueous subphase contained in a Langmuir trough (Meldrum and Fendler, 1996). The particles are prepared prior to their incorporation into the films, thus enabling their dimensions, physical properties, and particle size distribution to be precisely controlled. Films of CdS, TiO_2, Fe_3O_4, colloidal and micellar Ag, Pt, Pd, and $BaTiO_3$ have been formed by this method (Meldrum and Fendler, 1996).

3.3 Net Shape Formation with Layered Architecture

The layered architecture of biominerals such as bone and seashell has inspired new material designs for layered ceramics that exhibit increased fracture resistance over that of monolithic ceramics. Al-B_4C cermets were produced by stacking layers of B_4C tapes, which were then laminated using thermocompression, sintered and subsequently infiltrated with Al (Yasrebi *et al.*, 1990). These graded structures showed increasing strength and toughness with decreasing lamina width, with as much as a 40% improvement over that of monolithic materials. Graceful failure reminiscent of the conch shell fracture described earlier, due to a 400% increase in fracture toughness, has been observed in a synthetic composite material composed of SiC and graphite layers (Clegg, 1992). These are relatively crude imitations (100 times coarser) of the fine laminae in biological ceramics, and yet lead to a significantly improved fracture resistance.

While microstructural control is important, the most significant limitation of lamination techniques (as practiced to date) is in relation to the manufacture of complex shapes. Recent innovations have been made in fabricating components with well-defined complex geometries by methods that are reminiscent of the cellular deposition strategy of biological ceramics. These methods are generally referred to as solid free-form fabrication (SFF) and can in principle be used for rapid prototyping or for production of small quantities of engineering components. Complex three-dimensional parts are made through sequential deposition of layers of material that represent a two-dimensional slice of the three-dimensional object being formed. A specific cross section may be defined by cutting a layer of tape with a laser to a contour specified by a CAD (computer-aided design) representation, or by depositing a layer of binder onto a powder layer preferentially within the desired cross-sectional shape. The high cost of tooling, normally an obstacle to the implementation of design changes, or to material substitutions, can be overcome with these methods.

A number of approaches are now being pursued (Sachs *et al.*, 1990; Griffin *et al.*, 1994; Thissell and Marcus, 1994; Cawley *et al.*, 1996; 3D Systems in Valencia, CA, USA); we describe one here, the process known as CAM-LEM (for computer-aided manufacturing of laminated engineering materials). Fabrication begins with a combination of green ceramic tape and "fugitive" tape (Fig. 13) (Cawley *et al.*, 1996). As is common to all SFF technologies, each part originates from a computer description, which is analyzed and decomposed into boundary contours of thin slices. A laser is used to cut the two-dimensional shape into the green tape sheet stock. The resulting part-slice regions are extracted from the sheet stock and stacked to assemble a physical 3D realization of the original CAD description. Appropriately cut fugitive supports are placed, layer by layer, along with the cut tapes (Fig. 13). The green assembly is then laminated and is conventionally sintered. The use of laminated ceramic tapes is well suited to fabrication of high-density advanced structural ceramics, of functionally gradient materials, and of laminated composites. An impressive variety of Al_2O_3 components, many with complex internal channels, have been fabricated by this method (Cawley *et al.*, 1996).

There are very few synthetic processes that generate a shape or an architecture by microscopic remodeling of an existing ceramic structure. The primary limitation of synthetic additive or subtractive methods is the damage introduced by the chemical or mechanical removal techniques to the surface, which cannot be easily repaired by addition of new material. However, if the procedure could be done at the molecular level, it might be possible to effect new levels of control of microstructure.

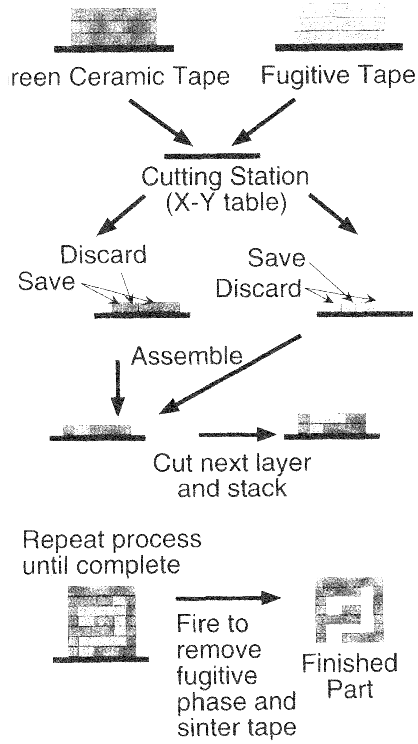

FIG. 13. A schematic representation of the principal steps involved in the CAM-LEM process for forming ceramics with a complex shape. To obtain complicated internal porosity, both green ceramic tape and a fugitive tape that supports overhanging elements are used. The tapes are separately cut, stacked, and then fired to sinter the laminae, remove the fugitive phase, and produce a finished product.

3.4 Living Systems Used for Materials Synthesis

More than 60 distinct minerals are known to be produced by living cells, many being produced by unicellular organisms (Lowenstam and Weiner, 1989). For example, magnetotactic bacteria such as *Aquaspirillum magnetotacticum*, discovered in 1979 (Blakemore *et al.*, 1979), produce magnetic minerals (Fe oxides and sulfides) that are believed to align anaerobic bacteria along the Earth's magnetic field, thereby directing the organism into the anaerobic zone. These bacteria might prove to be a source of particles that could be used directly in the production of Fe oxide magnetic coatings. The Fe oxide and CdS produced in such organisms are nonagglomerated 10–100-nm particles, a form that is difficult to prepare synthetically. Genetic manipulation of single-celled organisms is now widely practiced and presents an opportunity for the production of naturally occurring biopolymers in commercial amounts. The opportunity exists to use these organisms or their products in a biomimetic cell-mediated fabrication of synthetic ceramic/polymer composites.

4. CONCLUSIONS

Studies on biological ceramics have shown that many of the remarkable properties exhibited by natural materials arise from the complex microarchitectures that organisms can fabricate. Biomimetic approaches to ceramic processing seek to imitate the microarchitecture of biological materials, which are primarily layered or fibrillar. The production of biological ceramics involves an exquisite level of control of both the spatial regulation of the nucleation and growth of mineral and of the development of unique microarchitectures during formation. This is accomplished by organic "matrix" constituents secreted by cells. Conventional processing methods cannot replicate the fine-scale structure of biological ceramics, and thus several innovative methods have developed based on the three general biological processing principles that govern the composition, architecture, and methods of assembly of a variety of biological ceramics—the compartment principle, the specific mineralization principle, and the net shape by self-assembly of incremental units principle.

The research cited herein indicates that it is possible to extend the properties (most notably the fracture resistance) of synthetic materials by creating a fine-scale architecture within the material. While biomimetic material architectures improve toughness, it is usually at the cost of stiffness and strength. This may require a redesign of the macroscopic shape. Since Nature uses systems and not just materials in isolation, a concept focused on structures and not just materials is considered a further extension of biomimetics. The ultimate extension of biomimetics may involve the incorporation of genetically manipulated living cells modulating materials synthesis with tailored biomolecules and enzymatic reactions.

ACKNOWLEDGMENTS

The authors would like to thank the Department of Energy for financial support of the biomimetic processing work, the Electric Power Research Institute for supporting their ongoing research in this area, and the National Institutes of Health for financial support for L. Kuhn in the form of an NRSA training grant to the Department of Orthopaedic Surgery at Harvard Medical School administered by the Laboratory for the Study of Skeletal Disorders and Rehabilitation at Children's Hospital, Boston. The authors greatly appreciate the secretarial support provided by Carla Hines and Peggy Mayer.

INTRODUCTION

The past three decades have witnessed the rapid advance of solid-state electronics, from the replacement of hand-wired discrete elements to the integration of many circuit elements into a single semiconductor chip. Active devices such as semiconductors as well as resistive and capacitive elements have already been incorporated into modern integrated circuit (IC) technology. The only fundamental discrete circuit elements that have been left behind in the revolution are those involving magnetic materials.

In recent years, the field of micromagnetics and micromagnetic devices has attracted the attention of an increasing number of researchers. The objective of this field is to develop extremely small magnetic microdevices. Recent developments in microelectronic technology have revolutionized the fabrication techniques of magnetic devices and broadened the range of useful applications, such as in portable electronics and micromachines.

Micromagnetic devices use magnetic films, insulators, and planar coils. A planar inductor having a spiral coil sandwiched between Permalloy magnetic films was first fabricated by Saleh *et al.* (1970). Later, the importance of the IC inductor with magnetic films was pointed out by Soohoo (1979). In parallel with the development of computers, the bit-packing density of magnetic disk storage was steadily being increased following the proposal in 1977 of a thin-film head that combined a magnetic thin film and a planar coil. The thin-film head permits high-speed data transfer with good read/write performance, since it uses a magnetic film with a smaller magnetic circuit and better high-frequency characteristics than those of a bulk-type core. The use of lithography allows several heads to be produced on one substrate, resulting in the mass production of heads with high dimensional accuracy and stable characteristics.

In the latter half of the 1980s, active research on microinductors and microtransformers sought to resolve high-frequency application requirements for more compact switching power supplies for portable elec-

tronic devices that were proliferating then. Many reports were published on micromagnetic device materials, device structures, manufacturing processes, and characteristics, reflecting marked advances in the field of micromagnetics. A buck-converter switching power supply using a thin-film inductor was made by Mino *et al.* (1996). This power supply had an efficiency of 85%, which is sufficient for practical use. In the same year, a step-up switching power supply was made by Sato *et al.* (1996), using a thin-film inductor operating at 5 MHz.

In the 1990s, micromachine technology suddenly burgeoned, and ideas based on micromagnetic technology also came to the fore. Further research and development activities are expected in the promising field of micromachines in the future.

This article reviews the fundamental theory of micromagnetics and micromagnetic devices in terms of designs, fabrication techniques, and applications. No treatment of the basic physics of magnetic devices is attempted (see MAGNETIC DEVICES AND MAGNETIC MATERIALS).

1. GENERAL PRINCIPLES

1.1 Concept of Micromagnetics

Applied micromagnetics is a new concept aiming to develop more compact, more highly integrated magnetic devices in the same way that advanced microcircuit technologies led to the development of more compact, more highly integrated solid-state electronic devices. For example, the microinductor shown in Fig. 1(b) is a planar magnetic device formed using advanced magnetic thin-film technology. The microinductor differs from the three-dimensional, bulk-core type inductor shown in Fig. 1(a) in that it is nearly two-dimensional—its thickness being extremely small compared with its area.

1.1.1 Theory of Micromagnetics The field of micromagnetics developed along with high-frequency applications of magnetic devices. Magnetic properties and their relationship with high-frequency applications are particularly interesting subjects in this field. Other concerns include magnetic domain-wall displacement and magnetization rotation, which cause the reversal of magnetization in magnetic materials. Domain-wall displacement is the dominant factor in the low-frequency region, and the use of thin material is most effective for this. In the high-frequency region of several megahertz, high-speed displacement of the domain wall causes a large eddy-current loss, causing the characteristics in the direction of the wall movement to deteriorate. Thus, only the direction of magnetization rotation, in other words the hard axis of magnetic anisotropy, is utilized. Fortunately, comparatively large uniaxial anisotropy can be given to the thin-film material used for micromagnetic devices to decrease the loss, thanks to its magnetic anisotropy, magnetoelastic effect, and anisotropic shape. In the higher-frequency region, however, the eddy-current loss due to magnetization rotation will increase, causing deterioration of the magnetic properties. An effective countermeasure against this deterioration may be to increase the electrical resistance of the magnetic material. However, this cannot be the final solution because the loss due to magnetic resonance will increase in the higher-frequency region.

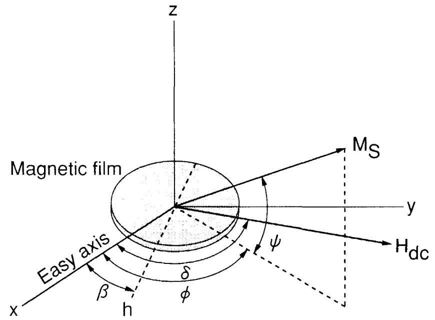

FIG. 2. Notation for Eqs. (1)–(8).

To gain a clear understanding of the frequency characteristics described above, let us consider permeability behaviors as previously reported (Shimada, 1993). The experiment on Ni–Zn ferrite known as Snoek's limit is famous for evaluating permeability behavior in the high-frequency region. This arises from the relationship between the above-mentioned natural resonance and magnetic anisotropy, and in a thin film, shape anisotropy is an additional major cause of magnetic anisotropy. The shape anisotropy works to hold magnetization within the thin-film surface, thus greatly increasing the resonant frequency.

The equation of motion of thin-film magnetization is expressed as below from the Landau–Lifshitz equation:

$$\frac{d^2\phi}{dt^2} + 4\pi\lambda\frac{d\phi}{dt} + \frac{\gamma^2}{\mu_0}\frac{\delta E}{\delta\phi} = 0, \tag{1}$$

where $\lambda = \alpha\gamma M_s/4\pi\mu_0$, α is the damping constant, γ is the gyromagnetic ratio, and μ_0 is the permeability of the vacuum.

Figure 2 shows the directions of external magnetic field H_{dc}, alternating current magnetic field h, and magnetization M_s with the x–y plane being the film surface. Energy E is expressed by the following equation when the easy axis of magnetic anisotropy is parallel to the x axis, as previously reported (Smith, 1958):

$$\begin{aligned} E = {} & K_u \sin^2\phi - M_s(H_{dc}\cos\delta + h\cos\beta) \\ & \times \cos\psi\cos\phi - M_s(H_{dc}\sin\delta + h\sin\beta) \\ & \times \cos\psi\sin\phi + (M_s{}^2/2\mu_0)\sin^2\psi, \end{aligned} \tag{2}$$

where K_u is the uniaxial anisotropy constant. The first three terms are obviously important in the static case, and the fourth term indicates the demagnetizing field energy produced by the thin-film shape; it acts to increase the resonance frequency.

The static energy E_0 is obtained from Eq. (2) with the magnetization directions stabilized by H_{dc} being ϕ_0 and ψ_0 when $h = 0$:

$$\begin{aligned} E_0 = {} & K_u \sin^2\phi - M_s H_{dc}\cos(\phi - \delta) \\ & + (M_s{}^2/2\mu_0)\sin^2\psi. \end{aligned} \tag{3}$$

The following equation is also obtained from Taylor's series of $\delta E/\delta\phi$ at (ϕ_0, ψ_0):

$$\frac{\delta E}{\delta\phi} = M_s h \sin(\phi_0 - \beta) + \left.\frac{\delta^2 E_0}{\delta\phi^2}\right|_{\phi_0,\psi_0} \Delta\phi \tag{4}$$

Equations (1), (3) and (4) give the equation of motion of thin-film magnetization:

$$\begin{aligned} & \frac{d^2(\Delta\phi)}{dt^2} + 4\pi\lambda\frac{d(\Delta\phi)}{dt} + \left.\frac{\gamma^2}{\mu_0}\frac{\delta^2 E}{\delta\phi^2}\right|_{\phi_0,\psi_0} \Delta\phi \\ & = -(\gamma^2/\mu_0) M_s h \sin(\phi_0 - \beta). \end{aligned} \tag{5}$$

The following equation is obtained from Eq. (5) with a small alternating current magnetic field $h = h_m \exp(j\omega t)$ and $\Delta\phi = \phi_m \exp(j\omega t)$:

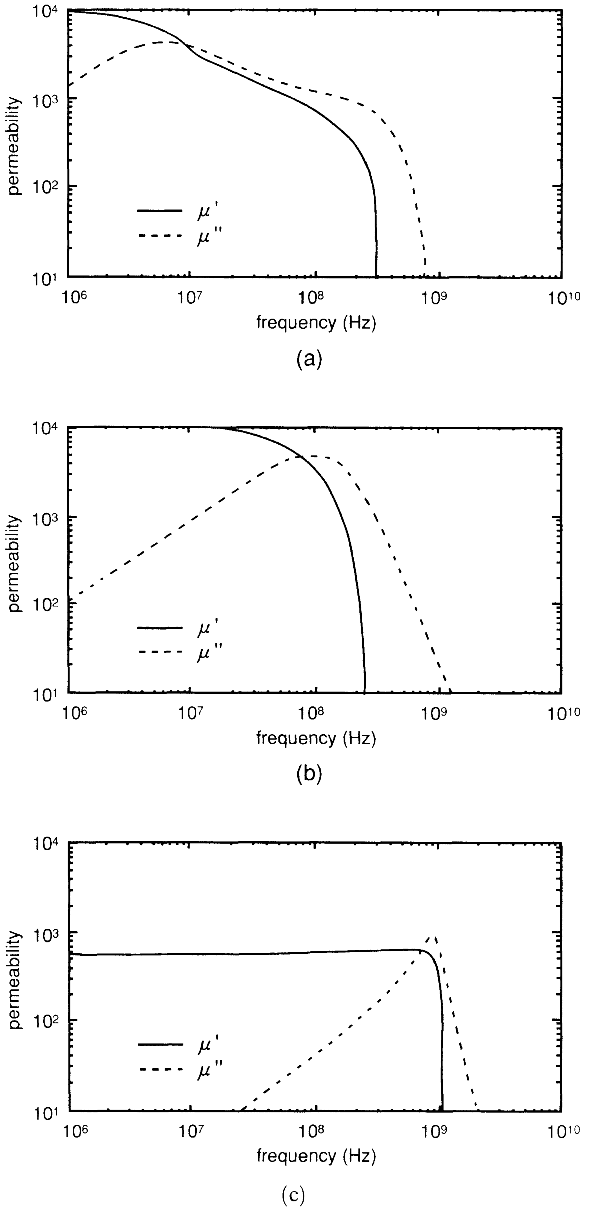
$$\begin{aligned} \phi_m = {} & -(\gamma^2/\mu_0)[M_s h_m \sin(\phi_0 - \beta)] \\ & \times \frac{(\omega_0{}^2 - \omega^2) - j4\pi\lambda\omega}{(\omega_0{}^2 - \omega^2)^2 + (4\pi\lambda\omega)^2}, \end{aligned} \tag{6}$$

where ω_0 is the resonant frequency.

The permeability μ_i is obtained by dividing ΔB, the change in magnetic flux density in the direction of h, by h:

$$\begin{aligned} & \mu_i = \Delta B/\mu_0 h = \mu_i{}' + j\mu_i{}'', \\ & \mu_i{}' = \frac{\gamma^2}{\mu_0^2}\frac{M_s{}^2\sin^2(\phi_0 - \beta)(\omega_0{}^2 - \omega^2)}{(\omega_0{}^2 - \omega^2)^2 + (4\pi\lambda\omega)^2}, \\ & \mu_i{}'' = \frac{\gamma^2}{\mu_0{}^2}\frac{4\pi\lambda\omega M_s{}^2\sin^2(\phi_0 - \beta)}{(\omega_0{}^2 - \omega^2)^2 + (4\pi\lambda\omega)^2}. \end{aligned} \tag{7}$$

If h is parallel to the hard axis for $H_{dc} = 0$, then $\omega_0 = \gamma(H_k M_s/\mu_0)^{1/2}$ for $\beta = \pi/2$, and so



(a)

(b)

(c)

FIG. 3. Permeabilities of magnetic films: (a) $\rho = 120\,\mu\Omega\,\mathrm{cm}, H_k = 80\,\mathrm{A\,m^{-1}}$; (b) $\rho = 3000\,\mu\Omega\,\mathrm{cm}$, $H_k = 80\,\mathrm{A\,m^{-1}}$; (c) $\rho = 3000\,\mu\Omega\,\mathrm{cm}, H_k = 1280\,\mathrm{A\,m^{-1}}$.

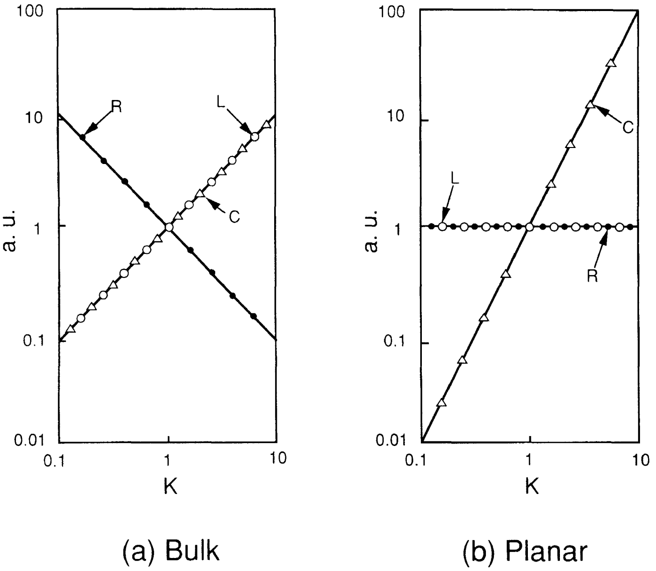
the natural resonance frequency of the magnetic thin film depends not only on the anisotropy field H_k but also on saturation magnetization M_s.

For a metallic magnetic thin film with high conductivity, the eddy-current loss is added to the above characteristics. When the permeability is determined by magnetization rotation, the equation of the eddy-current loss is obtained from Maxwell's formula, and the permeability is expressed by

$$\mu_e = \mu_i \tanh(pd/2)/(pd/2),$$
$$p = (j\omega\mu_i/\rho)^{1/2}, \qquad (8)$$

where d is the film thickness and ρ is the film resistivity.

Figure 3 shows the results from Eq. (7), assuming the film thickness $d = 5\,\mu\mathrm{m}$, saturation magnetization $M_s = 10^4\,\mathrm{G}$, anisotropy field $H_k = 80$ or $1280\,\mathrm{A\,m^{-1}}$, and resistivity $\rho = 120$ or $3000\,\mu\Omega\,\mathrm{cm}$, as reported by Shimada



(a) Bulk

(b) Planar

FIG. 4. The inductances, capacitances, and resistances depend on the size reduction factor *K*: (a) bulk device and (b) planar device.

(1993). Figure 3(a) shows the case of a high-permeability magnetic thin film, such as amorphous metal. The decrease in μ' due to the eddy current and natural resonance is clearly seen. Figure 3(b) is the case with increased resistivity, where the loss in the high-frequency region is reduced. Figure 3(c) shows the case where the anisotropy field is also increased with the result that resonance loss is markedly reduced, although permeability is decreased.

As discussed above, it is necessary to control the uniaxial anisotropy precisely, while increasing the resistivity of the magnetic thin film.

1.1.2 Advantages of Micromagnetic Devices

Micromagnetic devices are formed two-dimensionally using magnetic thin film. This feature allows the device to be integrated with solid-state electronic devices such as large-scale integrated circuits (LSIs). This implementation is promising for a variety of applications of such micromagnetic devices. Let us now consider the features of the micromagnetic device, by comparing the characteristics of two- and three-dimensional magnetic devices, taking the inductor as an example.

Let us change the size of the inductor, keeping the number of coil windings constant. Multiply the length, width, and height (l, w, t) of the bulk inductor by *K*, and multiply the length and width (l, w) of the planar inductor by *K*, while keeping its height t' constant because it is a thin-film structure. Then, the inductance, resistance and capacitance of the bulk-type inductor are expressed by

$$L_b \propto wtK^2/lK \propto K$$

$$R_b \propto lK/wtK^2 \propto 1/K$$

$$C_b \propto wlK^2/tK \propto K,$$

while those of the planar inductor are expressed by

$$L_p \propto wt'K/lK = \text{constant}$$

$$R_p \propto lK/wt'K = \text{constant}$$

$$C_p \propto wlK^2/t' \propto K^2.$$

Figure 4 shows their behavior as reported by Shirae *et al.* (1992). As the size of the bulk-type inductor becomes larger, its inductance increases and its resistance decreases, improving its characteristics as a magnetic device. When the size of the planar inductor is reduced, its inductance and resistance remain constant, and its capacitance decreases as K^2. The fact that the inductance of the planar inductor remains constant at a certain value as its size is reduced indicates that a compact planar inductor can be made using a thin-film structure. The fact that the capacitance of the planar inductor decreases indicates that it is suitable for use at high frequencies. These characteristics or features are common to both the planar inductor and the micromagnetic device formed with a magnetic thin film.

1.2 Materials for Micromagnetic Devices

The minimum requirements for a micromagnetic device material are that its loss should be low in the high-frequency region and that it can be made small. Thus, a thin film is the ideal magnetic material.

An amorphous metal film (see AMORPHOUS MATERIALS) is a magnetic material that can be processed into a thin film. Co-based amorphous metal, produced through sputtering deposition, is widely used for micromagnetic devices. This type of material first attracted attention as a magnetic head material because its magnetostriction is nearly zero and its saturation magnetization is large. Highly practical, soft magnetic thin films are now obtained as a result of the success in independently controlling the characteristics of magnetostriction, saturation magnetization, and crystallization temperature through the production of ternary amorphous films such as CoZrTa, CoMnNb and CoFeNb.

Films having multilayer structures have been studied in order to improve their high-frequency characteristics. A soft magnetic film demonstrating high permeability in the high-frequency region is desired to have the magnetic domain structure illustrated in Fig. 5(a). However, the actual soft magnetic single layer takes a thermodynamically stable form as shown in Fig. 5(b). The 180° opposite domains and closing magnetic domains are produced in the specimen to close the magnetic path to decrease magnetostatic energy, thereby preventing a free magnetic pole from being produced at each end of the specimen. The closure magnetic domain decreases the permeability of the magnetic film at high frequencies. Magnetic domains are controlled by using ceramics and thin nonmagnetic films to obtain multilayered soft magnetic thin films as shown in Fig. 5(c). Magnetization is closed between magnetic layers to suppress the generation of free magnetic poles or closure magnetic domains, since magnetostatic coupling occurs at the edges of magnetic layers that are separated by thin nonmagnetic films or ceramics. Thus, the domain geometry will have only 180° domains, resulting in high permeability. For example, with CoBN film, which has a high coercive force, the single layer shows the property of having coercive force in the perpendicular direction, while the multilayer film having in-plane magnetic films shows markedly decreased coercive force, as seen in Fig. 6 (Shirae *et al.*, 1992).

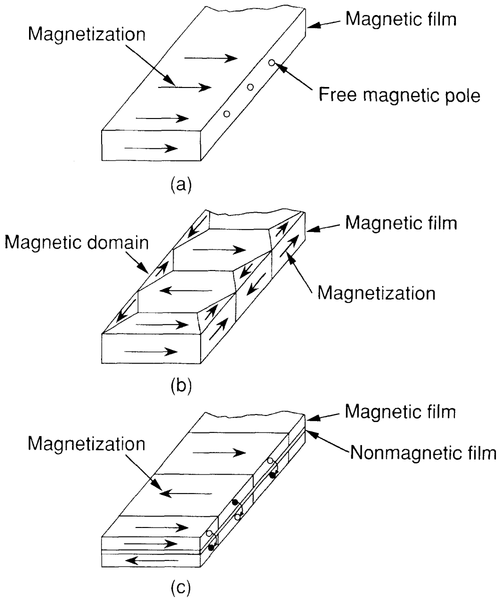


FIG. 5. Schematic diagrams of the magnetic domains in magnetic heads.

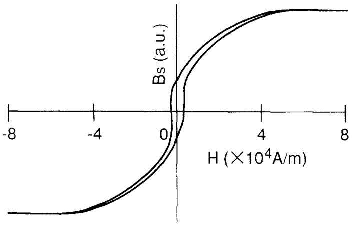
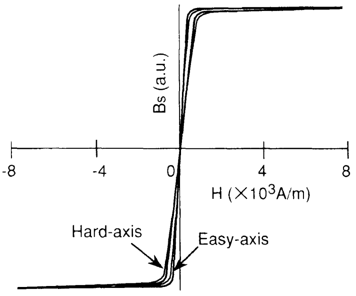
A multilayer film can improve the frequency characteristics. The eddy-current loss is proportional to the square of the frequency and the film thickness, and inversely proportional to the resistivity of the magnetic film. Thus, the thinner the film, the lower the loss, resulting in improved frequency characteristics.

1.3 Design of Micromagnetic Devices

Although micromagnetic devices employ many different types of structure, the most basic types are the meander and the spiral. A schematic diagram of the meander-type inductor is shown in Fig. 7. It is composed of a folded meandering conductor pattern and magnetic thin films sandwiching the pattern. The self-inductance of the meander-type in-



(a) Co·BN film



(b) Co·BN/BN multilayers (12nm/3nm) × 200

FIG. 6. *B–H* curves of CoBN single-film and multilayers.

ductor is generally expressed by the following equation, provided that there are $2N$ conductors of length b (Kawabe *et al.*, 1984):

$$L_l = \frac{\mu_0 ab}{2(2N-1)g/N + a^2/(2N-1)N\mu' t_m}, \tag{9}$$

where μ_0 is permeability of the vacuum, N is the number of turns of a pair of conductors, g is the gap between the upper and lower magnetic films, μ' is the relative permeability, and t_m is the magnetic film thickness. The following equation expresses the inductance when the inductance of the folded sections is taken into account:

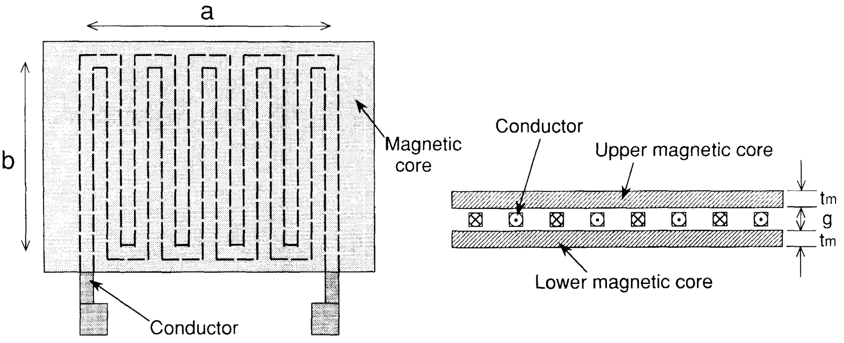
$$L = L_l(1 + a/2Nb). \tag{10}$$

This reveals that the self-inductance decreases as the pattern width a is reduced while the number of turns is kept constant. Making the inductor more compact markedly decreases its inductance.

Let us now consider the spiral-type inductor. A model of an elliptic spiral-type inductor was shown in Fig. 1(b). In this form a spiral thin-film conductor pattern is sandwiched by the upper and lower magnetic thin films. The following equation expresses the inductance of the elliptical spiral-type inductor if its air core without a magnetic film is ignored (Soohoo, 1979):

$$L = \mu_0 \mu' t_m w_m N^2 / l_m, \tag{11}$$

where w_m is the magnetic film width and l_m is the magnetic path. This reveals that the self-inductance increases as l_m is reduced while the number of turns is kept constant. More specifically, the structure of the elliptical spiral-type inductor is effective for micromagnetic devices because its inductance increases as it is made more compact.



(a) (b)

FIG. 7. Meander-type inductor geometry, in which a planar conductor is sandwiched between magnetic thin film cores.

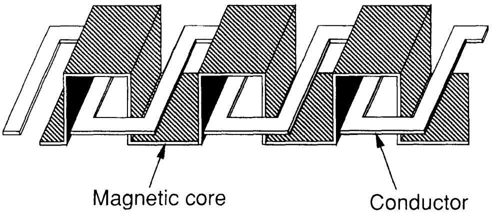


FIG. 8. Toroidal-meander–type inductor geometry, in which a magnetic core is wrapped around a planar conductor.

Structures other than the meander and spiral types include the toroidal-meander (Ahn *et al.*, 1994), cloth (Shirakawa *et al.*, 1990), and outer-conductor (Mino *et al.*, 1992) types. The toroidal-meander type inductor (Fig. 8) is formed by a meandering conductor pattern enfolded with two layers of magnetic film. This structure can reduce the leakage flux without increasing the conductor pattern resistance. The cloth-type inductor (Fig. 9) is structured so that magnetic thin-film strips are sandwiched by two layers of conductor pattern. This structure allows one to form an inductor with less leakage flux in a similar manner to the toroidal-meander type. Both the toroidal-meander and cloth-type inductors only have a low inductance of a few microhenries because they are based on the meander method.

The outer-conductor type transformer (Fig. 10) is structured so that the magnetic thin film is wrapped by the upper and lower conductor patterns via an isolation layer. The primary and secondary coils are formed in parallel and through-holes connect the upper and lower conductor patterns. This type keeps the leakage flux comparatively low, but has the disadvantage of increased conductor pattern resistance due to the contact resistance in the through-holes.

Micromagnetic devices, like LSIs, are usually produced by photolithography. Figure 11 shows the photolithography process. Thin films of magnetic, conductive, and isolation materials are deposited on a substrate through processes such as sputtering deposition and vacuum evaporation, then photoresist is applied to the top film layer. The photoresist surface is exposed to light through a mask pattern made of, for example, a glass plate, and is then developed to produce a photoresist pattern on the top thin film. Etching the thin film, using the photoresist pattern as a protective film, forms the desired thin film pattern on the substrate. Repeating the above photolithography process produces a micromagnetic device composed of thin films over the substrate.

Micromagnetic devices must be made flat because they often handle power and use films thicker than those of the LSI. Figure 12 illustrates an example of the planarization etch-back process. A planar isolation layer is deposited over the conductor pattern formed on the substrate by applying photoresist to the isolation layer through, for example, spin coating, to produce a planar surface. Then the surface is etched back evenly using an etching process with a low etching ratio.

2. TYPES OF MICROMAGNETIC DEVICE

2.1 Planar Inductors and Planar Transformers

2.1.1 Meander Coil Many researchers have studied and experimented on the mean-

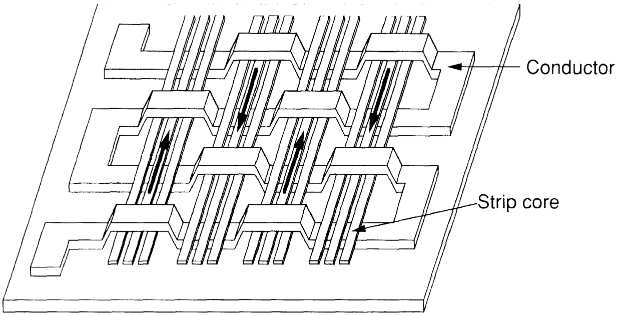

FIG. 9. Cloth-type inductor geometry with a magnetic strip core array.

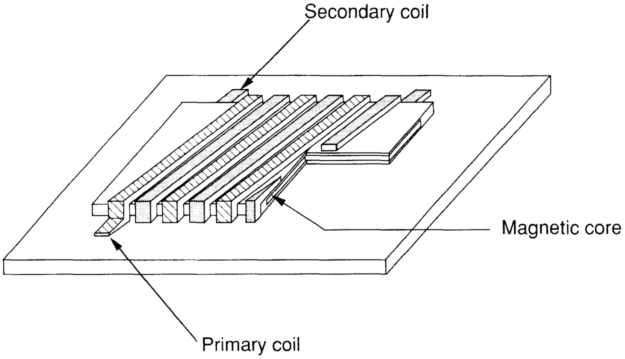

FIG. 10. Outer-conductor-type transformer geometry, in which a thin magnetic film core is wrapped around planar conductors.

der coil because it has a simple structure and is relatively easy to fabricate. Figure 13 shows the results of an experiment conducted by the present authors, as an example of the magnetic properties of the planar inductor using a meander coil. This coil used a copper pattern deposited by sputtering. Amorphous CoZrRe layers deposited by sputtering were used as the two magnetic layers to sandwich the coil. The coil had eight turns with a pattern width of 100 μm and a pattern separation of 50 μm. In addition, the half-turn length of the coil was 3.5 mm and the coil copper film thickness was 5 μm. The magnetic film was 5 μm thick.

The inductance of the meander-type inductor remained constant, up to approximately 10 MHz, and then decreased in the higher-frequency region. The equivalent resistance of the inductor also remained constant, up to approximately 10 MHz, and then increased in the higher-frequency region. The inductance on a chip a few millimeters square was as low as 20–30 nH. Inductance increased in proportion to the number of turns or the half-turn length of the coil. It is, however, extremely difficult with the presently available magnetic material to obtain an inductance of a few microhenries, which is appropriate for a switching power supply with an output as low as 1 W.

2.1.2 Spiral Coil Although its fabrication process is somewhat complex, a micromagnetic device using a spiral coil provides a relatively large value of inductance. The photograph in Fig. 14(a) shows an example of the spiral-type inductor, the top view of the planar inductor manufactured by the present authors.

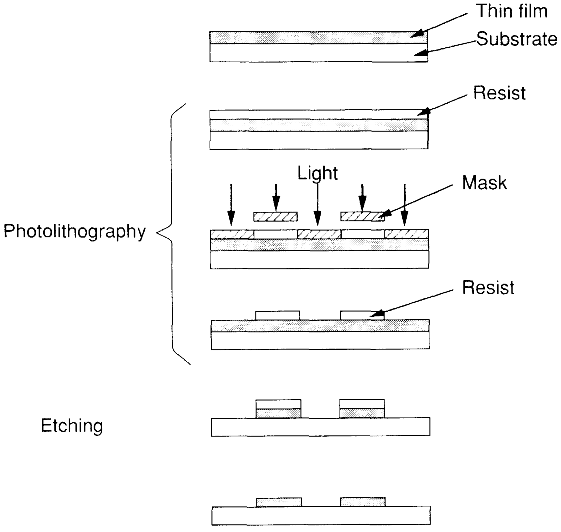

FIG. 11. Fabrication sequence of micromagnetic devices.

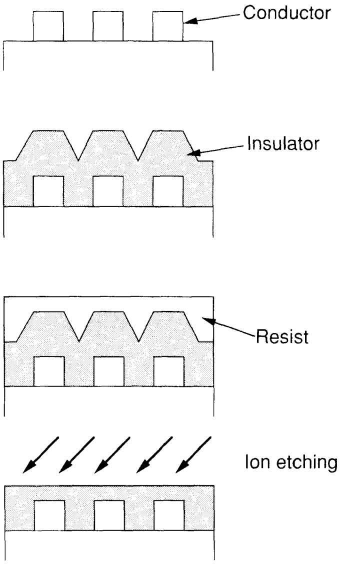

FIG. 12. Planarization process using the dry-etching technique.

Its coil, made of thin copper films, has six turns, and is 100 µm wide. Its magnetic film, made of CoZrTa amorphous film, is a total of 4 mm wide from both sides, and the magnetic path is 3 mm long. Compared with a circular spiral coil, it is easier to provide an elliptical spiral coil with uniaxial anisotropy. Figure 14(b) is a photograph showing the cross-section of the planar inductor. On a silicon wafer a thermal oxidization film was used for the substrate, on which the lower magnetic film was deposited, over which two layers of coil patterns were formed, which was then covered with the upper magnetic film. Polyimide was used for the intermediate insulation film. A multilayer magnetic film structure was used, using SiO_2 films for intermediate insulation films to decrease the eddy-current loss. The coil film was 15 µm thick and the coil separation was 20 µm. A smooth shape with little height variation was obtained, even though relatively thick multilayer films of about 120 µm were deposited on the substrate. A planar transformer was obtained by using the upper and lower coil patterns of the above planar inductor for its primary and secondary coils.

Figure 15 shows the magnetic properties of a spiral-coil type inductor as previously reported (Mino *et al.*, 1996). Similar to that of the meander-type inductor, the inductance of the spiral-coil type planar inductor remains constant, up to 10 MHz, and then decreases in the higher-frequency region. Its equivalent resistance, on the other hand, remains constant up to several hundred kilohertz, and then increases in the higher-frequency region. Thus inductance of a few microhenries, applicable to a converter with an output of approximately 1 W, is obtained with a chip only a few millimeters square. Inductance increases in proportion to the number of turns, but the equivalent resistance increases. The *Q* value has a its maximum of 4.5 at around 1 MHz.

To improve the high-frequency characteristics of the planar inductor, an anisotropy

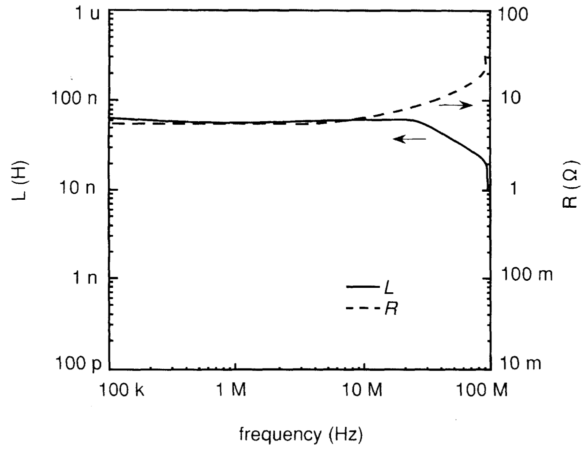

FIG. 13. Characteristics of a meander-type inductor: equivalent inductance and equivalent resistance versus frequency.

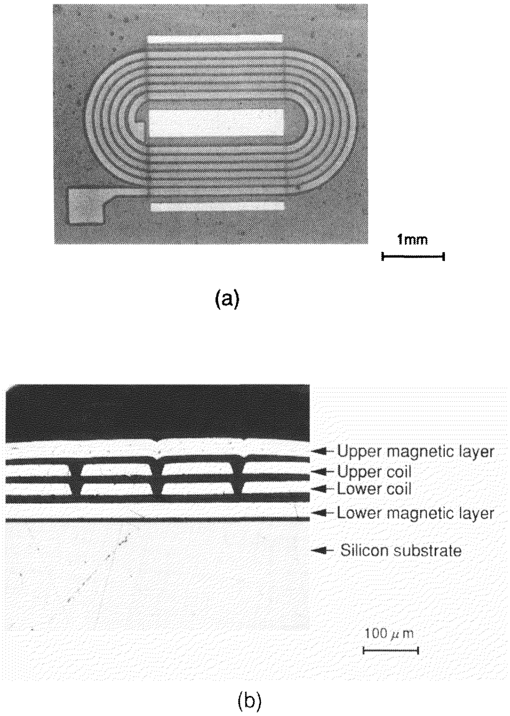

FIG. 14. Spiral-type inductor: (a) top view and (b) cross-sectional photograph.

field is generally induced into the magnetic thin-film deposition. This gives a hard-axis characteristic, providing inductance with a flat characteristic up to approximately 100 MHz. This, however, causes a problem in that the absolute inductance value is lowered by the decreased relative permeability. Because of this, the anisotropy field of the actual planar inductor is adjusted according to the conversion frequency of the switching power supply. Fox example, the desired properties are obtained with an amorphous CoZrTa magnetic thin film by annealing at around 200 °C in a magnetic field.

2.2 Thin-Film Magnetic Heads

This article reviews only thin-film magnetic heads because magnetic recording heads are described elsewhere (see MAGNETIC DEVICES). Figure 16 shows a schematic cross-sectional view of a thin-film head. The thin-film head is composed of spiral coils deposited in an insulator in the middle of the head, and upper and lower magnetic thin films surrounding the coils and the insulator. A read/write gap of 0.2 μm is provided in part of the magnetic film. The entire thin-film head is approximately 20 μm thick, and its gap is approximately 10 μm wide.

Basically, there are two ways of fabricating a thin-film head: the wet method using electroplating and the dry method using ion milling. Both methods are fundamentally the same as the thin-film inductor manufacturing method. The dry-etching method for manufacturing a thin-film head is outlined below. An SiO_2 film is deposited on an Al_2O_3–TiC substrate, and a lower magnetic thin-film pattern is deposited by sputtering. The coil patterns are produced by sputtering a copper film onto an isolation layer. An isolation layer is deposited over the coil patterns for planarization, and a through-hole is placed for contact between the upper and lower magnetic films. Then, an SiO_2 film is deposited in the gap section to form the gap, and the upper magnetic film is deposited. Finally, a protective film is deposited, terminals are opened, and cutting, grinding, and slider processing are carried out.

Today, recording (write) heads exclusively use the inductive-type thin-film head. This is because increases in the speed of magnetic disk drives need to take into account that reproduction (read) output is proportional to the relative speed between the head and the disk. High-sensitivity heads utilizing the magnetoresistance effect (MR) or the giant magnetoresistance effect (GMR) are used for reproduction (read) heads.

2.3 Microactuators and Microstators

The field of micromachines has been actively studied along with the advancement of technology for processing silicon semiconductor devices. Of the various reported ideas concerning micromachines, many use electrostatic force as their driving force, but some use electromagnetic force instead.

Figure 17 shows, as an example of a microactuator using electromagnetic force, a microvalve made of soft magnetic material whose thin film spring moves vertically with an external coil (Yanagisawa *et al.*, 1994). Figure 18 shows the microvalve manufacturing method using photolithography, and film de-

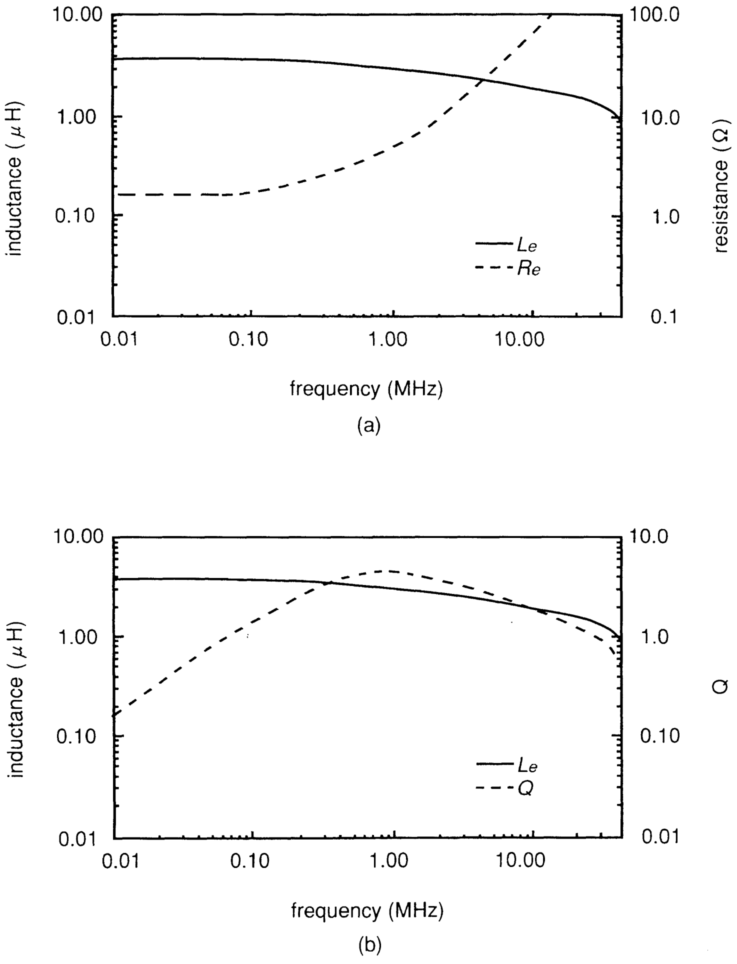

FIG. 15. Characteristics of a spiral-type inductor: (a) equivalent inductance and equivalent resistance versus frequency and (b) equivalent inductance and *Q* versus frequency.

position and patterning by ion beams. An SiO_2 film is deposited on the back of a silicon wafer, and a valve plate of Permalloy film is formed on the front of the silicon wafer. A sacrificial SiO_2 film is deposited on the valve plate, over which is produced a valve cap of Permalloy. Then, the SiO_2 film on the rear side of the substrate is windowed and the silicon is etched anisotropically. Finally, the sacrificial film and the SiO_2 film on the rear side of the substrate are removed, completing the manufacturing process.

Since the microactuator employs an angular-spiral spring structure, the stress is released perpendicular to the spring motion. This ensures precise positioning between the valve plate and the valve cap. The angular-spiral valve cap measures $300 \times 300\,\mu m^2$, the beam width is $20\,\mu m$, and the film thickness is $2\,\mu m$. The valve-plate hole in the center of the valve plate is $30\,\mu m$ in diameter.

Another example of a micromachine using electromagnetic force is the microstator. A larger torque can be obtained with electromagnetic force than with electrostatic force. It is more advantageous to use electromagnetic force for a device a few millimeters in size. Figure 19 shows a schematic diagram of a microstator employed for a microgenerator (Ota *et al.*, 1995). The cylindrical stator is 1 mm in

diameter and 0.5 mm high. The microstator is composed of a core die made of Permalloy and six coils manufactured by photolithography and plating that are inserted in the core die. Each coil consists of 20 turns of a copper pattern whose cross-section measures $7 \times 15\,\mu\mathrm{m}^2$. It is reported that a microgenerator 1.2 mm in diameter has been manufactured using the above microstator, and that a voltage of a few millivolts was obtained.

3. APPLICATIONS OF MICROMAGNETIC DEVICES

Interest has been growing in the field of micromagnetics and micromagnetic device applications. Some of the more novel aspects of micromagnetic technology are presented below to illustrate further this diversity.

3.1 Switching Power Supplies

Explosive growth has been seen in the field of portable electronics such as cellular telephones, radio pagers and notebook computers. These devices need more compact and highly efficient switching converters. Micromagnetic components based on thin-film magnetic materials, constructed with microfabrication

techniques, show great promise for compact and efficient high-frequency power conversion circuits.

An example of a microswitching converter using a spiral type microinductor is shown in Fig. 20 as previously reported (Mino *et al.*, 1996). It is a one-watt class, compact buck-converter, whose circuit topology is shown in Fig. 21. The circuitry that is shaded and enclosed by the dashed lines is a microinductor. The control circuit, which regulates the output voltage using square-wave pulse-width modulation, is fabricated by BiCMOS 1-μm process technology. This technology keeps the power consumption at 10 mW; it can operate up to 2 MHz. To enable high-frequency operation, a low-capacitance MOSFET switch, a Schottky-barrier rectifier diode, and multilayer ceramic capacitors are used. The semiconductor devices are mounted on one side of a four-layer printed ceramic board with printed resistors, while the microinductor and input and output capacitors are mounted on the other side. These design conditions result in high-frequency operation, making it possible to achieve low power dissipation with an extremely small volume of 0.2 cm^3.

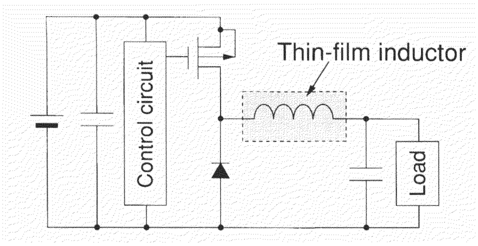

FIG. 21. Circuit diagram of a buck-converter.

The voltage wave forms for the microswitching converter are shown in Fig. 22, where V_{in} is the input voltage, V_{G} is the gate voltage of the MOSFET, V_{D} is the voltage across the diode, V_{out} is the output voltage, and V_{ac} is the output ripple voltage. Switching

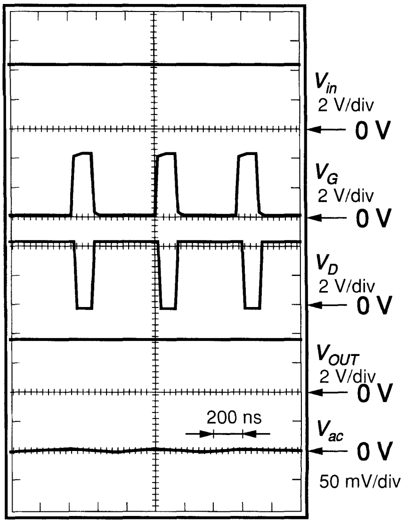

FIG. 22. Wave forms of the microconverter.

frequency is 1.6 MHz, V_{in} is 4.4 V, V_{out} is 3.3 V, output current I_{out} is 0.12 A, and output power is 0.4 W. The wave form of the output ripple voltage is very small. The maximum overall efficiency reached 85%.

Another microconverter using a spiral-type transformer has also been reported (Sullivan *et al.*, 1996). It achieved a power-handling density of 22.4 W cm^{-3} at 61% efficiency. The circuit topology was a simple half-bridge forward converter. These microconverters using micromagnetic devices are expected to meet the demands of both today's and tomorrow's portable-equipment market.

3.2 Magnetic Disk Storage

Because magnetic disk-drive technology is a key technology supporting today's computer age, efforts have been increasing the bit-packing density of drives, boosting recording density by a factor of more than 10^4 during the past 30 years. The thin-film head, the essential component of the magnetic disk drive, contributed greatly to the development of drives in the 1980s. Figure 23 shows an arm with a thin-film head. The thin-film head is mounted on a slider at the tip of the arm.

The combined magnetic head, which has a recording (write) head with a coil and MR or GMR heads for reproduction (read), was brought into use in the early 1990s as described in Sec. 2 (see Fig. 24). A recording density of 0.5 Gbit cm^{-2} was attained with a track width of 1.5 μm. This translates into a capacity of 5–50 Gbytes for a 3.5-in. hard disk drive.

The GMR head is considered to be more promising than the thin-film head as the magnetic head of the future. However, micromagnetic technology using the planar coil remains the key technology for the GMR head.

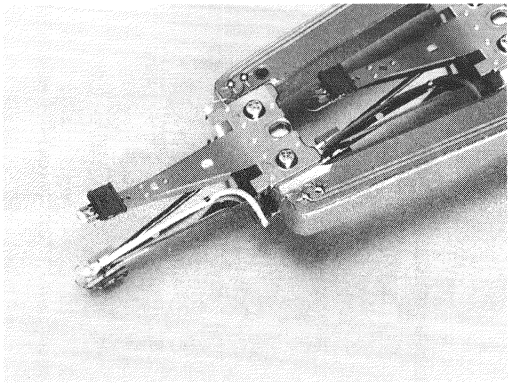

FIG. 23. Magnetic heads.

3.3 Micromachines

The study of micromachines has become suddenly active since the early 1990s, but micromachines have not yet been put to practical use. Although many reports on micromachines concern the use of electrostatic force, some reports involve micromagnetic technology.

Figure 25 shows the basic configuration of a microvalve utilizing an external coil, described in Sec. 2. The thin-film spring, made of soft magnetic material, is moved vertically by the external coil to control the flow of fluids. Figure 26 illustrates an example of fluid flow control by the microvalve shown in Fig. 25. Air was used as the motive gas. The valve was operated at driving frequencies of 0.1–100 Hz, and changes in the pressure were observed. A good flow response characteristic was obtained.

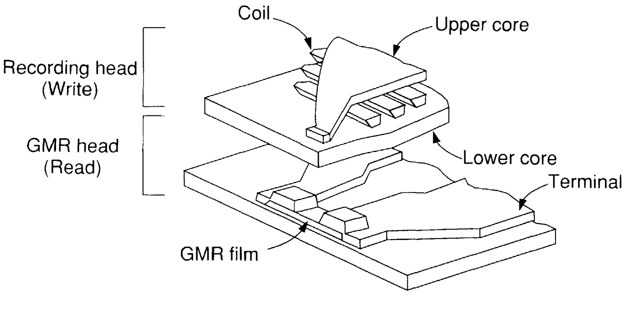

FIG. 24. Schematic diagram of giant magnetoresistive head.

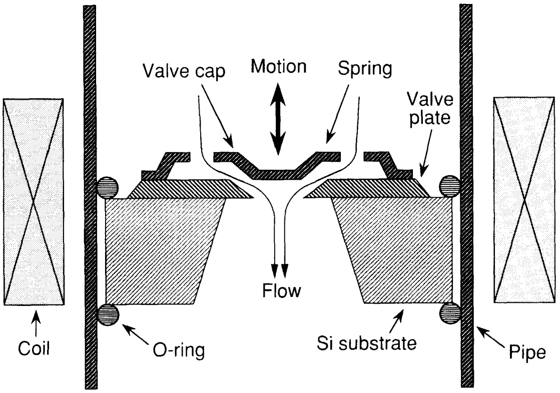

FIG. 25. Schematic cross-sectional view of the magnetic microvalve.

Further developments in the field of micromachines are expected as we enter the 21st century. The authors hope that great efforts in micromagnetic technology research and development will be made in the future.

ACKNOWLEDGMENTS

The authors wish to acknowledge the help afforded by Dr. H. Kuwano and Mr. K. Yanagisawa through frequent discussions.

GLOSSARY

Amorphous Metal: A glass-like metallic alloy with a random atomic arrangement. Excellent corrosion resistance, strength, and magnetic properties because of random atomic arrangement, which is different from an alloy consisting of fine crystals. Used for devices such as high-performance magnetic heads and low-loss transformers.

Eddy-Current Loss: Energy loss caused by an eddy current flowing through a metallic material.

Inductive Head: A head that uses the principle of electromagnetic induction to write to and read from a magnetic disk.

Magnetic Anisotropy: The phenomenon in which a thermodynamic quantity of a magnetic crystal varies with the direction of magnetization against the crystal axis. Often referred to as the phenomenon in which the internal energy varies with the spontaneous magnetization inside a ferromagnetic crystal.

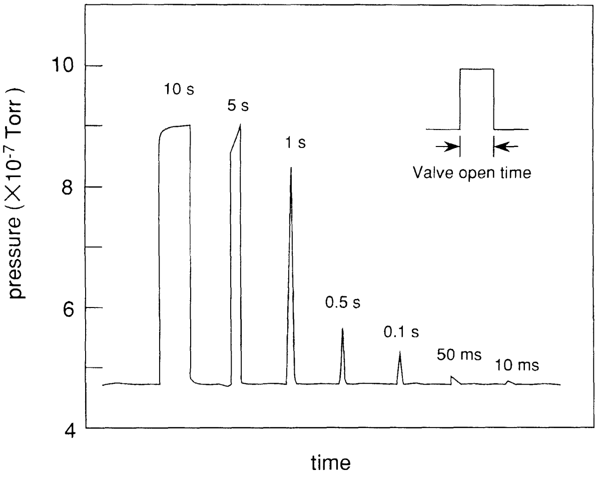

FIG. 26. Example of fluid flow characteristics using the magnetic microvalve. (1 Torr = 133.322 Pa.)

Magnetic Thin Film: Magnetic alloy deposited from 100 to 1000 nm thick over a substrate by vacuum evaporation or electrodeposition. If the deposition process is performed in a magnetic field, inductive magnetic anisotropy will be produced, and the magnetization will take place in the positive or negative direction along the easy axis.

MR (Magnetoresistive) Head: A read-only head utilizing the anisotropic magnetization effect.

Sputtering Deposition: A method of depositing a film over a substrate by sputtering atoms from a target material with ions of argon or other gas discharged in a vacuum.

INTRODUCTION

Nitrogen is one of the most familiar elements known to man. In its gaseous molecular form, N_2, it comprises some 80% of the Earth's atmosphere; moreover, it is essential to life, and provides an important area of study in disciplines such as agriculture, biology and food technology. Here, the nitrogen is normally present in the form of groups such as ammonium (NH_4), nitrate (NO_3), and amide (NH_2). The term *nitrides* is reserved for those compounds in which nitrogen is acting as a nonmetal in its own right, not as a group in combination with either oxygen or hydrogen, and in that capacity exercises its conventional valence of three (very occasionally five). Nitrogen does not occur naturally in the form of nitrides because most nitrides react very rapidly with water even at room temperature, with evolution of ammonia. For this reason, they must be prepared synthetically, under controlled conditions of water vapor, oxygen, and other oxygen-containing species, and need to be kept under similarly controlled conditions if subsequent hydrolysis is to be avoided. Many of the uses of nitrides rely on the presence of a thin passivating layer of surface oxide to prevent attack by atmospheric moisture.

The difficulties associated with the preparation and handling of nitrides are an important reason why, despite the abundance and familiarity of nitrogen, the detailed study of nitrides has developed relatively recently, in response to the general progress of science and technology in requiring materials with specific combinations of properties that only nitrides can provide. Table 1 summarizes the main properties of nitrides that have caused them to find application in the last 50 years.

Adamantine (i.e., diamond-like) nitrides (Parthé, 1972) are of interest because of their combination of high melting point, high hardness, and good thermal conductivity, and silicon nitride and aluminum nitride fall into this category, along with the recently developed carbon nitrides. Transition-metal nitrides (Toth, 1971) were originally far less important than their structurally related carbide analogs, but their occurrence as inclusions in steels (Obara and Tsunoyama, 1995), their use as hard coatings on metals (Sundgren and Hultman, 1995), and their novel magnetic proper-

Magnetic properties	$Ln_2(Fe,M)_{17}N_{3-x}$, M = transition metal

ties (Hadjipanayis *et al.*, 1992) have resulted in their receiving a considerable level of attention recently. The drive to find new materials for electronic applications has resulted in the preparation of nitrides in the form of thin films; aluminum nitride has emerged as a good electronic substrate material because of its combination of low electrical conductivity but high thermal conductivity. More recently, gallium and indium nitrides have received attention because their band gaps make them useful for light-emitting diode (LED) applications. Lithium nitride is the sole stable alkali-metal nitride, and finds limited application as an ionic conductor.

1. CLASSIFICATION

1.1 Definition

The definition of nitrides given above excludes compounds in which the nitrogen is present combined as a group with other elements (especially oxygen), but includes compounds where other nonmetals may be present. Examples of the latter include nitrofluorides (*e.g.*, Ba_2NF, Mg_2NF, Mg_3NF_3) and oxynitrides [*e.g.*, ALON aluminum oxynitride spinel, $\approx 3Al_2O_3 \cdot AlN$; sialon ceramics (Ekström and Nygren, 1992)]. Mixed metal nitrides have been developed and are finding applications; a special group of these comprises nitrided interstitial alloys (*e.g.*, $Sm_2Fe_{17}N_{3-x}, NdFe_{12}N_y$), where the small amount of nitrogen introduced exercises an important role in modifying magnetic properties (Nagata and Fujii 1991).

1.2 Bonding

A convenient way of classifying nitrides is in terms of their bonding. The Group I and Group II metals that form nitrides produce compounds that contain essentially ionic bonds, and display very rapid hydrolysis reactions. Elements in Groups III and IV form covalently bonded nitrides, which are often compared with diamond in the combination of properties they exhibit. Transition metals form nitrides that are interstitial in form and show intermediate properties between their parent metals and the covalent nitrides in Groups III and IV. Rare-earth nitrides show mixed behavior in between those of the transition metal nitrides and the ionic nitrides. More complex ternary and quaternary nitrides have been prepared that exhibit bonding made up of ionic, covalent, and metallic contributions, in proportion to the particular metallic elements they comprise.

1.3 Common Structure Types

Morgan (1977) made a detailed study of bonding in nitrides and concluded that it was surprising in view of the considerable electronegativity difference between oxygen and nitrogen to find that most nitride structures were the same as those observed in oxide crystal chemistry. Thus many transition-metal and rare earth nitrides have the rocksalt (NaCl or MgO) structure, TaON has a rutile (TiO_2) structure, UN_2 has a fluorite (ZrO_2) structure and silicon nitride has the phenacite (Be_2SiO_4) structure. This similarity in structure is very convenient for the classification of nitrides (Marchand *et al.*, 1991). Clearly, the generalisation that oxides are "more ionic" and nitrides are "more covalent" is not a classification that can be translated into structural implications.

Lang (1977) used cation coordination as a convenient parameter for categorizing the structures of nitrides. Thus in lithium nitride (Sec. 3.1), lithium atoms are 2- and 3-coordinated by nitrogen, whereas in boron nitride (graphite structure) the boron atoms are 3-planar coordinated by nitrogen atoms in the form of a triangle, with much weaker bonds joining them to nitrogen atoms in adjacent layers.

Metal atoms 4-coordinated by nitrogen represent perhaps the most common situation in nitrides. Nitrogen prefers to stack in a hexagonal close-packed manner compared with the cubic close-packed arrangements observed for the other elements in Group V. Thus 1:1 compounds involving Group III metals and nitrogen usually adopt the wurtzite structure, exemplified by AlN, GaN and InN. This arrangement forms the basis of more complex superlattices for mixed metal nitrides represented in group number terminology by the formulas II/IV/N_2 and I/IV_2/N_3 (Lang, 1977). Divalent metal nitrides of formula M_3N_2 commonly adopt the antibixbyite structure (Sec. 3.2), and metal nitrides of overall formula M_2N (*e.g.*, LiMgN, LiZnN, Li_3AlN_2) generally adopt the antifluorite structure or ordered variants of this.

Carbon nitrides occur either with graphite-like layers or with a silicon nitride arrangement. Silicon and germanium nitrides are isostructural, and both occur in two forms α and β, with arrangements related to the mineral phenacite (Wild *et al.*, 1972). The structures of sialon ceramics are extremely varied (Thompson, 1989) and in many cases can be considered as nitride analogs of the mineral silicates. This is discussed in more detail in Sec. 4.1.

Metal atoms 6-coordinated by nitrogen are most commonly observed in transition-metal nitrides. Structures are determined by the radius ratio ($r_N : r_M$), and if this is less than ≈ 0.59, simple structures with the metal atoms in hexagonal or cubic close-packed arrangements occur, whereas above this value, more complex structures result (Evans, 1964). Mixed metal nitrides with the nitrogen in 6-coordination often display the perovskite structure (Lang, 1977).

Specific details of the structures of the more important nitrides are given later under the relevant sections.

2. PREPARATION

Routes for preparing nitrides can be divided into two groups depending on whether the final product is a powder or a thin film or surface coating. Nitride powders are often subsequently converted into bulk solids by appropriate densification procedures. Techniques for this are dealt with in the sections covering the particular nitrides concerned. There is also some interest in the production of single crystals of nitrides, especially for electronic applications (Motojima and Iwanaga 1992). Gas-phase growth by CVD (chemical vapor deposition) (*q.v.*) is generally easier than growth from the melt.

2.1 Preparation of Nitride Powders

Direct nitridation of metals using molecular nitrogen is the most commonly used technique for the production of nitride powders, especially when the metal melts at high temperature; this has been used extensively for the production of the nitrides of lithium, silicon, and aluminum. Even though ammonia can be used for nitriding, and offers advantages of a higher nitrogen potential and hence lower nitriding temperatures, it has the disadvantage that only the surface of the metal powder grains is nitrided, and diffusion into the centers of the grains requires higher temperatures or long times. Nevertheless, many ionic nitrides can be successfully prepared in pure form by reacting appropriate metal salts with ammonia.

Carbothermal reduction of oxides in nitrogen (Van Dijen *et al.*, 1985) is generally the cheapest method of nitride production and, because of the large volumes of carbon monoxide generated, always produces a powder as the finished product. This process has been used for producing AlN, Si_3N_4, and BN powders, and is also a cheap process for producing more complex nitrides and oxynitrides starting from aluminosilicates or more chemically diverse naturally occurring starting materials. An excess of carbon is generally beneficial; this is burnt off later at a temperature low enough not to oxidize the nitride. Transition metal nitrides can also be made by the carbothermal route, but the final product is invariably deficient in nitrogen, and contains either carbon or oxygen depending on the metal:carbon ratio in the starting mix.

The purest nitride powders are produced by methods in which metal–nitrogen complexes are synthesized by low-temperature chemical routes, and are then subsequently decomposed by heating to higher temperatures to form the nitride (Büchner *et al.*, 1984). In the case of silicon, either silicon amide, $Si(NH_2)_4$, or silicon imide, $Si(NH)_2$, is formed by reaction between silicon tetrachloride and ammonia in ammoniacal solution, and this is then heated to form initially an amorphous powder at ≈900 °C, which then subsequently crystallizes into the nitride on heating to higher temperatures. It is also possible to prepare low-temperature Si-N–based polymers starting with carbosilazane derivatives, which on decomposition break down to give silicon nitride at high temperatures. In general these methods are expensive, especially when large volumes of powder are being produced; they also require careful attention to safety features because of the presence of chlorine and ammonia; nevertheless, they yield powders of high purity and controlled grain size. The production of pure, ultrafine (*i.e.*, nanometer range) particles is becoming increasingly important, and CVD-based routes allow particles to be produced of uniform size in the range 10–500 nm (Kato 1992). Alternative methods involving the use of either dc or radio-frequency coupled plasmas (Leflamme *et al.*, 1992) are increasingly being introduced.

2.2 Preparation of Nitride Thin Films

The last five years has seen an enormous increase in the number of methods that have been used to produce nitride thin films or coatings. In this article, the term coating is used to denote a thin film that has been deposited to provide improved corrosion resistance and/or mechanical protection, and where it is important to have a strong bond to the underlying substrate; the term thin film is used to denote layers of material deposited on a substrate where the properties of the deposited layer provide the principal interest. The latter term is more commonly used to denote thin films deposited for the purpose of imparting particular electronic or magnetic properties.

CVD techniques (Hoffmann, 1994) were some of the first to be used to produce nitride thin films; these have been further developed using novel precursors (Gordon, 1994), and techniques have been devised to speed up the rate of deposition (Lackey *et al.*, 1991). However, CVD procedures often require high temperatures, which, in addition to being expensive, may be beyond the capability of the substrate to withstand. For this reason they have given way to a range of PVD (physical vapor deposition) techniques, which allow much lower temperatures to be used. Sputtering (Howson, 1994) is a technique that is cheap, easy, and safe to use, but cannot easily control the chemistry and grain size of the final film. It is feasible to produce mixed nitrides by this technique (Belkind *et al.*, 1991), and concentration gradients can be introduced (Monaghan *et al.*, 1993) Plasma-based methods (Korhonen *et al.*, 1990; Jehn, 1994), pulsed laser deposition (Donley and Zabinski 1994), and arc ion plating (Khono *et al.*, 1993; Vetter 1995) are commonly employed to deposit hard-metal coatings. Ion-implantation routes (Bolse 1994; Takano and Isobe, 1991; Armour, 1994) provide an alternative way of nitriding a metal surface, and this can also be used to achieve varied compositions (Lieb *et al.*, 1994).

3. IONIC NITRIDES

The number of compounds in this category is small because of the poor stability of alkali-metal nitrides. Lithium forms an ionic nitride of formula Li_3N, but the other Group I metals do not form equivalents; instead they form azides (NaN_3, KN_3, *etc.*) of limited stability. In Group II, beryllium nitride is a fairly covalent solid, but is dealt with here for comparison with the other nitrides in Group II. Ionicity increases on moving down Group II, and all metals in this group form stable nitrides.

3.1 Lithium Nitride

Figure 1 shows the unusual crystal structure of lithium nitride (Zintl and Brauer 1935). In most compounds, lithium adopts fourfold coordination, but clearly this is impossible in Li_3N because the nitrogen would be 12-coordinated by Li. Instead, the two 3-coordinated lithium atoms occupy positions on triad axes in the basal plane of the hexagonal unit cell with nitrogen occupying the origin site, and with the third (2-coordinated) lithium atom linking adjacent layers of these planes in the *z* direction. As a result, each nitrogen atom is 8-

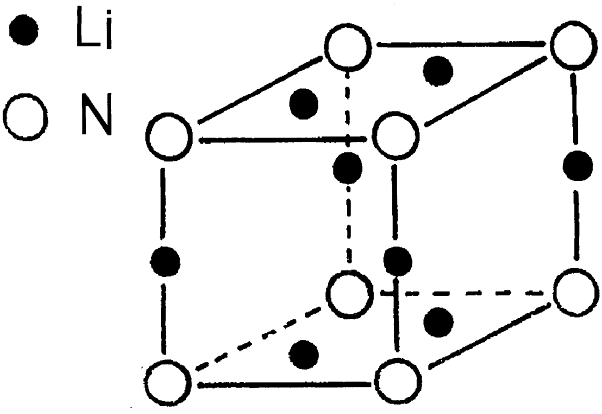

FIG. 1. Atomic arrangement in the hexagonal structure of Li_3N.

coordinated by lithium atoms. Small amounts of other metals (Cu, Co, Ni) can substitute in the 2-coordinated lithium site. The closeness of the 3-coordinated lithium atoms in the basal plane permits easy diffusion from one site to the next, and this forms the basis of the ionic conductivity observed for this compound. As with ionic nitrides, lithium nitride hydrolyses readily in the presence of water with emission of ammonia gas.

3.2 Group II Metal Nitrides

Group II nitrides have the general formula M_3N_2, and the basic structure is the cubic antibixbyite (anti-Mn_2O_3) type, which adopts the space group I*a*3 (Lang, 1977). This structure can be considered as comprising eight fluorite unit cells placed in a 2 × 2 × 2 arrangement along each crystallographic axis, but in each subcell, one quarter of the metal atoms have been removed in an ordered fashion, thus changing the metal:nonmetal ratio from 4:2 to 3:2. As a result, the cations are in a fairly regular 4-coordinated environment, wheras the nitrogen atoms are in a distorted 6-coordination.

Beryllium nitride occurs in two structural modifications, α and β. The α form has the antibixbyite structure discussed above, whereas the β form is hexagonal, with a polytypic structure (Thompson, 1989). This compound forms the basis for a series of polytypoid ternary and quaternary compounds in the Be–Si–O–N system (Roebuck and Thompson, 1977). Magnesium nitride, Mg_3N_2, occurs only in the antibixbyite form, and is characterized by a greenish-brown color.

Calcium nitride occurs in several uncharacterized forms in addition to the antibixbyite type (Lang, 1977). It is very surprising to find calcium in a 4-coordinated environment; moreover, the Ca–N distances are large, and this, combined with the unoccupied sites characteristic of the antibixbyite structure, combine to give the compound a low density. Its sensitivity to moisture means that it must be handled very carefully to avoid hydrolysis.

Strontium forms two nitrides of composition SrN and Sr_2N, the former having a sodium chloride structure and the latter a rhombohedral variant with nitrogen atoms omitted (Lang, 1977). Barium nitride is similar, and data for the various barium nitrides have been published, but further characterization is needed (Linke and Schroedter, 1975).

4. COVALENT NITRIDES

4.1 Silicon Nitride

Forty years ago, silicon nitride appeared as one of several new "special ceramics", which showed promise for development as a high-temperature engineering material because of a good combination of mechanical properties up to ≈1400 °C. Government research programs carried out in the U.K., the U.S.A., Europe and Japan confirmed this promise, but showed that the production of reliable components from this material was difficult because of its poor sinterability and the very high temperatures ($\approx 1750\,^\circ$C) needed. As a result, silicon nitride has subsequently found more applications at low ($< 1000\,^\circ$C) temperatures, where its good wear resistance combined with good thermal shock and chemical resistance are the principal advantages.

An important feature of silicon nitride chemistry is the extent to which simultaneous replacement of silicon and nitrogen by aluminum and oxygen can occur to produce a wide range of alternative structures. These materials (sialons) more readily sinter to high density at lower temperatures than silicon nitride itself because of the presence of low–melting-temperature metal-silicon-aluminum oxynitride liquid phases, which aid densification. The name β-sialon is given to the range of solid solutions of composition $Si_{6-z}Al_zO_zN_{8-z}$, where $0 < z < 4$, which form by direct replacement of silicon and nitrogen in β-Si_3N_4 by aluminum and oxygen; the related compound, α-sialon, has a composition $M_xSi_{12-m-n}Al_{m+n}O_nN_{16-n}$, and has a unit cell similar to that of α-silicon nitride but with $m+n$ Al atoms replacing Si, and valency balance being restored by inserting x metallic cations (M = lithium, magnesium, calcium, yttrium and most rare earths) into the large interstices in the structure. Ranges for the various compositional parameters in the formula are approximately $0 < x < 2$, $0 < n < 3$, and $0.5 < m < 3.5$.

In the early years of silicon nitride development, germanium nitrides were also prepared and it was found that there were also two forms, α and β, isostructural with the α and β forms of silicon nitride (Wild *et al.*, 1972). However, the germanium analogs are not as stable, decomposing into the elements below 1000 °C.

The importance of silicon nitride is such that a complete article of the Encyclopedia has been devoted to it; see SILICON NITRIDE. Further information on sialon and other oxynitride derivatives is given in Sec. 6.2.

4.2 Aluminum Nitride

Aluminum nitride is a refractory, covalently bonded nitride, stable up to temperatures of $\approx 2500\,^\circ$C. It is prepared in powder form either by the nitridation of aluminum powder, by carbothermal reduction of alumina, or by decomposition of preprepared organic derivatives containing aluminum and nitrogen. Aluminum nitride powder hydrolyses easily even at room temperature, but solid samples resist hydrolysis because of partial passivation. Bulk samples are prepared by sintering the powder either at high temperatures (1750–1950 °C) with additions of small amounts of metal oxides (most commonly MgO, CaO, Y_2O_3). The oxygen on the surface of the AlN grains reacts with the oxide additive to form a liquid at sintering temperatures, which aids densification, and then cools to form mainly a crystalline ternary oxide phase in the grain boundaries.

Even though aluminum nitride was originally developed for its refractoriness and mechanical properties, it does not find extensive application in this area. A more important area of application is as an electronic substrate, where its high thermal conductivity (up to $200\,\mathrm{W\,mK^{-1}}$) is the main property of interest. However, dense samples of AlN sintered using oxide additives exhibit much lower thermal conductivities (typically $50\,\mathrm{W\,mK^{-1}}$) because of residual oxygen present both in the aluminum nitride grains and also in the grain boundaries. To produce a high-conductivity material, it is necessary to remove oxygen (especially lattice oxygen within the grains), and this can be achieved either by a higher temperature post-treatment, or by use of reducing additives that extract the oxygen in gaseous form during the sintering stage (Kuramoto *et al.*, 1986).

4.3 Other Group III Nitrides

The preference of nitrogen for a hexagonal close-packed stacking sequence results in the wurtzite (AlN-type) structure being adopted by both gallium and indium nitrides, even though the cubic form can occur for GaN. As with AlN, small amounts of oxygen easily remain dissolved in the crystal lattice. The main interest in both compounds is in their electronic properties, because their band gaps are 3.5 and 1.9 eV, respectively. GaN is a good source material for high-brightness blue-light–

emitting diodes; InN is used for similar device applications and also for high-efficiency solar cells.

4.4 Boron Nitride

Boron nitride is a unique material, which in many ways can be regarded as a white, insulating form of graphite. Normally prepared by reaction between boric oxide and ammonia, it is produced as a white powder, with a graphite-like crystal structure, which is stable in reducing environments up to ≈3000 °C. In steam BN hydrolyses to boric oxide and oxidizes in air at higher temperatures, and since boric oxide melts at 420 °C, this can result in the formation of a viscous glass. Thus BN is useful as a lubricant, as an inert refractory filler and in other applications where its electrically insulating properties offer advantages over carbon.

As with carbon, BN can be prepared in cubic form with a diamond crystal structure and dense forms (with trade names such as Amborite, Borzan, or Sumiboron), exhibiting similar mechanical properties to diamond. Because of the different chemical reactivities of diamond and boron nitride, cubic boron nitride is often used as a cutting tool for materials which show extensive reaction with diamond.

5. TRANSITION METAL NITRIDES

Transition metals form interstitial nitrides that are generally similar in formula and in chemical behavior to the analogous carbides.

5.1 Bonding and Structure

The formula of interstitial nitrides bears no relationship to the valency of the cation, and most transition-metal nitrides have relatively simple formulae of the type MX, M_2X, M_3X, etc., with the metal usually present in the larger proportion. In the absence of balanced valences, there are obviously free electrons as in the pure metal, but the nitrogen changes the outer electronic band structure imparting a covalent influence, which as a consequence increases the resistivity compared with the pure metal. Usually, the arrangement of metal atoms in interstitial nitrides is either face-centered cubic or hexagonal close-packed, but other arrangements are known. A measure of the increased bonding in these compounds compared with the parent metals can be seen from the increased melting point (see Table 2). However, this increase is not constant for all compounds, and on moving across a period of transition metals, the stability of the nitrides decreases from left to right (*i.e.*, with increas-

Table 2. Physicochemical data for selected transition-metal nitrides. T_M = metal melting point; T_{MN} = metal nitride melting point (if known).

		Fe_2N	NiAs	1535	d.[b]

[a] Fe_4N has the nitrogen atom in the body-centered position of a face-centered cubic distribution of iron atoms.

[b] d = Decomposes.

ing atomic number). Thus, for example, scandium nitride can be regarded as a stoichiometric compound, in which both metal and nonmetal atoms exhibit their conventional valences, and the bonding is mixed ionic/covalent with very little metallic contribution. Therefore ScN has a very high melting point compared with metallic Sc. The next element, titanium, forms TiN, and the loss of balanced valences results in an increased metallic contribution, but nevertheless there is an appreciable difference in melting points between the metal and the nitride. At the other end of the first-row transition metals, both copper and zinc form extremely unstable nitrides that decompose at low temperatures. The elements in between show an increase in metallic behavior and a decrease in ionic/covalent influence with increasing atomic number. As a result of this the chromium–, manganese–, and iron–nitrogen systems show a larger number of relatively unstable nitrides, which are not easy to prepare. Chapter 5 in Goldschmidt (1967) should be consulted for a detailed discussion of these compounds. The work of Jack (1950) was particularly important in elucidating the compositions and structures of the iron nitrides. The same general trends are evidenced across the second (Y–Cd) and third (La–Hg) rows of transition metals. The rare-earth metals, in contrast, generally form nitrides of formula LnN; this might appear to be consistent with the general metal valence of 3 in this series, but is also true for the elements which show other valences under normal conditions (Ce, 4; Eu, 2). These compounds behave more like ionic nitrides than transition-metal nitrides, but their electrical conductivities still show some evidence of a metallic contribution.

It is rare to find transition-metal nitrides as pure nitrides. Both oxygen and carbon can readily displace nitrogen in the interstitial sites with very little effect on either the chemical or physical properties. Most "nitrides" are in fact "oxynitrides", but demonstrating this, and achieving an accurate value for the oxygen content, is often quite difficult.

5.2 Classification

The simple formulas adopted by transition-metal nitrides form the easiest basis for their classification. As mentioned in Sec. 1.3, if the radius ratio $r_N : r_M$ is less than a value of ≈ 0.59, the nitrogen will behave interstitially in an fcc/hcp framework, and Table 2 shows that this covers most of the transition-metal nitrides of interest. If the radius ratio is greater than 0.41, the nitrogen will occupy a 6-coordinated interstice, and this is the normal case. For 6-coordination, and an overall formula of the type MN, the structure adopted is that of a normal fcc metal, with the nitrogen occupying sites half way between metals. For M_3N structures, a hcp metal arrangement is common, with (in conventional ABC close-packing terminology) nitrogen atoms occupying A-type sites in between three neighbors above and below in B- and C- type layers, respectively. For M_2N structures a similar hcp metal-atom arrangement occurs, with a different proportion of the interstitial sites occupied. What is clear from Table 2 is how common the rock-salt (sodium chloride) structure is for MN-type transition metal nitrides. Detailed studies have been made of defect structures, electronic behavior and properties, especially for those nitrides used as hard coatings on metals (Johansson, 1995).

5.3 Titanium Nitride

This is singled out for special mention here as being the most common of the transition metal nitrides. This is because it offers greater stability compared with the oxide than most other nitrides, and the thin layer of oxide that does form as a result of hydrolysis gives total protection against further degradation. In the competition with other nitrides as a hard surface coating material, TiN is cheaper than most other competitors, can be readily produced as a good-quality, adherent coating by the methods discussed in Sec. 2.2, and remains chemically and thermally stable up to high temperatures (Rickerby and Matthews, 1991). Its characteristic gold color may also add to its attractiveness for certain applications.

6. COMPLEX NITRIDES

A wide range of ternary nitrides exist in which nitrogen is bonded to more than one cation. These compounds have structures that can often be related to the binary nitrides described in Secs. 3 and 4, and have similar chemical and physical properties. This section also deals with mixed nonmetal nitrides, where the nitrogen occurs in conjunction with (commonly) oxygen or fluorine. Both crystalline and vitreous oxynitrides are fields of considerable research interest.

6.1 Mixed Metal Nitrides

These can be divided into either more ionic or more covalent types, in the same way that the binary nitrides were subdivided earlier (Sec. 1.2).

By far the largest group of complex ionic nitrides comprises those based on lithium (Lang, 1977). There is a group of strongly ionic nitrides such as LiMgN, LiZnN, and Li_3AlN_2, which adopt anti-fluorite structures and exhibit very strong hydrolysis reactions. Related nitrides exist with the general formula $Li_{2n-3}M^{n+}N_{n-1}$ (M = Mg, Zn, Al, B, Ba, Si, Ti, V, Ta, Mn, Cr), which also adopt the anti-fluorite structure. Other mixed nitrides with this structure include $Li_{15}Cr_2N_9$ and Li_8SiN_4. A further group of compounds have the anti-La_2O_3 structure and the general formula Li_2MN_2, where M = Si, Zr, Ce. Although these compounds do exhibit ionic conductivity, they are not suitable for battery applications (Metselaar, 1994).

Barium is another element that forms a wide range of ternary nitrides in combination with other metals. Compounds of the type $BaMN_2$ (M = Ti, Zr, Ce) and Ba_2MN_3 (M = Nb, Ta) (Green and Hughbanks, 1993) form with tetragonal and monoclinic structures, respectively, and more complex variants (*e.g.*, $Ba_2Si_5N_8$, $Ba_3Ga_2N_4$, and $Ba_5Ti_2N_6$) have been reported. Interstitial nitrides based on barium are also common. Compounds of BaMN with M = Li, Ni, Co exist; CaNiN has a body-centered arrangement of Ca and Ni with –N–Ni–N– chains arranged in criss-cross fashion. A review of this and related structures is given by Röhr (1996). A series of barium sodium nitrides exist, in which nitrogen is octahedrally coordinated by Ba, with Ba_6N units present either as individual octahedra (as in $Na_{16}Ba_6N$) or linked together in chains (in $NaBa_3N$ and Na_5Ba_3N). More complex units form when calcium is also present. A series of quaternary nitrides of the type $Ba_2Li_3MN_4$ with M = Nb, Ta has been reported. In these compounds, chains of interconnected LiN_4 and NbN_4 tetrahedra are linked by barium atoms (Chen and Eick, 1984).

Ternary nitrides with the overall composition MT_3N are common, where M is a nontransition metal and T a transition metal (Metselaar, 1994). A similar formulation and structure is also exhibited by Ca-containing compounds of the type Ca_3MN, where M = P, As, Sb, Bi, Ge, Sn, and Pb. The latter compounds exhibit interesting electrical properties, with the P and As derivatives being insulating, the Bi and Sb derivatives being semiconducting, and the Pb, Sn and Ge derivatives being metallic.

Molybdenum and tungsten form a variety of ternary nitrides in combination with other metals. $LiMoN_2$ can be formed by ammonia treatment of lithium molybdate at 800 °C, and metal tungsten nitrides of formula MWN_2, with M = Mn, Fe, Co, Ni can be prepared in a similar way. η–Fe_3Mo_3N and Fe_3W_3N nitrides (and related variants with iron replaced by other first-row transition metals) are all cubic with a unit-cell dimension of ≈ 1.13 nm. Compositionally similar compounds of the type Ni_2W_3N are cubic with a cell dimension of 0.67 nm and have a stuffed β-manganese structure.

Iron-rich magnetic alloys with formulations of the type LnT_{12} and Ln_2T_{17} (Ln = rare earth; T = first-row transition metal) were developed in the 1980s because of their increased magnetic moments, and these phases readily accommodate interstitial atoms (boron, carbon, nitrogen). The most explored nitride in this series is $Sm_2Fe_{17}N_x$, where x is a maximum of three but more typically has a value in between 1 and 2. The crystal structure is that of Th_2Zn_{17} (Helmholdt and Buschow 1989), which includes three 6-coordinated interstitial sites per unit cell in which the nitrogen is accommodated. An important effect of the nitrogen in this series of compounds is to increase the Curie temperature (Nagata and Fujii, 1991).

Covalent mixed metal nitrides occur, based on the covalent binary nitride structures discussed in Sec. 4. Thus, a range of compounds exist of the type $M^{II}M^{IV}N_2$, where M^{II} = Be, Mg, Mn, Zn, and M^{IV} = Si, Ge, and also a smaller number of ternary and quaternary nitrides of stoichiometry 1:2:3, exhibited by the compounds $LiSi_2N_3$ and $MAlSiN_3$, where M = Mg, Mn, Ca. Both types of compounds exhibit superlattices of the basic wurtzite type, and the reader is directed to more detailed works (*e.g.*, Thompson, 1989) for a full description of these structures. Boron readily forms ternary nitrides with rare-earth metals. Thus neodymium forms $Nd_3B_2N_4$ and praseodymium $PrBN_2$ (Klesner and Rogl, 1992).

6.2 Mixed Nonmetal Nitrides

Nitrofluorides were mentioned briefly in Sec. 1.1. However, these have little significance apart from demonstrating that the combination of one nitrogen and one fluorine atom can generally behave in the same way as two oxygen atoms. The compound ZrNCl finds some application as a source of nitrogen. A much more important group of compounds in this category comprises the oxynitride glasses and crystalline solids, which have been researched extensively during the last 25 years.

Oxynitride glasses (Thompson, 1992) are derived from oxide glasses of similar cation ratio by the substitution of up to 25 at.% of oxygen by nitrogen. Compositions are often quoted in equivalent % of nitrogen, which refers to the percentage of nitrogen valences expressed relative to the total number of nonmetal valences. Metal atoms present almost invariably include silicon and aluminum, plus also one of the cations Y, Mg, Ca, Li, and Ln. Nitrogen solubility increases with the valence of the third metal cation, with a maximum of $\approx$25 at.% being observed for the low-Z rare earths. These glasses are of interest partly because they occur in the grain boundaries of the commercially important group of sialon ceramics and partly because in comparison with their oxide analogs, they have better refractoriness and higher hardness, viscosity, and refractive index. Amorphous P-O-N oxynitrides form another interesting emergent group of materials, which have been mainly explored in the Zr-P-O-N and Al-P-O-N systems (Fripiat *et al.*, 1997).

Crystalline oxynitrides are best known in combination with higher-valence metals. Silicon oxynitride, Si_2N_2O, is a similar material to silicon nitride, and in the Al-O-N system the spinel compound, $3Al_2O_3 \cdot AlN$ (commonly referred to as ALON), has importance as a more easily sintered, cubic form of alumina, which can be produced in transparent form, suitable for use as infrared windows. Three oxynitrides occur in the ZrO_2-ZrN system, of composition Zr_2N_2O, $Zr_7O_8N_4$, and $Zr_7O_{11}N_2$; the first is an antibixbyite derivative and the last two are defect fluorite structures. Mixed-cation oxynitrides are numerous, and a good summary is given by Thompson (1989).

Considerable interest has been expressed in the four Y-Si-O-N compounds nitrogen melilite ($Y_2Si_3O_3N_4$), nitrogen apatite [$Y_{10}(SiO_4)_6N_2$], nitrogen wollastonite [$(YSiO_2N)$], and nitrogen YAM ($Y_4Si_2O_7N_2$). These compounds often occur in silicon nitride ceramics densified with yttrium oxide, and amply demonstrate that the replacement of oxygen by nitrogen can take place readily with the retention of mineral silicate structures. These compounds all have analogs in equivalent rare-earth systems.

7. APPLICATIONS

Nitrides have found increasing application during the last 25 years either because of good mechanical performance (at both room and elevated temperatures) or, in other cases, because of their good electronic/optoelectronic performance. It is convenient to distinguish between applications that require a thin film or coating of the nitride material and those that require a bulk sample.

7.1 Thin Films and Coatings

The use of transition-metal nitrides as hard metal coatings on metallic substrates was discussed in Sec. 6 as an important application for TiN (see Fig. 2). However, TiN is not unique in this respect, and other transition-metal nitrides have been used. Indeed, the whole field of coatings has grown as a result of these developments, and in consequence, coated tungsten carbide tools have remained competitive despite the onset of new ceramic cutting tools.

In the electronic field, thin layers of silicon nitride are often used to provide insulating

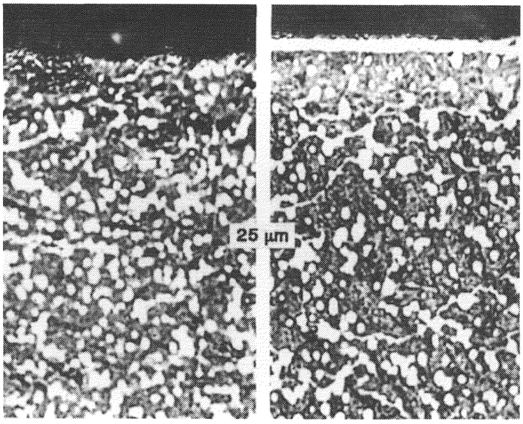

FIG. 2. Optical micrograph of a medium-carbon steel before and after coating with TiN (after Matthews *et al.*, 1993).

layers on silicon wafers (Fig. 3). In a similar way, thin layers of AlN provide a good thermal conductivity substrate material, which is particularly useful for circuits operating at high power levels that need to dissipate large amounts of heat (Fig. 4). The use of Group III metal nitrides (AlN, GaN, InN) as optoelectronic materials for devices because of their suitable band gaps has been discussed in Sec. 4.3. This area represents a significant growth area for these nitrides.

7.2 Bulk Nitrides

Silicon nitride is made into many shapes for components that find application in the aerospace and automotive industries, primarily as wear parts (Fig. 5). These include seals and dies (Fig. 6), the latter for both wire and tube drawing. For these purposes, alumina is added to the starting mix, and the resulting ceramic is strictly speaking a sialon product; this is preferable because the alumina not only helps densification, to produce a dense, fully sintered body, but sintering takes place at a lower temperature, with associated cost benefits. The original intention of using silicon nitride in high-temperature gas turbine engines (as envisaged in the 1960s) has been slow to take off because of the demanding nature of the application, and is unlikely to ever be a large-volume application. The use of refractory nitrides as crucible materials has been more successful; reaction-bonded silicon nitride is excellent for handling molten aluminum. For higher-melting metals, interaction between slags on the metal and the thin films of oxynitride glass in the grain boundaries of the silicon nitride causes degradation and limits lifetimes. Nitride-bonded carbide refractories, consisting of silicon carbide grains bonded by silicon nitride, are examples of high-performance materials finding application as steel-furnace refractories.

Boron nitride finds some application as a high-temperature crucible material for use in inert atmospheres. Aluminum nitride was originally developed for high-temperature structural applications, but its ease of hydrolysis combined with a worse portfolio of properties (hardness, strength, and toughness) compared with silicon nitride and silicon carbide has restricted its development.

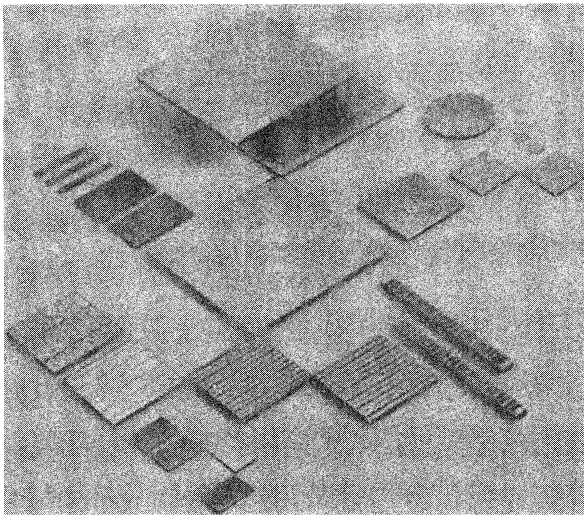

FIG. 4. A selection of partly metallized AlN substrates (after Werdecker and Aldinger, 1984).

8. SUMMARY

Nitrides are an emerging class of materials offering a very wide range of properties, which have been developed during the last 40 years to meet specific niche requirements in the spectrum of materials applications. New nitride materials are still emerging; well-established materials are being refined and new processing routes developed. This article has focused

mainly on binary nitrides because these are currently the most important as far as applications are concerned. However, new ternary and quaternary compounds are emerging, which in time will also find application. The field of thin films, for both electronic and mechanical applications, has rapidly developed in the last 15 years and will undoubtedly expand further. An important emphasis of future activity will be the development of low-cost processes for nitride production; this is necessary if structural nitrides are to become more competitive and is expected also to have a similar impact on markets in the thin films and coatings area.

GLOSSARY

Adamantine: Literally "diamond-like", and applied to those covalent solids formed between low atomic number elements in Groups III, IV and V of the periodic table and displaying high hardness and high melting/decomposition temperature.

Carbothermal Reduction: The reduction of an oxide by heating with carbon, the reaction forming either the metal (if carried out in inert atmosphere) or the nitride (if carried out in nitrogen).

Chemical Vapor Deposition: The deposition of a thin film at high temperature using mixtures of gases that react at that temperature to form the desired product.

Coordination: The number of neighbors surrounding an atom in a crystal structure.

Equivalent %: A term used especially when describing compositions of sialon ceramics, when the proportions of individual elements are expressed relative to the number of valences of that species. Usually metals and nonmetals are dealt with separately, and therefore $YSiO_2N$ would be described as containing 43 equivalent % of yttrium and nitrogen, and 57 equivalent % of silicon and oxygen.

Interstitial: Used to describe compounds containing small atoms, in which the small atoms can geometrically fit into the spaces between the large atoms.

Physical Vapour Deposition: Deposition of thin layers of a substance using nonchemical methods (*e.g.*, evaporation or sputtering).

Sialons: Compounds containing the elements silicon, aluminum, oxygen, and nitrogen (plus others).

YAM: The yttrium aluminate of formula $Y_4Al_2O_9$.

INTRODUCTION

We all know that Nature is disordered. We live in a world of composites and mixtures, ranging from man-made polymers and plastics that are used for manufacturing a variety of products, to oil reservoirs and groundwater aquifers, to our own body, which is perhaps the most complex system in Nature. Only theoreticians can think of ordered, pure, and perfectly characterized and geometrically immaculate systems. Even the experimentalist who focusses on the purest of subtances can seldom escape the effects of defects, trace impurities, and finite boundaries. There are few concepts in science more elegant to contemplate than an infinite, perfectly periodic system, and few systems as remote from experimental reality. We are therefore obliged to come to terms with disordered media, variation in shape and constitution often so ill characterized that we must deem it to be random if we are to describe it. In particular, we have to live with the apparent randomness in the morphology of many important systems, which is their topology—the interconnectivity of their individual microscopic elements—and geometry—the shape and size of these individual elements. However, this is only half of the story. We believe, at least above the quantum mechanical level, in the doctrine of determinism, yet important continuum systems exist in which deterministic descriptions are beyond hope. A typical example is Brownian motion where, over certain length scales, we observe an apparent random process, or disordered dynamics.

Nature, then, is disordered both in her structure and in the processes that she supports. The two types of disorder often conspire. An example is fluid flow through a porous medium (*e.g.*, flow of oil in a reservoir) where the interplay between the disordered morphology of the pore space and the dynamics of fluid motion gives rise to a rich variety of phenomena. Despite the rather obvious randomness in Nature, for several decades the problem of how to model a disordered system and the phenomena that occur there was more or less "swept under the rug." Research in this field made progress by taking advantage of periodic structures. However, as one always has to confront the real world, it became apparent that a statistical physics of disordered systems must be devised to provide methods for deriving macroscopic properties of such systems from laws governing the microscopic world, and by taking into account the effect of both the geometry and interconnectivity of their microscopic elements. Although the role of geometry was already appreciated in the early years of this century, the effect of the connectiveness, or the topology of the system, was ignored for many decades, or was treated in an unrealistic manner, simply because it was thought to be too difficult to be taken into account.

The effort for devising such a statistical physics of disordered systems was begun in earnest in the late 1960s and early 1970s. Over the past 30 years, statistical physics of disordered media has been in a rapid stage of progress, and the reason for it is fourfold.

1. Standard theoretical methods for calculating the average properties of such systems have been established.
2. The vast increase in computational power has enabled us to study by computer simulations very complex systems.
3. The advent of novel experimental techniques has allowed more precise data to be accumulated.
4. Perhaps, however, the most important reason for this rapid progress is that the role of interconnectivity of the microscopic elements of disordered media and its effect on their macroscopic properties have been appreciated.

Point (4) has been possible through the development and application of percolation theory, the subject of this article.

1. WHAT IS PERCOLATION?

Consider a square network in which each bond represents a resistor. We select at random a fraction p of the bonds and assign a unit conductance to them, while the rest of the bonds are assigned zero conductance. Thus, the network is a composite of conducting and nonconducting bonds. We now apply a unit voltage gradient between two opposite edges of the network and ask, What is the minimum value of p, the fraction of the conducting bonds, in order for the electrical current to flow from one face of the network to the opposite face? From a technological viewpoint, this is an important question because, for example, its answer tells us what (volume) fraction of a disordered material made of conducting and nonconducting constituents, such as carbon black composites that are routinely used in many applications, has to be conducting in order for the composite as a whole to be conducting. Clearly, if too many bonds are nonconducting, no macroscopic current will flow in the network, whereas for sufficiently large p one has conduction between the two opposite faces.

Consider another example. Imagine that the bonds of the square network are pores of a porous medium, *e.g.*, those of an oil reservoir. In reality, no porous medium looks as ordered as the square network, but as an idealization this network serves a useful purpose. Now suppose that the pores are filled with oil, and that there are two wells in the system at two opposite corners of the network. We would like to push oil out of this porous medium by injecting water into the system at one corner (the injection well) and producing oil at the opposite corner (the production well). Oil and water do not mix with each other, and therefore we assume that each pore is filled with either oil or water. As the water is pushed into the reservoir, it tries to find the smallest pores that it can reach and expel the oil from it (why this is so is explained in Sec. 3). In reality, the process is more complex than this, but we ignore all the complications. The key question is: What fraction of the pores are filled with water when it reaches the production well for the first time (this is called the *breakthrough point*)? In other words, we would like to know how much oil is produced up to the breakthrough point. This is obviously an important question, scientifically, technologically and economically.

Questions such as these are answered by percolation theory, which tells us when a system is macroscopically connected so that a given phenomenon can occur in it. For example, it tells us when one can have a flow of electrical current from one side of a composite solid to the opposite side, or how much oil one can hope to extract from an oil reservoir. The point at which a sample-spanning cluster of the conducting elements, or of the pores of an oil reservoir that are filled with the injected water, is formed for the first time is called the *percolation threshold* of the system, and the behavior of the system close to this point is of prime interest and importance.

This article attempts to outline the most important concepts of percolation theory and discuss their applications. Over the past 25 years percolation theory has been applied to modelling a wide variety of phenomena in disordered media. It is impossible to discuss all such applications in one article. Thus, we discuss only those percolation models for which not only is there broad practical and scientific importance, but also there is quantitative (numerical) agreement between their predictions and the relevant experimental data. Stauffer and Aharony (1992), Bunde and Havlin (1996), and Hughes (1996) provide the necessary theoretical foundations of percolation theory. Hence, we only summarize the main concepts that will be used in the rest of this article.

1.1 Percolation Processes

Percolation processes were first developed by Flory (1941) and Stockmayer (1943) to describe polymerization in which small branching molecules react and form large macromolecules (see Sec. 6). However, they did not use the terminology of percolation theory, and also they developed their theory for a special type of lattice, called the Bethe lattice, an endlessly branching structure without any closed loops. Percolation processes, as we know them today, were introduced by Broadbent and Hammersley (1957) who were interested in the spread of a hypothetical fluid through a random medium. Generally speaking, such a process may involve some random elements, but the underlying randomness may be of two very different types. In one type, the randomness is dictated by the *fluid*, in that it is the fluid that decides which path to take in the system; this is the classical diffusion process. In the other type, the randomness in the path of the particle is imposed by the *medium*: this was the situation that was newly considered by Broadbent and Hammersley (1957). They called this phenomenon a *percolation process*; the spread of the fluid through the random

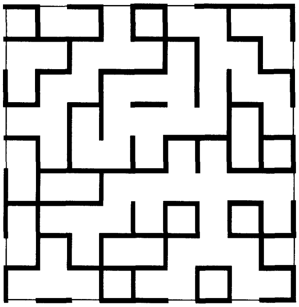

FIG. 1. Configuration of a square lattice in bond percolation. Thick lines are the occupied bonds, whose fraction is 0.57.

medium resembles the flow of coffee in a percolator. Since percolation theory deals with various properties of a disordered medium, we need to have a model of the medium in order to discuss its concepts. We represent the medium by a network or lattice. What the bonds and sites of the lattice represent depends on the particular application of percolation theory. In their original paper, Broadbent and Hammersley focussed on two problems, site and bond percolation, which we now discuss.

1.1.1 Bond Percolation In this problem the bonds of the network are either occupied or intact, randomly and independently with probability p, or they are vacant or removed with probability $1 - p$. For a large network, this assignment is equivalent to removing a fraction $1 - p$ of all the bonds at random. Figure 1 shows configuration of a bond percolation process on the square network. The occupied bonds may represent the conducting elements of a composite material, or the high-permeability regions of a pore space through which most of the fluid flow and transport take place, or the chemical bonds between the monomers during polymerization, and so on. The vacant bonds represent, *e.g.*, the low-permeability, or impermeable, regions of the pore space that contribute very little to flow or transport. Of course, in many heterogeneous media the disorder is not necessarily distributed randomly, but for now we ignore such complications.

Two sites are called *connected* if there exists at least one path between them consisting solely of occupied bonds. A set of connected sites bounded by vacant bonds is called a *cluster*. If the network is very large, and if p is of sufficiently small, the size of any connected cluster is likely to be small. However, if p is close to 1, the network should be entirely connected, apart from occasional small holes. At some well-defined value of p, there is a transition in the topological structure of the network; this value is called the *bond percolation threshold* p_{cb}. For $p < p_{\mathrm{cb}}$ there is no sample-spanning cluster of the occupied bonds, whereas for $p > p_{\mathrm{cb}}$ a cluster of the occupied bonds spans the system. In the context of the problem of composite solids, for example, for $p < p_{\mathrm{cb}}$ the system is not conducting, whereas for $p > p_{\mathrm{cb}}$ the overall conductivity of the composite is nonzero.

1.1.2 Site Percolation In this problem, sites of the network are occupied with probability p and vacant with probability $1 - p$.Two nearest-neighbor sites are connected if they are both occupied, and connected clusters on the network are again defined in the obvious way. For example, in the context of the polymerization problem, the occupied sites are the monomers and the connected sites are those that have reacted with each other and have formed a chemical (covalent) bond between them. Similar to bond percolation, there is also a site percolation threshold p_{cs} above which a sample-spanning cluster of occupied sites spans the network. Figure 2 shows site percolation clusters on a square network. Depending on a specific application of percolation theory to a problem of interest, many variants

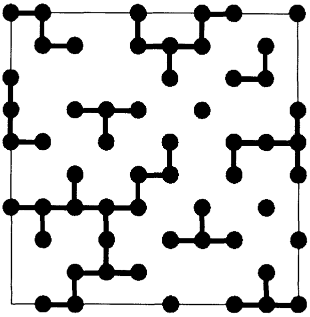

FIG. 2. Configuration of a square lattice in site percolation. Circles denote the occupied sites, whose fraction is 0.57.

of the classical percolation processes have been developed. The interested reader is referred to Stauffer *et al.* (1982) for a list of many variants of the classical percolation problem.

From a practical view point, generating a percolation network by randomly removing sites or bonds is not suitable for most applications, because in addition to the sample-spanning cluster, this method also generates isolated finite clusters. In most applications one uses only the sample-spanning cluster, or at least the phenomenon of interest starts with a single cluster, and therefore one must first delete all the isolated clusters from the system. In such cases, one can use an efficient method due to Leath (1976) and Alexandrowicz (1980) that generates only the sample-spanning (or the largest) cluster. In this method one starts with a single occupied site at the center of the network. One then identifies the nearest-neighbor sites of the occupied site and considers them occupied and adds them to the cluster if random numbers r, uniformly distributed in $(0, 1)$ and attributed to the sites, are less than the fixed value p. The perimeters (the nearest-neighbor empty sites) of these sites are found and the process of occupying the sites continues in the same way. If a selected perimeter site is not made occupied, then it remains unoccupied forever. The generalization of this method for generating clusters of occupied bonds is obvious. Figure 3 presents a sample-spanning cluster on the triangular lattice that was generated by this method.

1.2 Percolation Thresholds

Exact values of p_{cb} and p_{cs} are known only for certain lattices related to the Bethe lattice and for a few two-dimensional (2D) networks. For the Bethe lattice one has

$$p_{\text{cb}} = p_{\text{cs}} = 1/(Z-1), \tag{1}$$

where Z is the coordination number of the lattice, *i.e.*, the number of bonds connected to any one site. The current estimates of p_{cb} and p_{cs} for three common 2D lattices are compiled in Table 1, while the most accurate estimates of p_{cb} and p_{cs} for four common 3D lattices are compiled in Table 2. A very accurate approximation to p_{cb} is given by $p_{\text{cb}} \simeq d/Z(d-1)$.

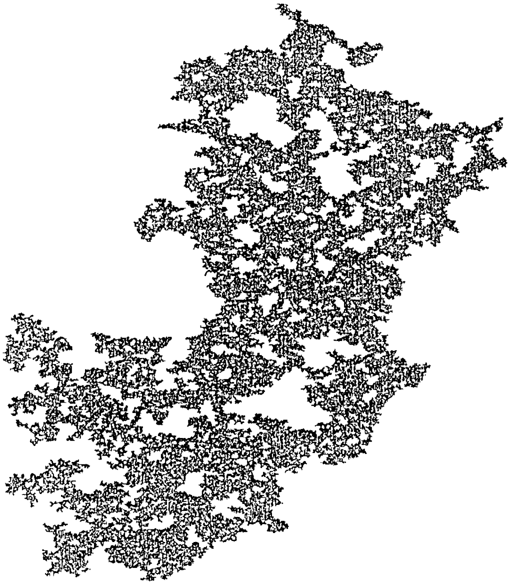

FIG. 3. The sample-spanning cluster in site percolation on a very large triangular lattice, generated by the Leath–Alexandrowicz method.

Thus, the product $B_{\text{c}} = Zp_{\text{cb}} \simeq d/(d-1)$, the average number of conducting bonds at p_{cb}, is an essentially invariant quantity that depends only on the dimensionality d of the system. This is demonstrated in Tables 1 and 2 where we also present B_{c}. The significance of B_{c} is discussed in Sec. 1.8.

1.3 Characteristics of Percolation Systems

In addition to p_{cb} and p_{cs}, the structure of percolation networks is characterized by several other quantities, the most important of which are as follows (for brevity, we use p_{c} to denote p_{cb} or p_{cs}).

The *percolation probability* $P(p)$ is the probability that, when the fraction of occupied bonds is p, a given site belongs to the sample-spanning cluster of occupied bonds.

The *accessible fraction* $P_{\text{A}}(p)$ is the fraction of the occupied bonds (or sites) belonging to the sample-spanning cluster.

The *backbone fraction* $P_{\text{B}}(p)$ is an important quantity in flow and transport in percolation systems. In such phenomena, the sample-spanning cluster, through which flow and

[a] Exact result.

transport occur, can be divided into two parts: the dead-end part that carries no flow or current, and the backbone, which is the multiply connected part of the cluster through which a fluid flows. The fraction of the occupied or conducting bonds in the backbone is $P_B(p)$, and clearly, $P_A(p) \geq P_B(p)$. Near the percolation threshold, the bonds in the backbone are also divided into two groups (Stanley, 1977): those in the *blobs* that are multiply connected and make the transport paths very tortuous, and the *red* bonds, which are those that, if cut, would split the backbone into two parts, and which thus control transport and flow through the backbone. Figure 4 shows a sample-spanning percolation cluster and its backbone on the square network.

The *correlation length* $\xi_p(p)$ is the typical radius of percolation clusters for $p < p_c$, and the length scale over which a percolation network is macroscopically homogeneous for $p > p_c$. For a very large network, ξ_p is the dominant length scale in the system. If the network is finite with a linear size L, then for $L > \xi_p$ the system is macroscopically homogeneous, while for $L < \xi_p$ it is inhomogeneous.

The average number of clusters of size s (per lattice site) $n_s(p)$ is an important quantity in some of the problems of interest here because it corresponds, for example, to the number of islands or blobs of a fluid that are formed during the displacement of that fluid by another fluid in a porous medium. The important task of calculating n_s is done efficiently by an algorithm due to Hoshen and Kopelman (1976). This algorithm is described in detail by Stauffer and Aharony (1992), where a computer program is also given for counting the clusters.

1.4 Flow and Transport Properties of Percolation Systems

Because a major application of percolation theory has been modeling of flow and transport in disordered media, and in particular porous media and composite solids, we must also consider the effective flow and transport properties of percolation systems, namely, their conductivity, diffusivity and permeability. We first consider the conductivity of percolation networks. Consider a two-component network in which each bond has a conduc-

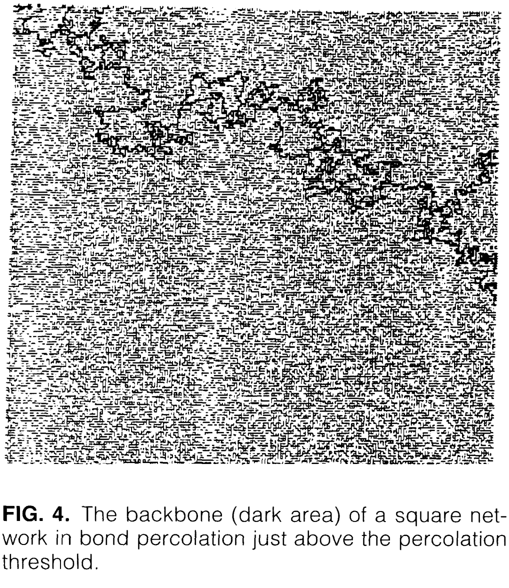

FIG. 4. The backbone (dark area) of a square network in bond percolation just above the percolation threshold.

tance g_1 with probability p or g_2 with probability $q = 1 - p$. It is straightforward to show that the effective conductivity G of the network is a homogeneous function and takes on the following form

$$G(p, g_1, g_2) = g_1 F(p, h), \tag{2}$$

where $h = g_2/g_1$, and F in a homogeneous function. By definition G is invariant under the interchange of g_1 and g_2, and therefore we must have

$$G(p, g_1, g_2) = G(q, g_2, g_1) \quad \text{and}$$

$$F(p, h) = hF(q, 1/h). \tag{3}$$

The limit in which $g_2 = 0$ and g_1 is finite corresponds to conductor-insulator mixtures. In this case, as $p \to p_c$, more and more bonds are insulating, and therefore the conduction paths become very tortuous and G decreases; at p_c one has $G(p_c) = 0$. The conductance g_1 can be distributed according to a given distribution, which is the case in most real disordered systems, such as porous media and composite solids.

The limit in which $g_1 = \infty$ and g_2 is finite represents superconductor–conductor mixtures. All quantum-mechanical aspects of real superconductors are ignored in this definition, and we are concerned only with the effect of the connectivity of the percolation system on this conductivity. (Application of percolation theory to granular superconductors is discussed in Sec. 5.) It is clear that the macroscopic conductivity G of this system is dominated by the superconducting bonds. If $p < p_c$, then a sample-spanning cluster of the superconducting bonds does not exist, and G is finite. As $p \to p_c^-$, G increases. At $p = p_c$ a sample-spanning cluster of the superconducting bonds is formed for the first time, and G diverges. The significance of superconducting percolation networks will be discussed in Sec. 2.3. Note that both cases correspond to $h = 0$, and therefore the point $h = 0$ at $p = p_c$ is particularly important.

In a similar way, the effective diffusivity D and hydrodynamic permeability K of the system are defined; namely, since fluid flow or diffusion occurs in the occupied bonds, the effective permeability and diffusivity are defined in a manner similar to the conductivity of conductor–insulator mixtures. Figure 5 shows the typical behavior of some of these properties for a simple-cubic network in site percolation.

1.5 Scaling Laws of Percolation

One of the most important characteristics of percolation processes is their universal properties. The behavior of many percolation

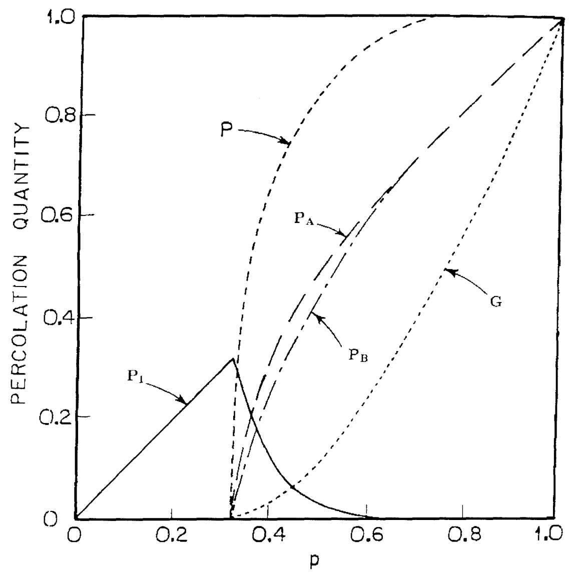

FIG. 5. Typical variations of the percolation quantities in site percolation on the simple cubic lattice. $P_I = P_A - P_B$ is the fraction of the isolated occupied sites.

quantities near p_c is insensitive to the network structure and to whether the percolation process is a site or a bond problem. The quantitative statement of this universality is that many percolation properties obey power laws near p_c, and that the critical exponents that characterize such power laws are universal and depend only on the Euclidean dimensionality d of the system. In general, near p_c we have the following power laws:

$$P(p) \sim (p - p_c)^{\beta}, \tag{4}$$

$$P_A(p) \sim (p - p_c)^{\beta}, \tag{5}$$

$$P_B(p) \sim (p - p_c)^{\beta_B}, \tag{6}$$

$$\xi_p(p) \sim |p - p_c|^{-\nu}, \tag{7}$$

$$G(p) \sim (p - p_c)^{\mu}, \tag{8}$$

$$G(p) \sim (p_c - p)^{-s}, \tag{9}$$

$$K(p) \sim (p - p_c)^{\chi}, \tag{10}$$

where Eqs. (8) and (9) refer to the conductor–insulator and conductor–superconductor cases, respectively. For length scales $L < \xi_p$, the resistance R between two end points of a box of linear size L scales with L as $R \sim L^{\tilde{\zeta}}$. It is not difficult to show that

$$\mu = (d - 2)\nu + \zeta, \tag{11}$$

where, $\zeta = \tilde{\zeta}\nu$. In 2D it has been shown that $\mu = s$.

Equations (8) and (9) can be unified by using the two-component resistor network described above. In the critical region where both $|p - p_c|$ and $h = g_2/g_1$ are small, G obeys the following scaling law (Efros and Shklovskii, 1976; Straley, 1976):

$$G \sim g_1 |p - p_c|^{\mu} \Phi_{\pm}(h|p - p_c|^{-\mu-s}). \tag{12}$$

where Φ_+ and Φ_- are two homogeneous functions corresponding, respectively, to the regions above and below p_c, and are, like μ and s, universal. For any fixed and nonzero h, G has a smooth dependence on $p - p_c$. This becomes clearer if we rewrite Eq. (12) as

$$G \sim g_1 h^{\mu/(\mu+s)} \Psi(|p - p_c| h^{-1/(\mu+s)}), \tag{13}$$

where

$$\Psi(x) = x^{\mu}\Phi_+(x^{-\mu-s}) = (-x)^{\mu}\Phi_-((-x)^{-\mu-s}).$$

The power law that characterizes the behavior of the effective diffusivity $D(p)$ near p_c is derived from that of $G(p)$. According to Einstein's relation, $G \sim \rho D$, where ρ is the density of the carriers. Although a diffusing species can move on all the clusters, above p_c only diffusion on the sample-spanning cluster contributes significantly to D, so that $\rho \sim P_A(p)$. Hence, $G(p) \sim P_A(p)D(p)$, and therefore

$$D(p) \sim (p - p_c)^{\mu-\beta}. \tag{14}$$

For large clusters near p_c, $n_s(p)$ obeys the following scaling law:

$$n_s \sim s^{-\tau} f((p - p_c)s^{\sigma}), \tag{15}$$

where τ and σ are two more universal critical exponents, and $f(x)$ is a scaling function such that $f(0)$ is not singular.

These topological exponents are not all independent. For example, one has $\tau = 2 + \beta\sigma$ and $\nu d = \beta + 1/\sigma$, and in fact knowledge of ν and another exponent is sufficient for determining most of the percolation exponents. However, no exact relationship is known between the flow and transport and the topological exponents. This is perhaps because the transport exponents describe dynamical properties of percolation systems, whereas the topological exponents describe the static properties, and in general there is no reason to expect a direct relationship between the two. The implied prefactors in the above power laws depend on the type of lattice and are not universal. If two phenomena are described by two different sets of critical exponents, the physical laws governing the two must be fundamentally different. Thus critical exponents can help one to distinguish between different classes of problems and the physical laws that govern them. Moreover, since the numerical values of the percolation properties are not universal and vary from one system to another system, but the scaling laws that they obey near p_c are universal and do not depend on the details of the system, the critical exponents are used for establishing the relevance of percolation to a given phenomenon in disordered media. In

1.6 Fractal Structures in Percolation Systems

As mentioned above, the correlation length ξ_p has the physical significance that for length scales $L > \xi_p$ the percolation system is macroscopically homogeneous. However, for $L < \xi_p$ the system is not homogeneous, and the macroscopic properties of the system depend on L. In this regime, the sample-spanning cluster is statistically self-similar at all length scales less than ξ_p. This means that if at such length scales we magnify or shrink the sample-spanning cluster, it looks the same. Under this condition the mass M of the sample-spanning cluster (its total number of occupied bonds or sites) scales with L as

$$M \propto L^{D_F}, \quad L < \xi_p, \tag{16}$$

where D_F is called the fractal dimension of the cluster. For $L > \xi_p$, $M \propto L^d$ and thus $D_F = d$, where d is the Euclidean dimension of the system. However, for fractal objects, $D_F < d$, implying that they do not fill the space in which they are embedded. The crossover between the two regimes takes place at $L \simeq \xi_p$. Thus, similar to Eqs. (12) and (13), we can combine the two regimes and write down a unified scaling equation for $M(L, \xi_p)$:

$$M(L, \xi_p) = L^{D_F} h(L/\xi_p), \tag{17}$$

where $h(x)$ is a scaling function. For $L \gg \xi_p$ ($x \gg 1$) we expect to have $M \sim L^d$, and hence $h(x) \sim x^{D_F - d}$, whereas for $x \ll 1$ we must have $h(x) \simeq$ constant. In the case of the sample-spanning percolation cluster D_F can be related to the other percolation exponents. The mass M of the sample-spanning cluster is proportional to $P_A(p)\xi_p^d$, since only a fraction $P_A(p)$ of all the occupied bonds or sites are in the cluster. Therefore, we must have $M \propto \xi_p^{d-\beta/\nu}$. For $L < \xi_p$ we must replace ξ_p with L, since now L is the dominant length scale of the system. Thus, $M \propto L^{d-\beta/\nu}$, which when compared with Eq. (16), yields

$$D_F = d - \beta/\nu, \tag{18}$$

so that $D_F(d = 2) = 91/48 \simeq 1.9$ and $D_F(d = 3) \simeq 2.53$. Similarly, for $L < \xi_p$, the backbone is also a fractal object, and its fractal dimension D_B is given by

$$D_B = d - \beta_B/\nu. \tag{19}$$

Herrmann and Stanley (1984) argued that the backbone at p_c is a *volatile* fractal, *i.e.*, its structure is not stable under a length scale change. Note that at $p = p_c$ the correlation length is divergent, so that at this point the sample-spanning cluster and its backbone are fractal objects at any length scale.

Near and at p_c, the number M_r of the red bonds in a box of linear size L, with $L < \xi_p$, scales with L as $M_r \propto L^{D_R}$, where D_R is the fractal dimension of the set of the red bonds. It has been shown (Coniglio, 1981) that

$$D_R = 1/\nu. \tag{20}$$

Another important concept is the minimum or chemical path between two points of a percolation cluster, which is the shortest path between the two points. For $L < \xi_p$ the length L_{min} of the path scales with L as

$$L_{min} \sim L^{D_{min}}, \tag{21}$$

so that D_{min} is the fractal dimension of the minimal path.

If $L < \xi_p$, *i.e.*, if the percolation system is in the fractal regime, all the percolation properties become scale dependent. Since $|p - p_c| \sim$

$\xi_p^{-1/\nu}$, one can rewrite Eqs. (4)–(10) and (14) in terms of ξ_p. For example, Eq. (4) is rewritten as $P(p) \sim \xi_p^{-\beta/\nu}$. For $L < \xi_p$ one replaces ξ_p by L, since now L is the dominant length scale in the system (for $L > \xi_p$ the correlation length is the dominant length scale), and therefore Eqs. (4)–(10) and (14) become

$$P(L) \sim L^{-\beta/\nu}, \tag{22}$$

$$P_{\mathrm{A}}(L) \sim L^{-\beta/\nu}, \tag{23}$$

$$P_{\mathrm{B}}(L) \sim L^{-\beta/\nu}, \tag{24}$$

$$G(L) \sim L^{-\mu/\nu}, \tag{25}$$

$$G(L) \sim L^{s/\nu}, \tag{26}$$

$$K(L) \sim L^{-\chi/\nu}, \tag{27}$$

$$D(L) \sim L^{-\theta}, \tag{28}$$

where $\theta = (\mu - \beta)/\nu$, and Eqs. (25) and (26) refer to the conductor–insulator and conductor–superconductor mixtures, respectively. Thus, *scale-dependent properties are a signature of a fractal structure.* Similar to the mass of the sample-spanning cluster for which we could write scaling Eq. (17), we can also write down scaling equations for length-scale dependence of all other percolation properties. For example, Eqs. (8) and (25) can be combined to yield

$$G(L, \xi_p) = \xi_p^{-\mu/\nu} w(L/\xi_p), \tag{29}$$

where $w(x)$ is a scaling function. Once it is established that a system is a fractal, many classical laws of physics have to be significantly modified. For example, Fick's law of diffusion with a constant diffusivity is no longer appropriate for describing diffusion processes in fractal systems; this is discussed in Sec. 3.3.

For random percolation, or for correlated percolation in which the correlations are short-ranged, all the topological critical exponents and the fractal dimensions are completely universal. The exponents μ, s, and χ are also universal if two conditions are satisfied. One is that there should not be any long-range correlations in the system. If the conductances of the bonds are distributed according to a distribution $\psi(g)$, then the second condition is (Kogut and Straley, 1979; Straley, 1982; Sahimi *et al.*, 1983a)

$$\psi_{-1} = \int_0^\infty \mathrm{d}x\, \psi(x)/x < \infty. \tag{30}$$

Moreover, for any percolation system that satisfies these two conditions, $\chi = \mu$. Percolation in some correlated or continuum systems violates one or both of these conditions. We now discuss percolation in such systems, which are also of practical importance.

1.7 Correlated Percolation

In the classical site- and bond-percolation problems discussed above, there are no correlations between various segments of the system. However, the nature of disorder in many important physical systems and phenomena is not completely random, and there usually exist some correlations. For example, in packing of solid particles, whose mechanical properties are described by the elastic percolation networks discussed in Secs. 6.1–6.3, there are some short-range correlations. In some other system, such as field-scale porous media, there are long-range correlations.

Thus, we divide all the correlated percolation models into two groups. In one group are those that contain short-range correlations. An example of this type of model is the correlated bond-percolation model due to Kirkpatrick (1973). In his model, which was intended for hopping conduction in disordered solids (see Sec. 4), to each site of a lattice is assigned a random number s_i, uniformly distributed between -1 and $+1$. Random numbers b_{ij} for the bonds are calculated by

$$b_{ij} = (|s_i| + |s_j| + |s_i - s_j|)/2, \tag{31}$$

and all the bonds with $b_{ij} > \varepsilon$ are removed, where ε is some selected value. Thus a bond remains conducting only if b_{ij} is sufficiently small, implying that $|s_i|$ and $|s_j|$ must both be small. This also means that if a bond is conducting, its neighbors are also likely to be conducting, and hence such bonds are clustered together. Another example of this type of model is the site-bond–correlated percolation problem developed by Coniglio *et al.* (1979). Their model was intended for gelation processes in which the effect of the solvent, which had been ignored in the original theories of Flory and Stockmayer, is taken into account. In their model each site of a lattice is occupied by either a monomer or a solvent molecule, and the probability that a bond is present depends on the relative interaction energy between its two end sites (monomer–monomer, monomer–solvent, solvent–solvent) and thus on the temperature of the system. A third example is a correlated-site percolation model developed by Stanley (1979; see also Stanley *et al.*, 1981) which was intended for explaining some unusual features of supercooled water. In this model, the bonds of a lattice are occupied randomly, as in random percolation. One then observes that each site can be considered to be a member of one of $Z+1$ different species, depending on whether $0, 1, 2, \ldots, Z$ bonds emanate from that site. Thus, a site is occupied only if, for example, all the Z bonds emanating from it are also occupied, and hence the presence or absence of a site depends on the bonds that are connected to it.

In the second class of correlated percolation models are those that contain long-range correlations, by which we mean those in which the extent of the correlations is comparable to the linear size of the system. A prime motivation for developing such models has been the observation that the permeability, porosity, and other properties of field-scale porous media, such as oil reservoirs and aquifers, are correlated with each other, with the extent of the correlations being comparable to the linear size of system. The first of such models was probably developed by Weinrib (1984). An example of such percolation models is that of Prakash *et al.* (1992), who considered a percolation model in which the correlation function $C(r)$ in a d-dimensional system, defined by

$$C(r) = \langle v(r')v(r+r')\rangle, \tag{32}$$

where $v(r)$ is a random variable obeying a distribution with long-range correlations and $\langle \cdot \rangle$ denotes an average over all values of r', given by

$$C(r) \sim r^{-(d-\lambda)}, \tag{33}$$

where $-2 \leq \lambda \leq 2$ is a parameter of the model, such that $0 \leq \lambda \leq 2$ represents positive correlations, while $-2 \leq \lambda \leq 0$ corresponds to negative correlations. Another model was developed by Sahimi and Mukhopadhyay (1996), in which the correlations between the conductances of the bonds of a networks were of the same type that one observes in the hydraulic conductances of field-scale porous media. They used their percolation model to derive several scaling laws for transport coefficients in flow through geological formations, with the results being in agreement with field observations.

Positive correlations usually reduce the percolation threshold of the system. For example, in Kirkpatrick's model, $p_{\mathrm{cb}} \simeq 0.1$ for the simple-cubic lattice, sharply lower than $p_{\mathrm{cb}} \simeq 0.2488$ for random bond percolation. However, Bug *et al.* (1985) showed by computer simulations that positive correlations may increase or decrease p_{c}, depending on the distance between two occupied sites that are considered, the dimensionality, and the temperature of the system. The effect of correlations in experimental percolation systems is discussed below.

As discussed above, the scaling properties of percolation systems with short-range correlations are the same as those of random percolation, if the length scale of interest is larger than the correlation length. For example, if the correlation function decays as r^{-d} or faster, where r is the distance between two points and d is the dimensionality of the system, then the critical properties of the systems are identical with those of random percolation. This is not totally unexpected because random percolation itself already has nonzero correlation function, and hence the introduction of any type of short-range correlation cannot change its scaling properties. However, with long-range correlations the scaling properties of such phenomena are nonuniversal. In the case of flow through porous media, this nonuniversality is consistent with field observations and data that indicate that there is not a unique scaling law (*i.e.*, unique critical exponent) for a given transport property, *i.e.*, the exponents change from field to field; see Sahimi and Mukhopadhyay (1996) for more details.

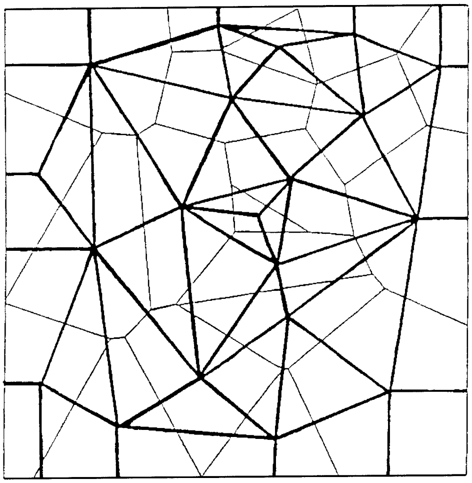

FIG. 7. Two-dimensional Voronoi tesselation of space (thin lines) and Voronoi network (thick lines).

1.8 Continuum Percolation

Although percolation in regular networks has been used extensively for investigating flow and transport in disordered media, percolation in continua is also of great interest, since most real disordered media can be represented as a continuum, at least up to certain length scales. There are at least three ways of realizing a percolating continuum. In the first method, one has a random distribution of inclusions, such as circles, spheres or ellipses, in an otherwise uniform system. Figure 6 shows the so-called Swiss-cheese model in which spherical (circular in 2D) inclusions are punched at random in an otherwise uniform system. If the spheres or circles are not overlapping, and if transport takes place through the channels between the inclusions (as in, for example, flow through a packed bed of solid particles), then the problem can be mapped exactly onto the same transport process on the edges of a Voronoi tessellation of space, a 2D example of which is shown in Fig. 7. Voronoi tessellation (see, for example, Winterfeld *et al.*, 1981) is made by distributing points randomly in the plane and drawing the perpendicular bisector between each pair of points. From the line segments formed by intersections of the perpendicular bisectors between a given point A and its neighboring points is constructed the convex polygon within which every point is closer to A than to any other point. The extension to 3D is obvious. If in the Voronoi tessellations one constructs a network by connecting the centers of the neighboring 3D polyhedra (polygons in 2D) to each other, one obtains a Voronoi network, which is used as a model of a random network (see Fig. 7). One can also construct an inverted Swiss-cheese model in which the roles of the two different media in the Swiss-cheese model are switched, *i.e.*, transport takes place through the inclusions (as in, for example, conduction in granular materials), in which case the problem can be mapped onto the Voronoi network. In both models it is assumed that all the inclusions have the same size. If this assumption is relaxed, then van der Marck (1996) has proposed a general method for mapping such continua onto equivalent network models.

In the second method, one generates a percolating continuum by dividing the space into regular or random polyhedra, a fraction of which is conducting while the rest of them are insulating. This is particularly useful for modelling transport in composite solids. Finally, in the third method, one distributes at random conducting sticks of a given aspect ratio, or plates of a given extent, and studies transport in such a system. This model has been proposed for representing fractured rock, and

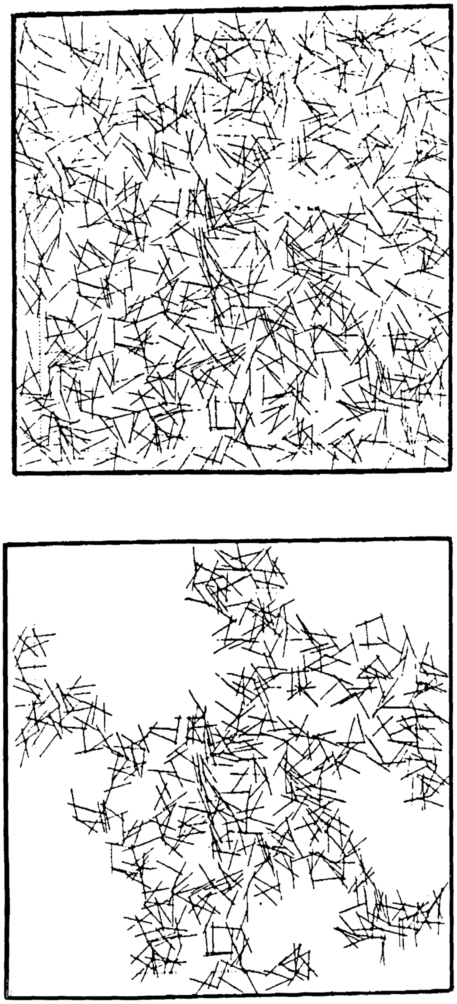

FIG. 8. A two-dimensional model of fibrous material (top) and its backbone (bottom).

also fibrous materials. An example is shown in Fig. 8.

One of the most important discoveries for continuum percolation (Scher and Zallen, 1970) is that the critical value of the occupied volume fraction ϕ_c, defined as

$$\phi_c = p_{cs} f_l, \tag{34}$$

where f_l is the filling factor of a lattice when each site of the lattice is occupied by a sphere in such a way that two nearest-neighbor impermeable spheres touch one another at one point, appears to be an almost invariant of the system, whose value is about 0.17 for 3D systems. Shante and Kirkpatrick (1971) generalized this idea to permeable spheres, and showed that the average number of bonds per sites $B_c = Zp_{cb}$ at p_c is related to ϕ_c by

$$\phi_c = 1 - \exp(-B_c/8), \tag{35}$$

and that the continuum B_c is the limiting value of $p_{cs}Z$ when Z becomes large. It is clear from Table 2 that in 3D, $B_c \simeq 1.5$, and hence $\phi_c \simeq 0.17$, in agreement with the discovery of Scher and Zallen.

It has been established that the topological exponents, defined by Eqs. (4)–(7) and (15), are the same for lattice and continuous systems. For example, Jerauld *et al.* (1984) showed that these exponents for random networks, such as the Voronoi networks, are the same as those for regular networks. Moreover, they established that as long as the average coordination number of a regular network and that of a topologically random network are about the same, most transport properties of the two systems are, for all practical purposes, identical, so long as the same distribution of the transport properties is used in both networks. For example, a 2D Voronoi network has an average coordination number of about six, and the triangular network's coordination number is exactly six.

However, if one uses the equivalent network of a given continuum, one can no longer assign the transport properties of the bonds from an arbitrary distribution, because there is a natural distribution of the conductances of the transport channels in the continuum that can be constructed on the basis of the particular shapes and sizes that the channels take on. Such natural distributions give rise to new scaling laws which cannot be predicted by the network models, unless the same natural distributions are also used in the networks. To see the difference between flow and transport in random percolation networks and continua, we consider a few examples that have been studied thoroughly. It was shown by Halperin *et al.* (1985) and Feng *et al.* (1987) that the scaling of the transport properties of the Swiss-cheese and the inverted Swiss-cheese models near their percolation thresholds is very different from those of percolation networks. In particular, if μ_{sc} and μ_{isc} denote the critical exponents of the conductivity of the Swiss-cheese and the inverted Swiss-cheese models, then in 2D $\mu_{\text{sc}} = \mu_{\text{isc}} = \mu$, while in 3D $\mu_{\text{isc}} = \mu$ and

$$\mu_{\text{sc}} \simeq \mu + 1/2. \tag{36}$$

Moreover, unlike the case of lattice percolation discussed above (for which $\chi = \mu$), the permeability exponent of continuum percolation is very different from the conductivity exponent μ. In 2D, $\chi_{\text{isc}} = \mu$ and

$$\chi_{\text{sc}} \simeq \mu + 3/2, \tag{37}$$

whereas in 3D

$$\chi_{\text{sc}} \simeq \mu + 5/2, \quad \chi_{\text{isc}} = \mu + 1/2, \tag{38}$$

so that the permeability is much more strongly affected by the continuous structure of the system. It was also shown by Straley (1982), Halperin *et al.* (1985), and Feng *et al.* (1987) that if the conductance distribution of a random continuum is of power-law form, $\psi(g) = (1-p)\delta(g) + p(1-\alpha)g^{-\alpha}$, where $0 \leq \alpha \leq 1$, then the conductivity exponent $\mu(\alpha)$ of this systems is not universal and is given by

$$\begin{aligned}\mu_1(\alpha) &= 1 + (d-2)\nu + \frac{\alpha}{1-\alpha} \\ &\leq \mu(\alpha) \leq \mu + \frac{1}{1-\alpha}.\end{aligned} \tag{39}$$

Such power-law conductance distributions are actually very common among disordered continua. For example, for the Swiss-cheese models in d dimensions, one has $\alpha = (2d-5)/(2d-3)$. In 2D, $\alpha = -1$, and the conductance distribution is not singular at $g = 0$ [inequality (30) is satisfied], and therefore $\mu_{\text{sc}} = \mu$. In 3D, $\alpha = 1/3$, and the conductance distribution is singular at $g = 0$, hence giving rise to Eq. (39). Moreover, Straley (1982) argued that

$$\mu(\alpha) = \min[\mu, \mu_1(\alpha)]. \tag{40}$$

These results have not only been confirmed by computer simulations, they have also received experimental verification (see, for example, Garfunkel and Wiessman, 1985).

1.9 Calculation of Flow and Transport Properties of Percolation Systems

Let us now discuss how flow and transport properties of percolation systems are estimated. Here we review briefly a few of the methods that have proven to be efficient and, at least under certain conditions, accurate.

1.9.1 Monte-Carlo Simulation This method is the most accurate technique for estimating flow and transport properties of percolation networks, although extensive numerical work may be involved. We first discuss calculation of the effective conductivity of a percolation network. According to Kirchhoff's law, for every site of the network the sum of all the currents reaching it is zero. Thus, if J_{ij} is the current in the bond ij, then for site i of the network we must have $\sum_j J_{ij} = 0$. Since according to Ohm's law, $J_{ij} = (V_i - V_j)g_{ij}$, where V_i is the voltage or potential at i, and g_{ij} is the conductance of the bond ij, we obtain

$$\sum_j (V_i - V_j)g_{ij} = 0. \tag{41}$$

Equation (41), when written for every interior site of the network, yields a set of simultaneous linear equations for the nodal voltages or potentials. As the boundary conditions, one typically imposes a fixed voltage drop between two opposite faces of the network and periodic boundary conditions in the other direction(s). Alternatively, one can use a constant-current boundary condition in which a fixed current is injected into the network at one or several sites. The set of equations is typically solved by an efficient iterative algorithm such as the conjugate-gradient method. Having solved the set, one can easily determine the overall conductivity G of the network. For example, if as the boundary condition a constant voltage drop has been imposed on the network, G is determined by calculating the total current that flows through the network, and dividing it by the applied voltage drop. One can use exactly the same method for calculating the effective thermal conductivity of a composite solid.

The number of iterations for the convergence of the set of equations to their true solution increases rapidly as $p \to p_c$. To avoid this difficulty, special methods have been devised that build up the network one bond at a time (Derrida *et al.*, 1984b; Duering and Bergman, 1990), or take advantage of laws of electrical networks (Gingold and Lobb, 1990). However, these methods are most efficient near p_c, but not far from it. For an efficient method both near and away from p_c see Mehrabi and Sahimi (1997).

The same type of Monte-Carlo simulation can also be used for calculating the effective permeability K or diffusivity D of a porous medium, modeled by a percolation network. Consider, for example, the problem of estimating K. Each occupied bond represents a pore throat through which a fluid flows, while each site represents a pore body at which the throats meet. A porous medium is typically represented by a pore size distribution $\Psi(r)$, so that we assign an effective radius r, selected from $\Psi(r)$, to the bonds. Assuming, for example, that the flow is laminar, the volumetric flow rate in the throat ij is given by, $Q_{ij} = \pi(P_i - P_j)r_{ij}^4/(a\eta l_{ij})$, where P_i is the pressure at i, η is the viscosity of the fluid, l_{ij} is the throat (bond) length, and a is a constant geometrical factor that depends on the shape of the throats. We must have conservation of mass at every site i of the network, *i.e.*, the net mass of the fluid reaching i must be zero, and therefore, $\sum_j \rho Q_{ij} = 0$. If the fluid density ρ is constant, and if the pressure drops in the sites are negligible (which is often true, as the pore bodies are typically much larger than the throats which are long and narrow), then we must have

$$\sum_j \pi(P_i - P_j)r_{ij}^4/(a\eta l_{ij}) = 0, \qquad (42)$$

which is completely analogous to Eq. (41). The rest of the analysis is obvious: writing down Eq. (42) for each site i of the network yields a set of simultaneous equations for the nodal pressures, from the solution of which the effective permeability K of the network is computed in a manner completely similar to G. The same type of model and method can also be used for estimating the effective diffusivity of the network.

1.9.2 Effective-Medium Approximation

One of the simplest, and in many cases accurate, analytical methods of estimating effective transport properties of disordered media is the effective-medium approximation (EMA). The original EMA was developed by Bruggeman (1935), and independently by Landauer (1952; for a review of history of the EMAs see Landauer, 1978) for a continuum. It was extended by Kirkpatrick (1973) to regular networks of random conductances, and has been shown to be accurate under a variety of conditions.

We first consider estimating the effective conductivity of a percolation network by an EMA. Consider a network of coordination number Z, and suppose that the conductance of the bonds is selected from a distribution $\psi(g)$. In an EMA approach, the random conductances of all the bonds are replaced by G to create a uniform network. The potential differences along the bonds of such a network are known exactly. One then replaces, in the uniform network, the effective conductance of one bond with its true value g, which causes fluctuations in the potential difference in that bond with respect to its value in the uniform network. One insists that the average of these fluctuations, when the averaging is taken with respect to $\psi(g)$, should be zero. This results in a simple equation for G given by (Kirkpatrick, 1973)

$$\int_0^\infty \frac{G - g}{g + G(Z/2 - 1)} \psi(g)\, \mathrm{d}g = 0. \qquad (43)$$

If we use a percolation distribution (which corresponds to bond percolation)

$$\psi(g) = (1 - p)\delta(g) + (1 - p)\delta(g - g_0), \qquad (44)$$

then it is easy to see that Eq. (43) predicts that G vanishes at $p_{cb} = 2/Z$. Thus, EMA predicts the exact value $p_{cb} = 1/2$ for the square lattice, and $p_{cb} = 1/3$ for the simple cubic lattice, which should be compared with the numerical estimate $p_{cb} \simeq 0.2488$. Moreover, EMA predicts that the critical exponent $\mu = 1$, which does not agree with the numerical estimates (see Table 3). For a d-dimensional disordered continuum with randomly distributed spherical or circular inclusions, Eq. (43) can still be used if $Z/2$ is replaced by d.

We can also use an EMA for estimating the permeability and diffusivity of a porous medium. Consider an effective-medium network in which each bond or pore throat has a conductance G. We fix the pressures at two opposite faces of the network so as to produce an average pressure gradient $\langle \nabla P\rangle$. The total volume Q of fluid crossing any plane perpendicular to the average pressure gradient is the sum of the individual fluid volumes in the bonds intersecting the plane. If we approximate the local pressure difference as the projection of the average pressure gradient along the bond length l, we find

$$Q = \sum \frac{G}{\eta} \langle \nabla P\rangle \cdot \boldsymbol{l}. \tag{45}$$

If we divide Q by the area S of the plane, we obtain an average velocity and hence an estimate of the permeability:

$$K = G\left\langle \frac{1}{S} \sum \boldsymbol{l} \cdot \boldsymbol{n} \right\rangle, \tag{46}$$

where $\mathbf{n}$ is a unit vector along the pressure gradient. However, if the porous medium is statistically homogeneous and isotropic, any unit vector can be used. As in the case of the conductivity, EMA predicts that the critical exponent of the permeability is $\chi = 1$.

The effective diffusivity D of the porous medium can also be estimated by an EMA. It is not difficult to show that

$$D = \frac{1}{3\pi} \frac{Gl}{\langle r^2\rangle} \varphi, \tag{47}$$

where φ is the porosity of the porous medium, and $\langle r^2\rangle = \int_0^\infty r^2 \Psi(r)\,\mathrm{d}r$, where $\Psi(r)$ is the pore size distribution of the porous medium. Note that in both Eqs. (46) and (47), G is the EMA estimate of the conductivity of the network. The accuracy of the EMA has been checked under a wide variety of conditions. In general, it is very accurate if the system is not close to its percolation threshold, regardless of the structure of $\psi(g)$ or $\Psi(r)$. It is also more accurate for 2D systems than 3D ones. We refer the reader to Koplik (1981) and Doyen (1988) for typical experimental and Monte-Carlo tests of the EMA's accuracy.

1.9.3 Position-Space Renormalization Group Method If the disorder is strong, or if the system is near its percolation threshold, then the EMA is no longer accurate. In such cases, a position-space renormalization-group (PSRG) method is more accurate. Consider, for example, a square or a cubic network in which each bond is occupied (conducting) with probability p. In a PSRG approach one partitions the network into $b \times b$ or $b \times b \times b$ cells (this corresponds to bond percolation), where b is the number of bonds in any direction, and calculates their percolation properties, which are hopefully representative of the properties of the original network. The shape of the cell can be selected arbitrarily, but it should be chosen in such a way that it preserves, as much as possible, the properties of the original network. Figure 9 presents examples of such RG $b = 2$ cells for the square and cubic networks, which have been shown to yield the most accurate results for these networks. The next step in a PSRG method is to replace each RG cell with one bond in each principal direction. If in the original network each bond is conducting with probability p, then the bonds that replace the cells would be conducting with probability $p' = R(p)$ (see Fig. 9), where $R(p)$ is called the *renormalization-group transformation*, and is the sum of the probabilities of all possible conducting configurations of the RG cell, which is obtained as follows. We solve for the percolation and transport properties in each cell by applying a fixed potential difference across the cell in a given direction. For exam-

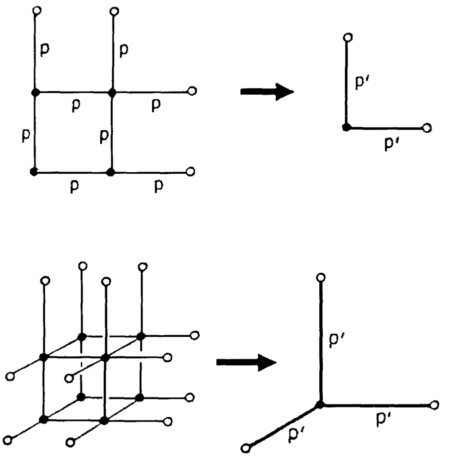

FIG. 9. Two- and three-dimensional RG cells with $b = 2$. $p' = R(p)$ is the RG transformation.

ple, as far as percolation and transport are concerned, the 2 × 2 cell of Fig. 9 is equivalent to the circuit shown there. Thus for this RG cell we only need to deal with five bonds, and for the 2 × 2 × 2 cell we have an equivalent 12-bond circuit (see Fig. 9). To obtain $R(p)$, we find all the conducting configurations of such circuits, with some bonds conducting and some insulating. Thus for the 2 × 2 cell we obtain

$$p' = R(p) = p^5 + 5p^4q + 8p^3q^2 + 2p^2q^3, \tag{48}$$

where $q = 1 - p$. It is easy to see how Eq. (48) is obtained: there is only one conducting cell configuration with all five bonds conducting (probability p^5), five conducting configurations with four bonds conducting and one bond insulating (probability $5p^4q$), and so on.

To obtain an estimate of p_c, we solve the following equation:

$$R(p_c) = a, \tag{49}$$

where $0 < a < 1$ is any arbitrary number. Often $a = p_c$ gives the most accurate results. For example, for the RG cells of Fig. 9 we obtain the exact result $p_c = 1/2$ for both $b = 2$ and $b = 3$ cells, if we use $a = p_c$. In fact, it can be shown (Bernasconi, 1978) that the RG transformation for such 2D cells for any b always predicts $p_c = 1/2$, if one uses $a = p_c$. For the 2 × 2 × 2 cell we obtain $p_c \simeq 0.208$, compared with the numerical estimate $p_{cb} \simeq 0.2488$. One then calculates p_c for several cell sizes b and uses finite-size scaling according to which

$$p_c(\infty) - p_c(b) \sim b^{-1/\nu}, \tag{50}$$

where $p_c(\infty)$ is the true percolation threshold of the network and ν is the critical exponent of the percolation correlation length ξ_p, to extrapolate the results to $b \to \infty$ and estimate p_c (Reynolds *et al.*, 1980). The critical exponent ν of the correlation length is estimated from $\xi'_p = \xi_p/b$, or

$$\nu = \ln b/\ln \lambda_p, \tag{51}$$

where $\lambda_p = dR(p)/dp$, evaluated at p_c. Thus for the 2 × 2 and 3 × 3 cells we obtain $\nu \simeq 1.43$ and 1.38, respectively. For the 2 × 2 × 2 cell we obtain $\nu \simeq 1.03$, compared with the numerical estimate, $\nu \simeq 0.88$.

In a PSRG approach for calculating the conductivity (or permeability) of a network (Stinchcombe and Watson, 1976), one starts with a conductance (or permeability) distribution $\psi_0(g)$ for the bonds of the RG cell and replaces it with a new distribution $\psi_1(g)$, the distribution for the conductance of a bond in the renormalized RG cell. The $\psi_1(g)$ value is calculated by determining the equivalent conductance of the RG cell. Thus one obtains a recursion relation relating $\psi_1(g)$ to $\psi_0(g)$:

$$\psi_1(g) = \int \psi_0(g_1)\, dg_1 \psi_0(g_2)\, dg_2 \cdots \psi_0(g_n) \times dg_n \delta(g - g'), \tag{52}$$

where $g_1, \ldots, g_n$ are the conductances of the n bonds of the cell and g' is the equivalent conductance of the RG cell. For example, for the five-bond cell of Fig. 9 one has

$$g' = \frac{g_1(g_2g_3 + g_2g_4 + g_3g_4) + g_5(g_1 + g_2)(g_3 + g_4)}{(g_1 + g_4)(g_2 + g_3) + g_5(g_1 + g_2 + g_3 + g_4)}, \tag{53}$$

and it is not difficult to show that, if we use distribution (44), then for the five-bond RG cell of Fig. 9, Eq. (52) yields

$$\begin{aligned}\psi_1(g) = {} & [1 - R(p)]\delta(g) + 2p^3q^2\delta(g - g_0/3) \\ & + 2p^2(1 + 2p)q^2\delta(g - g_0/2) \\ & + 4p^3q\delta(g - 3g_0/5) \\ & + p^4\delta(g - g_0).\end{aligned} \tag{54}$$

One iterates Eq. (52) again to obtain a new distribution $\psi_2(g)$ by substituting $\psi_1(g)$ into the right-hand side of Eq. (52). The iteration process continues until a distribution $\psi_\infty(g)$ is obtained, the shape of which does not change under further iterations. This is called the *fixed-point distribution*, and the conductance of the original network is simply an average of this distribution. However, it is difficult to iterate Eq. (52) analytically many times. The common practice is to replace $\psi_i(g)$ after iteration i by an *optimal* distribution $\psi_i^{\rm o}(g)$, which mimics $\psi_i(g)$ closely. The optimal $\psi_i^{\rm o}(g)$ is usually taken to have the form

$$\psi_i^{\rm o}(g) = [1 - R(p)]\delta(g) + R(p)\delta[g - g^{\rm o}(p)], \tag{55}$$

where $g^{\rm o}(p)$ is an optimal conductance. One of the most accurate approximations to $g^{\rm o}(p)$ was proposed by Bernasconi (1978). If after i iterations $\psi_i(g)$ is given by

$$\psi_i(g) = [1 - R(p)]\delta(g) + \sum_i a_i(p)\delta(g - g_i), \tag{56}$$

then $g^{\rm o}(p)$ is approximated by

$$g^{\rm o}(p) = \exp\left[\sum_i a_i(p) \ln g_i / R(p)\right]. \tag{57}$$

Once $g^{\rm o}(p)$ is calculated, Eq. (52) is iterated again, a new distribution $\psi_{i+1}(g)$ and the associated $\psi_{i+1}^{\rm o}(g)$ are determined, and so on. In practice, after a few iterations even an initially broad $\psi_0(g)$ converges quickly to a distribution whose shape does not change under further rescaling. When this happens, $\lambda_{\rm c}\psi_{n+1}(\lambda_{\rm c}g) \simeq \psi_n(g)$, where $\lambda_{\rm c}$ is a constant. The critical exponent μ of the conductivity is then given by

$$\mu = \nu \ln \lambda_{\rm c} / \ln b. \tag{58}$$

For the 2×2 RG cell of Fig. 9 we obtain $\mu \simeq 1.32$, and for the 3D cell of Fig. 9, $\mu \simeq 2.14$. These results should be compared with the numerical estimates given in Table 3. Moreover, the predicted conductivities in 2D are in good agreement with the simulation results, but are not as accurate in 3D (Bernasconi, 1978).

Renormalization methods are usually very accurate for 2D systems. However, they have a main drawback for 3D systems, in that the predicted conductivity or permeability for a percolation network with any type of $b = 2$ cell is not accurate, if the network is near $p_{\rm c}$. Moreover, even after the first iteration of (52) the renormalized conductance distribution $\psi_1(g)$ is very complex, making the computations very difficult.

1.9.4 Renormalized Effective-Medium Approximation Sahimi *et al.* (1983b, 1984) proposed a new method that combines EMA and PSRG, and is called the renormalized EMA (REMA). Their method takes advantage of two main strengths of EMA and PSRG, which are the facts that an EMA is accurate away from $p_{\rm c}$, and that when we rescale an RG cell, the renormalized cell is farther away from $p_{\rm c}$ than the original cell (because in the renormalized cell, $\xi_p' = \xi_p/b$). Thus one may use Eq. (43) with the renormalized conductance distribution $\psi_1(g)$, instead of $\psi_0(g)$. This method is drastically more accurate than both EMA and PSRG in both 2D and 3D. For example, with the 3D RG cell of Fig. 9, REMA predicts that $p_{\rm cb} \simeq 0.267$, only 7% larger than $p_{\rm cb} \simeq 0.2488$ for the cubic network. In general, if $R(p)$ is the RG transformation, REMA predicts that $p_{\rm cb}$ is the root of $R(p_{\rm cb}) = 2/Z$. Using REMA, Sahimi *et al.* (1983b, 1984) and Sahimi (1988) obtained very accurate predictions of transport properties of various 2D and 3D networks; an example is given in Fig. 10.

Having defined and discussed the basic concepts of percolation theory, and various methods for estimating the flow and transport properties of percolation systems, we now embark on discussing their applications.

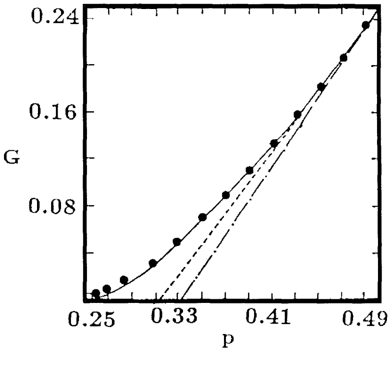

FIG. 10. Comparison of the predictions of the REMA for the conductivity G of a simple cubic network (solid curve) with those of the EMA (dash-dotted line), the cluster EMA (dashed line) and Monte Carlo results (circles).

2. APPLICATION TO COMPOSITE MATERIALS

Composite materials and media constitute a large and important class of naturally occuring or man-made disordered systems. Included in this class are granular materials, composite solids, metal–insulator films, porous media, polymers and aggregates, colloids, and many others. In this section we discuss the application of percolation theory to predicting the effective properties of such materials. Far from p_c, the effective properties of composite materials are predicted accurately by the EMA and PSRG methods discussed above; the interested reader should consult Lafait and Tanner (1989) and Cody *et al.* (1990) for discussion and references. Thus, we restrict our discussion to the scaling behavior of the composites near p_c where percolation effects are dominant and universal power laws should be observed. The existence of the universal scaling laws of percolation theory is the most stringent test of applicability of the theory. It is also often true that the critical region is quite broad, and therefore such universal scaling laws can be very useful for predicting the effective properties of a composite medium over a broad range of the volume fraction of its components.

2.1 Conductivity of Granular Media

One of the simplest 3D composite solids is a random packing of hard spheres, whose effective properties are relevant to those of a wide variety of systems of practical importance. For example, if all or some of the spheres are conducting, the packing is a model for the (electrical or thermal) conductivity of powders and other granular media. If in the pore space between the spheres a fluid flows, the packing is used for studying flow phenomena in unconsolidated porous media.

The first systematic and extensive study of percolation and conduction properties of packings of particles was carried out by Ottavi *et al.* (1978). They used molded plastic spheres a fraction of which were electroplated with a copper coating to make them conducting. Their data, shown in Fig. 11, indicate that the effective conductivity G vanishes at $p_c \simeq 0.29 \pm 0.02$. Since the filling factor f_1 (see Sec. 1.8) of such packings is about 0.6, one obtains

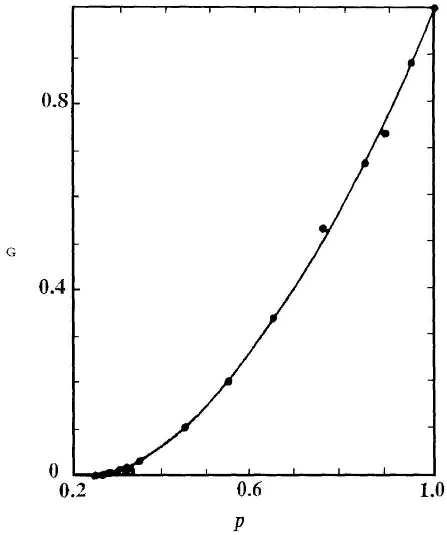

FIG. 11. Conductivity of a mixture of conducting and nonconducting spheres *versus* the fraction p of the conducting spheres (after Ottavi *et al.*, 1978).

$\phi_c = f_1 p_c \simeq 0.17$, in agreement with the prediction of Scher and Zallen (1970) for continuum percolation discussed above. In the critical region, their data followed Eq. (8) with $\mu \simeq 1.7 \pm 0.2$, not too far from $\mu \simeq 2.0$ for 3D percolation (see Table 3).

Similar studies were carried out by Deptuck *et al.* (1985), who investigated conduction in a sintered, submicrometer silver powder (and also its Young's modulus; see Sec. 6.3) with a volume fraction $\phi \sim 0.4$, commonly used for millikelvin and submillikelvin cryostats, and found that the conductivity vanishes with a critical exponent $\mu \simeq 2.15 \pm 0.25$, completely consistent with $\mu \simeq 2.0$ for 3D percolation (see Table 3); by Lee *et al.* (1986), who used silver-coated-glass–Teflon composites and found that $\phi_c \simeq 0.17$, in good agreement with the percolation threshold of 3D continuum percolation predicted by Scher and Zallen (1970), and $\mu \simeq 2.0 \pm 0.2$, in excellent agreement with that of 3D percolation; by Deprez *et al.* (1989), who measured the electrical conductivity of sintered nickel samples, and also found that Eq. (8) (with $\mu \simeq 2.0$) was applicable over the *entire range* of the volume fraction; and by Hsu and Berzins (1985), who studied percolation effects in a polymer composite, namely, perfluorinated ionomers, which have the general formula $[(CF_2)_n\ CF]_m$–O–R–SO_3X, where typically $n = 6$–13, R is a perfluoro alkylene group which may contain ether oxygen, and X is any monovalent cation. These composites possess exceptional transport, chemical, and mechanical properties, and have been used as membrane separators, acid catalysts, and polymer electrodes. Percolation effects are important in these composites because of a spontaneous phase separation occuring in the wet polymer, which is the conductive aqueous phase distributed randomly in the insulative fluorocarbon phase. Hsu and Berzins (1985) found that their data for the electrical conductivity of these polymer composites follow Eq. (8) with $\mu \simeq 2.0$ over the wide range $0.01 \leq p - p_c \leq 0.8$. For the most recent experimental work see Andrade *et al.* (1998), who studied the conductivity of vapor-grown carbon fiber (VGCF). They observed a percolation transition as the density of compressed VGCF was changed, with a conductivity exponent $\mu \simeq 1.91 \pm 0.06$, fully compatible with 3D percolation.

Another important class of composite solids whose electrical conductivity has been modeled by percolation theory is dispersed ionic conductors. Mixtures of solid ionic conductors that consist of fine particles and an insulating second phase exhibit a remarkable increase in their conductivity when compared with pure and homogeneous systems. For example, if we add small particles of an insulating phase, *e.g.*, Al_2O_3, to ionic conductors, such as LiI or AgI, the conductivity of the composite is enhanced by a few orders of magnitude. It is generally believed that this effect is caused by an enhanced conductivity along the interface between the conducting matrix and the dispersant particles. Bunde *et al.* (1985) and Roman *et al.* (1986) proposed a percolation model for predicting the conductivity of such composites. In their model one starts with a simple cubic lattice in which the elementary cubes are occupied randomly with probability p. The bonds that connect two neighboring sites are considered as resistors, and three types of resistors are recognized:

- **(1)** highly conducting bonds with interface conductance g_1;
- **(2)** normally conducting bonds with conductance g_2;
- **(3)** insulating bonds with zero conductance.

The bonds are highly conducting if they belong to one, two or three occupied cubes, and are insulating if they belong to four occupied cubes. The rest of the bonds are normal conductors. Thus, the fractions of the insulating, normally conducting and highly conducting bonds are, respectively, $p_3 = p^4$, $p_2 = (1-p)^4$, and $p_1 = 1 - p^4 - (1-p)^4$. There are also two percolation thresholds in the system. One of them, p_{c1}, defines the lowest concentration of the highly conducting bonds at which a sample-spanning cluster of such bonds is formed. The second one, p_{c2}, defines the percolation threshold where all the normal and insulating bonds get disrupted. In the simple cubic network, $p_{c1} \simeq 0.097$ and $p_{c2} = 1 - p_{c1} \simeq 0.903$. At both thresholds one has $p_3 \simeq 0.335$, somewhat larger than $p_{cb} \simeq 0.2488$ for the bond-percolation threshold of random two-component systems discussed above. Bunde *et al.* (1985) and Roman *et al.* (1986) showed that the electrical conductivity of this system exhibits a maximum as p is varied, in agreement with the experimental data, if p is interpreted as the mole fraction of the insulating phase. Roman (1990) extended this lattice model to continuous systems using random distribution of spheres; see also Lauer and Maier (1992).

Many composite materials are anisotropic, and the anisotropy influences their effective properties near p_c. However, the anisotropy should vanish at p_c, since near p_c the conducting paths are so tortuous that the current cannot distinguish between different directions. Indeed, Shklovskii (1978) proposed that the anisotropy ratio G_l/G_t obeys the following power law near p_c:

$$G_l/G_t - 1 \sim (p - p_c)^{\lambda}, \tag{59}$$

where G_l and G_t are the longitudinal and transverse conductivities and λ is a universal critical exponent; in 3D, $\lambda \simeq 0.5$ (Mukhopadhyay and Sahimi, 1994). If the system always remains conducting (as in a mixture of good and poor conductors), then the anisotropy should be minimum at p_c. The conductivity of anisotropic systems can also be predicted by an EMA (Bernasconi, 1974), and indeed EMA predicts that the conductivity anisotropy vanishes at p_c. These predictions of percolation theory have been confirmed by the experimental data of Smith and Lobb (1979), who measured the conductivities of 2D conductor–insulator networks generated photolithographically from laser speckle patterns; by those of Troadec *et al.* (1981), who measured thermal and electrical conductivity of conducting (WTe_2) and semiconduting (WSe_2) powders, characterized both by a geometrical anisotropy (grain shapes and sizes) and by anisotropy in a transport property; and by the results of Balberg *et al.* (1983), who measured the resistivity of a composite composed of elongated carbon black aggregates embedded in an insulating plastic, poly(vinyl chloride) (anisotropy of the system is due to elongation of the aggregates).

2.2 Percolation and Transport Properties of Metal–Insulator Films

Thin metal films are two-phase mixtures of metal and nonmetal components, which have interesting structural and transport properties. If the volume fraction of the metallic phase is large enough, it forms a sample-spanning cluster such that the electrical conductivity of the film is large and its temperature coefficient of resistance is positive. On the other hand, if the nonmetallic phase forms a sample-spanning cluster, the system is in the dielectric regime with a very small electrical conductivity. Transmission electron microscopy shows that thin metal films have a discontinuous structure in which the metallic phase constitutes only a fraction of the total volume of the system. Generally speaking, a metal film is considered as thin if its thickness l is less than the percolation correlation length ξ_p of the corresponding 3D film. Thick composite films also have interesting properties. Examples of such composites are Ni–SiO_2, Al–Si and Al–Ge. There are also strong correlations in the structure of thick metal films, so that a sort of correlated percolation may be applicable. Deutscher *et al.* (1978) proposed that thick metal films should be considered as random composites if the insulating phase is crystalline.

Percolation studies of thin (2D) metal films appear to have been begun by Liang *et al.* (1976), using SiO films deposited on a glass slide from a microscope. They found that the conductivity of the film near ϕ_c, the percolation threshold of the conducting phase, follows Eq. (8) with $\mu \simeq 1.15$, reasonably close to $\mu \simeq 1.3$ for 2D percolation. Important studies of morphological properties of thin metallic films were carried out by Voss *et al.* (1982) and Kapitulnik and Deutscher (1982). Voss *et al.* prepared Au films by electron-beam evaporation onto 30-nm-thick amorphous Si_3N_4 windows grown on an Si wafer frame. Figure 12 shows one of their samples at a fractional Au coverage $p \simeq 0.71$, just below $p_c \simeq 0.74$. At p_c the largest Au cluster was a fractal object with $D_F \simeq 1.9$, in excellent agreement with 2D percolation (see Table 3). Kapitulnik and Deutscher (1982) prepared samples by successive deposition of amorphous Ge as the substrate and of thin Pb films as the metal. Their study indicated that the sample-spanning cluster and its backbone exhibit fractal behavior, with $D_F \simeq 1.9$ and $D_B \simeq 1.65$, in excellent agreement with 2D percolation (see Table 3). Also analyzed was n_s, the number of metallic clusters of mass s below p_c, which was found to follow Eq. (15) with $\tau \simeq 2.1 \pm 0.2$, completely consistent with $\tau = 187/91 \simeq 2.054$ for 2D percolation. Similar results were obtained by Laibowitz *et al.* (1982), who used thin Al–Al_2O_3 films, by Gordon and Goldman (1988), who used Al thin films, and by Papandreou and Nédellec (1992), who used Pd films with a

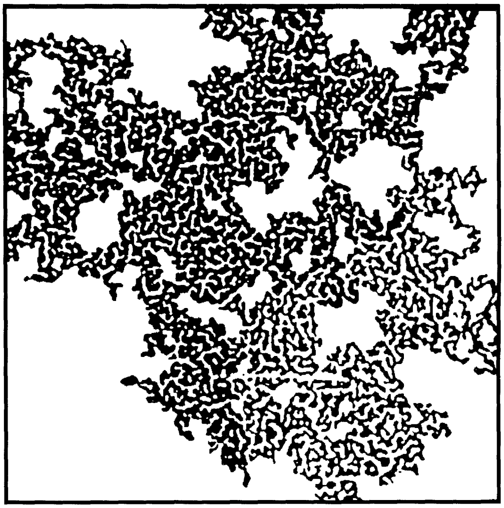

FIG. 12. Two-dimensional Au clusters at $p \simeq 0.71$ (after Voss *et al.*, 1982).

typical thickness of about 10 nm. The last authors also found a conductivity exponent $\mu \simeq 1.3$, in complete agreement with 2D percolation (see Table 3).

In a seminal paper, Abeles *et al.* (1975) studied the growth of the grains of the metals W or Mo in the insulators Al_2O_3 or SiO_2 using co-sputtering. Their measured conductivity exponent, $\mu \simeq 1.9 \pm 0.2$, is in very good agreement with $\mu \simeq 2.0$ for 3D percolation (see Table 3). Similar results were also reported by Kapitulnik and Deutscher (1983), who used Al–Ge films and found that $\mu \simeq 2.1 \pm 0.5$. More recent experimental data for In–Ge thin films were given by Tessler and Deutscher (1989), and for Al–Ge films by Kapitulnik *et al.* (1990). Finally, we should mention that optical properties of percolating metal films have also been measured and explained. The reader is referred to Yagil and Deutscher (1988), Gadenne and Gadenne (1989), Gadenne *et al.* (1989), and Robin and Souillard (1989) for details.

2.3 ac Conductivity and Dielectric Properties of Composite Media

An EMA can be used for predicting the ac conductivity of disordered media that are not near their percolation threshold (see, for example, Odagaki and Lax, 1981; Sahimi *et al.*, 1983a). A comprehensive review of this subject is provided by Clerc *et al.* (1990). Here we only summarize the main theoretical results, and discuss their experimental verification. Consider the two-component percolation network of resistors described in Sec. 1.4. In a percolation model for the ac conductivity and dielectric properties, one views g_1 and g_2 as complex conductances, with $g_1 = 1/R$ and $g_2 = \mathrm{i}C\omega$, where R is the resistance of the bond, C is the capacitance, ω is the frequency, and $\mathrm{i} = \sqrt{-1}$. The conductance ratio h is then given by $h = \mathrm{i}\omega/\omega_0$, where $\omega_0 = 1/RC$. In the static limit ($\omega = 0$) the capacitors become insulators, and the model reduces to the usual percolating conductor–insulator mixture. The key result is that near p_c one has

$$G(p,\omega) \sim \frac{1}{R}|p - p_c|^{\mu}\Phi_{\pm}\left(\frac{\mathrm{i}\omega}{\omega_0}|p - p_c|^{-\mu-s}\right), \tag{60}$$

which follows directly form Eq. (12). An immediate consequence of Eq. (60) is the existence of a time scale t_s that diverges as p is approached from *both sides*:

$$t_s \sim \omega_0^{-1}|p - p_c|^{-(\mu+s)}. \tag{61}$$
